and 'young' (post-'Nice event') of a factor of 2 should be of the order of 1.7 to shift the crater diameter for the same projectile from 45 to 60 km. Further investigations are needed to compare observations by Marchi et al. (2012a,b,c) with the celestial modeling results (Bottke et al., 2012), which predicted an increase of median velocity U from 9 to 21 km s^{-1} (the U-ratio $21/9 = 2.33^{0.528}$ should result in D-ratio for complex craters of $2.33^{0.528} \sim 1.56$), and the characteristic lunar crater diameter of 45 km shifts to ~70.4 km, not to 60 km as observed by Marchi et al. (2012a).

As demonstrated in **Figure 11** as well, the flux rate during the period younger than about 3.3 Ga for which constant flux

is suggested also depends on the shape of the crater SFD. Thus, these shape uncertainties leave room for speculations on, for example, the constancy of the bombardment flux. First, there are arguments of catastrophic collision of large MABs, which may have temporarily increased the bombardment flux into planetary-crossing orbits (e.g., Bottke et al., 2005) or dynamically more complex evolution of the solar system, such as outlined by Bottke et al. (2012). Second, there is a hypothesis (based on limited observational data) about the gradual decay of the bombardment flux during the last 3 Ga (Hartmann et al., 2007; Quantin et al., 2007). However, these observations could also be explained by lowering the flux throughout the period of constant flux.

10.10.7.3 Chronology Model Transfer from the Moon to Other Planetary Bodies

Already early on, different approaches on how to transfer the lunar chronology model to other solid surface planetary bodies were published and compared (e.g., Hartmann, 1973, 1977; Hartmann et al., 1981; Neukum and Hiller, 1981; Neukum and Wise, 1976; Soderblom et al., 1974). While for the standard cratering chronology approach, a monotonically and smoothly decaying cratering rate is assumed, competing interpretations suggested a peak in the cratering rate at about 3.9 Ga ago. The correlation of rates on other planetary bodies has been based on maximum crater frequencies (e.g., Neukum and Wise, 1976; Wetherill, 1975) although associated to different absolute age values. More modern approaches rely on the estimated cratering-rate ratios (**Section 10.10.5**). Following the idea of a temporal marker horizon (Wetherill, 1975) that most of the craters including the basins have formed either during the LHB (e.g., Wetherill, 1975) or as the smooth decaying flux of the planetary formation (e.g., Neukum and Wise, 1976, or Hartmann, 1977), it can be tested how the characteristics of the fluxes for the terrestrial bodies compare. Werner (2008) and Fassett and Head (2010) compared basin formation ages for Mars and the Moon and suggested that the basin-forming population disappeared and similarly the high-flux rates for smaller craters. However, the maximum surface age of the Moon seems older than on Mars. Fassett et al. (2011) studied crater frequencies for Mercury and the Moon with a qualitative comparison cratering rates, suggesting that the surface of Mercury is less cratered than the lunar one. Preliminary results by Werner and Ivanov (2012) revealed that general characteristics in the basin-superposing crater frequencies and basin formation ages for Mercury, Mars, and the Moon with the current chronology models are in agreement with each other, but details need further investigation, which require an updated crater scaling for craters and basins larger than about 250 km in diameter. In general, estimates based on asteroid bombardment-rate comparison could constrain these early correlations; examples for Mars and Mercury are Hartmann and Neukum (2001) and Neukum et al. (2001b) but are lacking a comparative test for all three together. Now, Werner (2014) could show for different types of cratering chronology models that appropriate impact rate ratios are crucial for the interpretation of the bombardment history for Mars and Mercury. A detailed and more fundamental description of deriving proper cratering rates for all terrestrial planets is given by Ivanov (2001) and Ivanov et al. (2001). Aspects of this treatment comprise the derivation of (1) the lunar impact velocity distribution, (2) the projectile SFD from the lunar cratering records, (3) the impact probability and impact velocity distribution for the target planet, and (4) the calculation of a crater SFD on the target planet using the lunar-derived projectile SFD:

Step (1). The lunar impact velocity distribution is derived based on probability estimates for near-Earth asteroids with Earth-crossing orbits to impact the Earth–Moon system, resulting in a function f_v to define the probability of impact with a given velocity.

Step (2). This is to determine the projectile SFD from the lunar cratering records in a full treatment, which requires the solution of the integral equation

$$\frac{dN}{dD} = \int_{U_{min}}^{U_{max}} dU \int_{\phi_{min}}^{90^\circ} d\phi \frac{dN}{dD_p} \frac{dD_p}{dD} f_U(U) f_\phi(\phi) \qquad [25]$$

to find the differential SFD for projectiles, dN/dD_p, from the measured SFD for craters, dN/dD. Therefore, the probability of impacts, f_U, for the impact velocity range from U_{min} to U_{max} has to be determined, and from cratering scaling laws, the dependence of the crater diameter D on the projectile size, D_p, impact velocity, U, and impact angle ϕ, so that $D = D(D_p, U, \phi)$, are available. The frequency of oblique impacts, f_ϕ, is known from theoretical considerations (eqn [17]). The current standard of scaling laws is discussed in **Section 10.10.3**.

In a simplified approach, as in the early publications, one can compute the average impact velocity $<U>$ (**Table 3**) and assume that all impacts occur at the most probable impact angle of 45°. In this case, the number of projectiles creating craters of diameter D is the same as the number of projectiles with diameter D_p, provided the scaling law $D = D(D_p, <U>, 45^\circ)$ is known. Hence, $dN/dD_p = dN/dD$. In both the simplified and full-treatment (eqn [25]) approaches, we still assume that all projectiles have the same density. In reality, realistic projectile densities range from about 500 kg m^{-3} (porous comet nucleus) to about 7000 kg m^{-3} (iron meteoroids), including most practically important values of 2700 kg m^{-3} for S-type asteroids and 1300 kg m^{-3} for dark (e.g., C-type) asteroids (Britt et al., 2002; Stuart and Binzel, 2004). However, for the S-type asteroid 25143 Itokawa, a density of only 2100–2300 kg m^{-3} was found (Fujiwara et al., 2006).

Step (3). This is the derivation of impact probability and impact velocity distribution for the target planet, which again requires model assumptions or observational information for the orbits of small bodies crossing the orbit of a target planet. While the average impact velocity estimated by different groups for various terrestrial planets is commonly in agreement (see **Table 3**), the determination of the average impact rate (the number of impacts of bodies of the same size per unit time per unit area of the target planet surface) is limited by the current understanding of orbital dynamics of asteroids and comets. However, the comparison of pioneer publications (Hartmann, 1977; Hartmann et al., 1981; Shoemaker, 1977), which based the estimates on a dozen of small-body orbits known that time, with recent estimates, which include hundreds of orbits, is not dramatically

different in estimates. Starting with observed small-body orbits, one can make estimates of the average impact-rate ratio for a given planet relative to the Moon, as illustrated in Table 3.

Step (4). Finally, a crater SFD for the target planet is calculated using the lunar-derived projectile SFD. For this purpose, cratering scaling laws are applied, which take the surface rock properties of the target planet and its gravity acceleration into account. The full-treatment approach uses eqn [25] to compute the crater SFD. In the simplified treatment, the average impact velocity and an impact angle of 45° are assumed.

In the succeeding text, we illustrate available data on the relative cratering rate for terrestrial planets.

10.10.7.4 The Earth–Moon System

The Earth and the Moon are subjected approximately to the same projectile flux (Table 3), so the Earth–Moon comparison is a good starting point to discuss challenges of interplanetary comparison of cratering rates. For the Moon, we have reasonably reliable crater counts; in a few cases, they are *calibrated* with isotope ages of lunar returned samples. Most available crater counts are for lunar mare surfaces, while crater records for younger surfaces are typically rare.

On Earth, only a very small number of craters are recognized, because of erosive losses of small ones and plate tectonic and subduction activity, which recycles two-thirds of the Earth surface within about 250 Ma (Figure 14). For most craters on Earth, good age estimates from isotope dating of impact melt or by stratigraphic relationships exist. In addition, the data on frequency of meteoroid entries to the terrestrial atmosphere give a snapshot of the modern bombardment rate (Ivanov, 2006).

The Earth–Moon bombardment history starts with the Earth–Moon system formation at about 4.5 Ga ago. Commonly accepted, the Moon has been formed near the Earth's Roche limit at a distance of about three Earth radii after a giant impact (e.g., Cameron and Ward, 1976, and recently reviewed by Canup et al., 2013) and has been moved to the current orbit at about 60 Earth radii by tidal forces (Ruskol, 1966; Touma, 2000). The impact-rate ratio in the Earth–Moon system partially depends on the Earth–Moon distance (Bandermann and Singer, 1973), defining the modest nearside/farside and leading/trailing asymmetry of impact rates decreasing for larger approaching velocity. The severity of this asymmetry depends also on the approach velocities of celestial projectiles. Attempts to reveal a (small) lunar cratering asymmetry are continuing (e.g., Morota and Furumoto, 2003). Recent theoretical efforts have been utilized to improve our understanding of the lunar cratering asymmetry issues (Gallant and Gladman, 2006; Le Feuvre and Wieczorek, 2005, 2006; Morota et al., 2006), but they do not give consistent results. The most robust of these resent studies (Gallant and Gladman, 2006) favor a minor (a few percent) enhancement of the cratering rate in the leading hemisphere of the Moon. Werner and Medvedev (2010) studied the global young rayed lunar crater distribution, which revealed a similar pattern as the predicted spatial asymmetries (Le Feuvre and Wieczorek, 2008, 2011). However, composition and microbombardment and statistical limitations restricted the interpretation (Werner and Medvedev, 2010). At the current level of lunar surface dating uncertainties, we consider that effects such as cratering asymmetries can be neglected.

The comparison of available data for the Earth–Moon system in general results in the conclusion that the modern (10 year-scale) and geologically recent (100–400 Ma) bombardment flux is the same as proposed for the 3 Ga averaged lunar cratering rate within a factor of 2 (Grieve, 1984; Grieve and Pesonen, 1995; Grieve and Shoemaker, 1994; Ivanov, 2006; Oberst et al., 2012; Stuart and Binzel, 2004; Werner et al., 2002). Some details of this comparison (compare Figure 17) point to difference, which could be a systematic misfit with physical meaning. In the succeeding text, we illustrate possible reasons for this and possible ways of the reconciliation.

Figure 15 summarizes observational data of cumulative collision probability of small bodies with projectile diameters larger than D_p for the Earth. Small-projectile diameter data (D_p in the range of 10–20 cm) are based on Earth-based fireball registration (Halliday et al., 1996), and the entry to the terrestrial atmosphere is considered as collision. Data for larger bodies (D_p in the range of 1–10 m) are derived from satellite registration of bolide flashes (Brown et al., 2002), where projectile masses are estimated from the light flash energy and converted to kinetic energy, with the sizes estimated for an average impact velocity of 20 km s^{-1} and average density of 2700 kg m^{-3}. For the large-sized range ($D_p \geq 5$ km), the estimate is derived from the observed NEO population with an albedo distribution for Near Earth asteroids (NEAs) according to a model by Binzel et al. (2004) and Stuart and Binzel (2004). The intermediate-sized crater range of $10\ \text{m} < D_p < 5$ km suffers from the observational incomplete set of observed NEAs, for which the uncertainty increases with decreasing size. A number of population prediction were published (Bottke et al., 2002; D'Abramo et al., 2001; Mainzer et al., 2011a; Rabinowitz et al., 2000; Stuart, 2001; Stuart and Binzel, 2004). However, these predictions also need to assume the albedo, which may change with size and orbital parameters (e.g., Mainzer et al., 2011b; Werner et al., 2002), and orbital parameters, to allow a complete assessment of the averaged population collision probability. (We note that the general update of the 10-year-old debiased NEA model (Bottke et al., 2002) is announced (Granvik et al., 2012, 2013).)

For the evaluation of realistic estimates of impact probability, astronomical and geologic records can be combined. For the compendium of terrestrial impact records shown in Figure 15, scaling laws are used to convert the terrestrial crater diameter into a projectile mass for an assumed average impact velocity and the average density of projectiles. Figure 16 shows the same data for the terrestrial cratering records, plotting the global probability of the formation of impact craters with crater diameter larger than D. The terrestrial cratering probability is directly derived from crater ages and spatial crater density (Grieve, 1984; Grieve and Shoemaker, 1994; Shoemaker and Shoemaker, 1990). Estimates for the NEO population are converted from a kinetic energy frequency model (Stuart and Binzel, 2004) into terrestrial impact crater diameter with scaling laws discussed in the preceding text (using eqns [8], [15a], and [15b]). To some extent, the NEO kinetic energy estimates depend on the assumed albedo

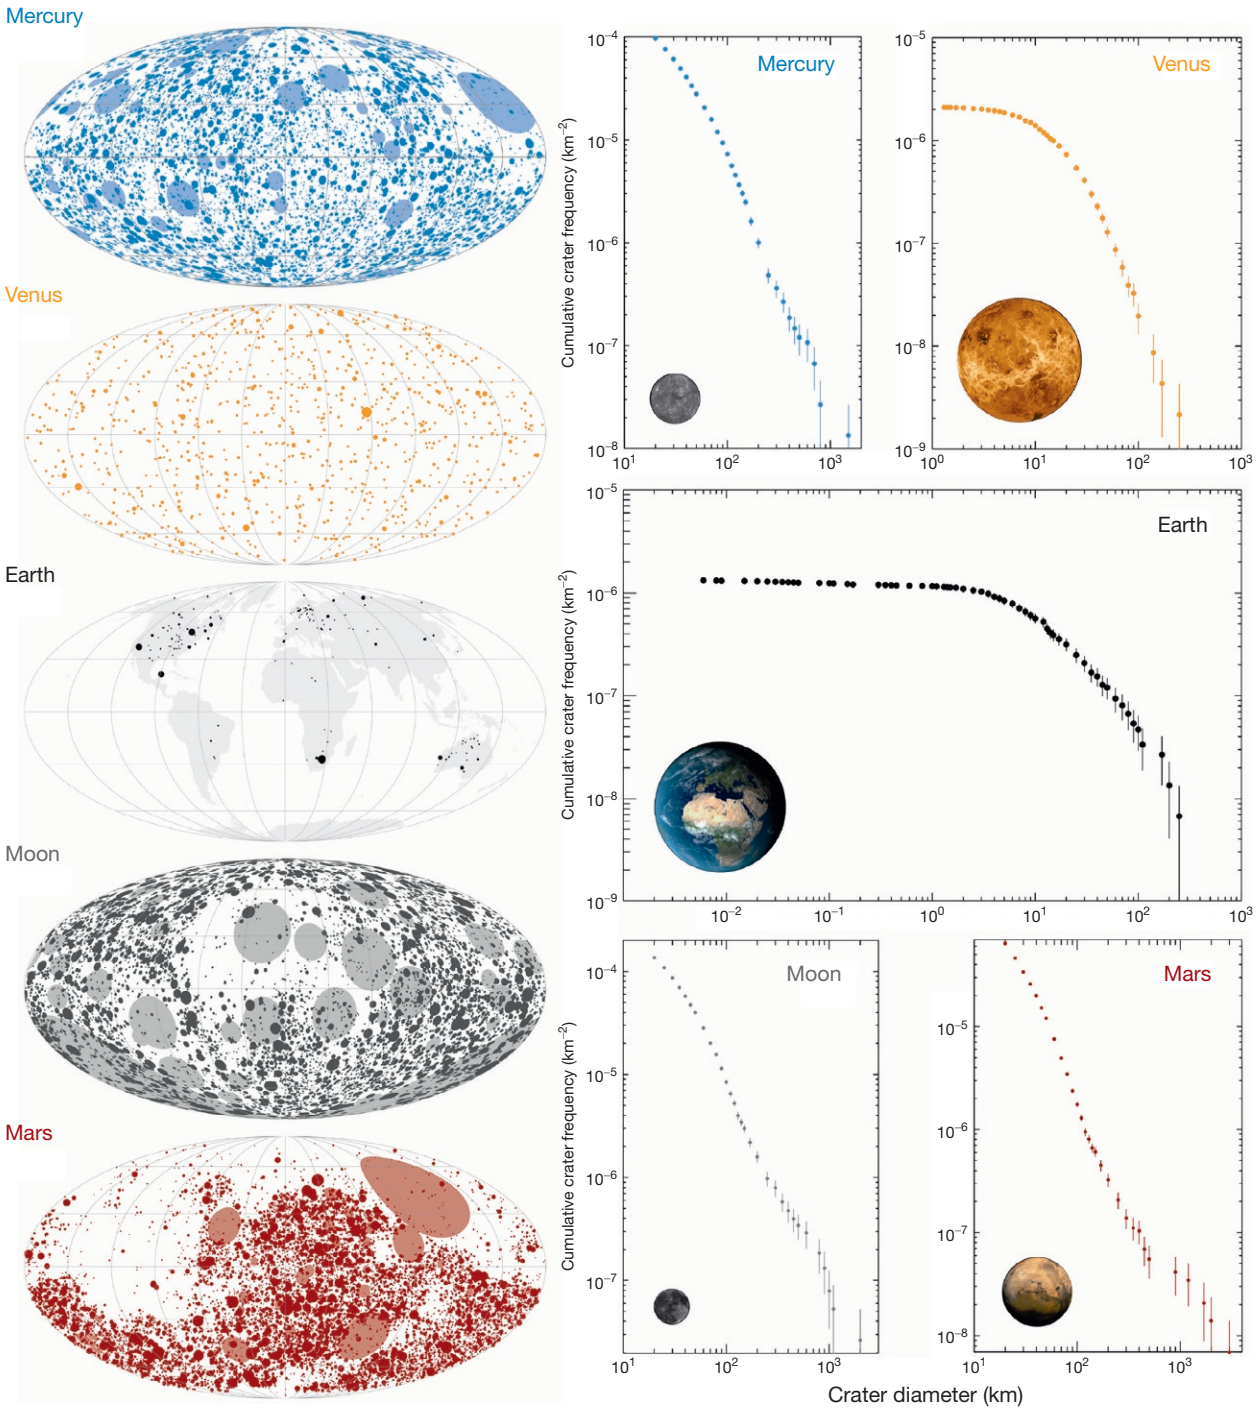

Figure 14 Global spatial crater distribution for the Earth, the Moon, Mercury, Venus, and Mars and the related global crater SFD for the same objects. The distributions for Venus and Earth include all craters, while for Mars, the Moon, and Mercury, only craters larger than 20 km are displayed. Because of geologic activity, as well as atmospheric interaction of the projectiles in the cases of Venus and Earth, all curves significantly deviate from the assumed crater-production function. Catalogs used for deriving the crater distributions are from Head et al. (2010) for the Moon, modified after Barlow (1988) for Mars; Venus' craters are plotted according to Herrick and Phillips (1994); for Earth, we used the Earth Impact Database (http://www.passc.net/EarthImpactDatabase/index.html) and our own database for Mercury.

distribution among NEOs on various orbits. Here, we follow the proportion of *dark* objects of low density and *bright* objects with higher density proposed by Stuart and Binzel (2004). Within a factor of 2, both astronomical (snapshot) and geologic (average for 100–400 Ma) estimates of the terrestrial cratering rate are similar, and the correlation confirms the relative constancy of the bombardment flux to Earth in recent time (<0.5 Ga).

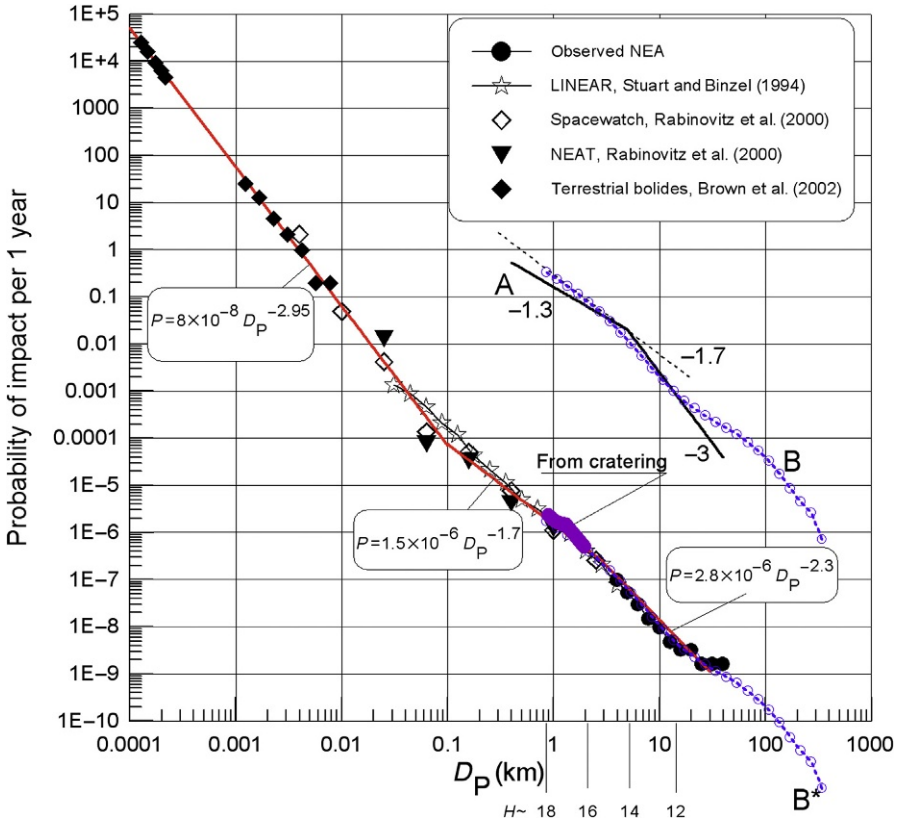

Figure 15 Probability estimates for impacts over the total Earth's surface for small bodies larger than the projectile diameter, D_p. Data for bolides and fireballs ($D_p < 10$ m) are from Halliday et al. (1996) and Brown et al. (2002); observed large near-Earth objects (NEOs) are selected from the 'astorb.dat' file (October 2005, provided through the Minor Planet Center); predictions for small NEOs are derived by Rabinowitz et al. (2000), Stuart (2001), and Stuart and Binzel (2004). Thick purple segment labeled 'From cratering' based on the terrestrial cratering rate over the last 100 Ma converted to D_p for average impact velocity (reproduced from Hughes (2000) A new approach to the calculation of the cratering rate of the Earth over the Last 125 ± 20 Myr. *Monthly Notices of the Royal Astronomical Society* 317: 429–437). Main asteroid belt SFD estimates (plotted here in the arbitrary vertical position) are from Ivezic et al. (2001) in the form of two-segment power law (curve A) with exponent indexes −1.3, −1.7, and −3 proposed by Ivezic et al.(2001) and from Jedicke et al. (2002) (curve B). The latter is scaled to the NEO's probability level (curve B*) to ease the comparison between the SFD of NEOs and main asteroid belts. Absolute magnitude $H < 18$ is given for comparison with the diameter D_p values.

The current bombardment rate derived as global terrestrial probability of impacts of small bodies with an average density of about 2700 kg m^{-3} (bolide and fireball data) and a mix of larger objects (**Figures 15** and **16**) can be analytically described by a simplifying set of power-law segments similarly to the lunar crater-production function of Hartmann (**Section 10.10.4.2**):

$$P(>D_P) \approx 8\times10^{-8} D_P^{-2.95} \quad \text{for } D_P < 100\,\text{m} \qquad [26a]$$

$$P(>D_P) \approx 1.5\times10^{-6} D_P^{-1.7} \quad \text{for } 100\,\text{m} < D_P < 1\,\text{km} \qquad [26b]$$

$$P(>D_P) \approx 2.8\times10^{-6} D_P^{-2.3} \quad \text{for } 1\,\text{km} < D_P < 20\,\text{km} \qquad [26c]$$

Equation [26a]–[26c] respect the general non-power-law behavior of the SFD of asteroids and are constructed to represent all published data within a factor of 2, valid for the different power-law segments, and extrapolation beyond the given ranges is invalid. The terrestrial composite-bombardment flux (eqn [26a]–[26c]) is constructed only to be compared to lunar cratering-rate estimates. For an average impact velocity of 20.9 and 19.2 km s^{-1} for the Earth and the Moon, respectively, and the effective gravity-enhanced cross sections of 7.12×10^8 km^2 and 3.85×10^7 km^2 (Stuart and Binzel, 2004), the Earth–Moon bolide ratio is 1.42. Note the difference with $R_b = 1.68$ estimated from observed orbits of NEA with $H < 17$ (see **Table 3**). Values derived by Stuart and Binzel (2004) for the Earth–Moon impact ratio and average lunar impact velocity are 1.61 and 19.3 km s^{-1}, while Le Feuvre and Wieczorek (2011) found 1.58 and 19.7 km s^{-1}. **Figure 17** shows a comparison of the modern Earth–Moon projectile distribution as derived in the preceding text with lunar production functions (**Sections 10.10.4.2**) in the form of the cumulative number of craters accumulated at the lunar surface per 1 Ga. This comparison is sensitive to the scaling laws (**Section 10.10.3**) used. For example, *nonporous* scaling (eqn [8]) provides a good fit for large craters with diameters $D > 10$ km. The production rate of small craters in regolith ($D < 300$ m) is fitted well with the *porous-rock* (dry sand) scaling (eqn [9]). In the intermediate-sized crater range, *nonporous* scaling overestimates the crater-production rate by an order of magnitude near diameters of about 1 km. If we assume that the upper lunar crust is porous enough in the roughly upper 1 km layer, such a variation in scaling laws and therefore differences in shape of the lunar and terrestrial crater SFD may be realistic

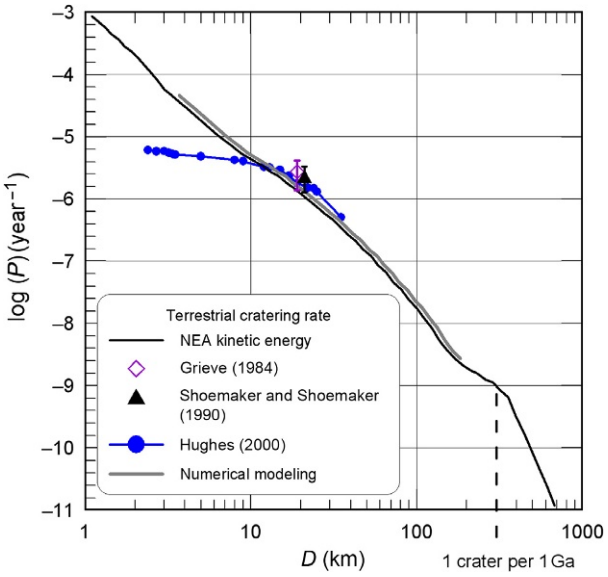

Figure 16 Cratering rate estimates for large terrestrial craters (Grieve, 1984; Shoemaker and Shoemaker, 1990) in comparison with NEOs' impact probability, derived for the population predicted by Stuart and Binzel (2004), using the scaling laws derived from experiments (eqns [8], [15a], and [15b] – black curve) and with the scaling law derived from the numerical modeling of terrestrial craters (eqn [16] – gray curve).

(Ivanov, 2006, 2008), suggesting also that albedo variations with size may not be the only explanation for the discrepancy between lunar crater and estimated asteroid SFDs (Mainzer et al., 2011b; Werner et al., 2002). This was used by Marchi et al. (2009), who interpreted variations in measured crater SFD by means of diameter-range-wise application of different scaling laws, when comparing with modeled asteroid SFDs. More thoroughly, this approach has been tested by numerical modeling of impact crater formation in a hypothetical three-layered lunar crust (Wünnemann et al., 2012), which suggests that the resulting crater diameter can vary up to 20% between impacts into basement rock and regolith, with the most effect near the layer boundaries, where the resulting transient crater cavity diameters become even larger. We note once more that many model results for transient cavity sizes should be verified in the future to make more solid prognoses of the final rim crater diameters.

Reevaluation of published lunar geophysical data (Horvath et al., 1980; Toksoz et al., 1972) by Lognonne et al. (2003) shows longitudinal seismic velocity as low as ~1 km s^{-1} above ~1 km depth below the lunar surface and an increase of 3–4 km s^{-1} to a depth of ~5 km, which is in agreement with and constrains the validity of a *porous* scaling law for lunar impacts applied for a 1 km thick upper layer (Ivanov, 2006). Present results from the GRAIL mission suggest significant density variations for the

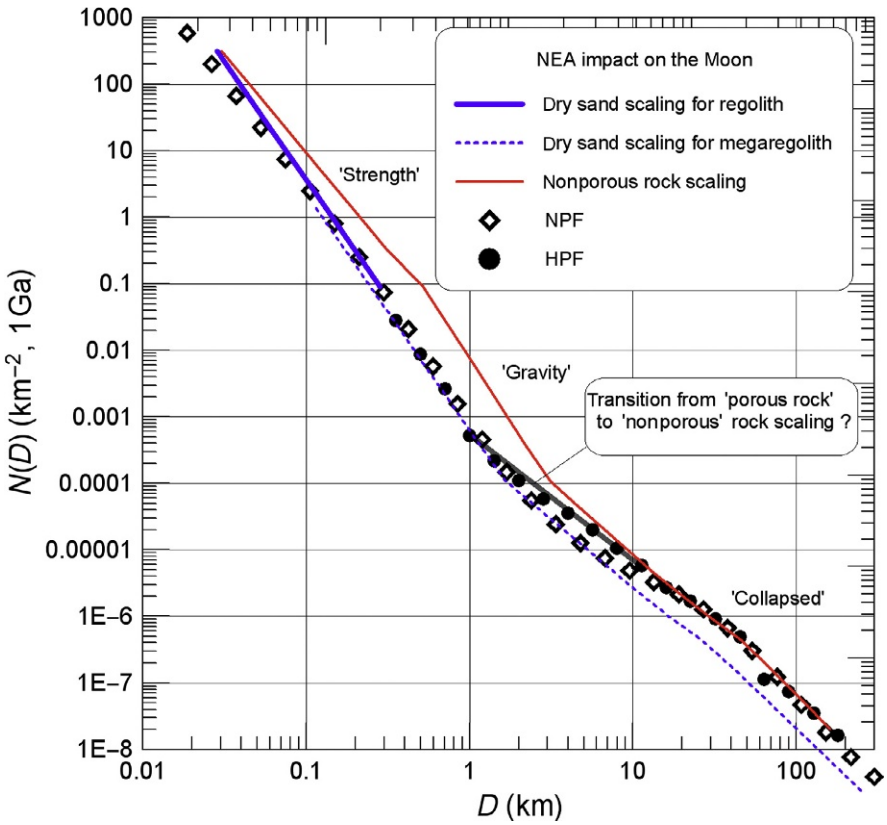

Figure 17 Comparison of the modern Earth–Moon projectile SFD with lunar production functions (**Sections 10.10.4.2**) in the form of the cumulative number of craters accumulated at the lunar surface per 1 Ga and derived with different scaling laws (**Section 10.10.3**).

upper few kilometers of the lunar crust, similarly to seismic observations (Wieczorek et al., 2013).

The spatial distribution and crater size–frequency distribution for the Moon are shown in Figure 14. Highland units are most densely cratered. The interior of most large impact basins was filled after their formation, and the crater density in these mare units is significantly less compared to the highlands.

When calibrating interplanetary surface dating, for example, for Mars and Mercury, porosity variations of the upper subsurface rocks may be different due to different gravity and/or the presence of mechanisms of pore space infilling (e.g., water-caused weathering and massive amounts of ground ice at depths below a few hundred meters). The scaling of crater size D for a given projectile may be different from that on the Moon and can affect the calculated crater-production rate for a specified D.

10.10.7.5 Mercury

Based on the observed asteroid orbit distributions, Neukum et al. (2001b) determined the cratering rate for Mercury relative to the Moon with an average impact velocity of 32 km s^{-1} and R_b of 0.7–0.85. Direct estimates for asteroids with $H<17$ give an average impact velocity of $U\approx35$ km s^{-1} and a bolide ratio of $R_b=0.92$ (Table 3). Scaling laws (eqns [8], [15a], and [15b]) result in the cratering-rate ratios of 1.1 for $D<1$ km and 0.9–1.3 for craters with $1<D$ (km) <100. In the last few years, several additional numerical models and semianalytic interpretations of the cratering-rate ratios have been published for Mercury (e.g., Le Feuvre and Wieczorek, 2008, 2011; Marchi et al., 2009). For these models, they consider layered target properties (Fassett et al., 2009) and size-dependent dynamical evolution of the projectile populations (Marchi et al., 2009, 2013). Although the results differ, depending on which input projectile population is used, detailed scaling laws and methods to determine the collision probabilities are used, and they generally agree within the range of uncertainties. Werner (2014) specifically tested the different models for Mercury in comparison with the Moon, based on basin formation ages, and came to the conclusion that cratering-rate ratios used are not sufficient and especially the model by Marchi et al. (2013) is incoherent with the Nice model assumptions.

The spatial distribution of craters and basins on Mercury is shown in Figure 14, together with the SFD of this observed crater distribution.

10.10.7.6 Venus

According to simple estimates (Table 3), the R_b Venus–Moon bolide ratio is close to 1.1 from observed inner solar system small-body population with $H<17$. This suggests an impact rate about 1.5 times smaller than on Earth, but with higher average impact velocity. First, average age estimates for the Venusian surface were based on radar images from the Russian Venera 15/16 mission (Ivanov and Bazilevskii, 1987; Ivanov et al., 1986) using the approximation of a nearly similar cratering rate on Earth and Venus, followed by Hartmann (1987) who derived lunar-based crater SFD isochrons for Venus. McKinnon et al. (1997) had used small-body orbital set derived from earlier observations (Shoemaker et al., 1990, 1994) to derive the average crater-retention age of Venusian surface as about 700 Ma. Venusian surface-age estimates range between 500 and 1000 Ma.

The global spatial crater distribution is shown in Figure 14, as well as its crater SFD. The crater distribution on Venus globally cannot be distinguished from random (Herrick and Phillips, 1994), so that it is impossible to derive detailed geologic time frames solely based on cratering statistics.

10.10.7.7 Mars

Mars is one of the few solar system bodies for which a group of meteorites has been recognized, the SNC meteorites (Wood and Ashwal, 1981). However, for most the source sites on Mars are unknown (Werner et al., 2013), but ages derived at laboratories on Earth suggest long-lasting geologic, especially volcanic, activity on Mars. Starting with Mariner 9 data, both Hartmann and Neukum (reviewed by Hartmann and Neukum, 2001) have worked on improving the calibration of the crater chronology for Mars (Ivanov, 2001). As for the comparison of the Moon and Mercury, many aspects of crater scaling (Section 10.10.3), the actual shape of the crater SFD (Section 10.10.4), and cratering-rate estimates (Section 10.10.5) impose uncertainties on the comparison. Nevertheless, studies of volcanic activity on Mars (e.g., Hartmann et al., 1981; Neukum and Hiller, 1981; Werner et al., 2009) show a good agreement between the phases of active volcanism on Mars and basaltic Martian meteorite ages. Mars is now also the first planet (after Moon and Earth) for which in-situ radiometric and exposure ages exist (Farley et al. 2014). Thus, the Martian cratering chronology model by Werner et al. (2014) is calibrated in situ by ages measured at Gale crater and Mojave crater, which is suggested to be the source crater for all shergottites (Werner et al. 2014).

Figure 14 shows the Martian global spatial crater distribution, with densely cratered highland units, similar to the lunar ones. The less densely cratered units are the largest impact basins, the almost hemisphere-sized northern lowlands, and all volcanic provinces.

10.10.7.8 Cratering on Asteroids

Several asteroids are imaged, and parts of their cratering record are studied. Asteroids with (partially) measured crater distributions are listed in Table 4. Only for a few asteroids, for

Table 4 A compilation of asteroids for which crater size–frequency distributions are determined

example, for Vesta, it is the class of HED meteorites, meteorites can possibly be linked and thus provide temporal constraints, else calibration of cratering chronologies for asteroids is nearly impossible. The challenge is to find appropriate parameters for the crater scaling to compare the measured crater SFDs with the lunar one. Important parameters are gravity, target properties, and impact velocities to understand crater erasing processes. The irregular shape and unknown heterogeneities of the body add to the scaling uncertainties. The cratering records observed on the surface of asteroids, especially small ones, are cited to discuss the proportion between primary and secondary craters in planetary records, because the primary ejecta probably do not fall back on small asteroids. On the other hand, the surfaces of these small bodies are supposedly as old as the solar system and the surface will probably be saturated with craters at most sizes. The bombardment history of these bodies can influence the asteroid spin rate and axis.

10.10.7.9 Interpretation of the Small-Sized Crater Statistics

Challenges in determining the crater-production function from crater size–frequency measurements are a number of well-known and long-standing difficulties. These difficulties not only are partly inherent issues of the cratering process but also more significantly are related to the interpretation of the crater record and thus made some questions about the overall credibility of the method. Numerous crater-production functions exist, because *the* major challenge in the development of the crater-counting technique and for surface-age determination is to find large, homogeneous, and undisturbed surfaces and to determine the *true* crater-production function. Observed crater distributions could be diverted due to the following:

1. *Average impact velocities*, which compress or stretch the curve along the diameter axis
2. *Target properties*, which change the curve at the small crater range
3. *Admixture of secondary craters*, which steepens the curve
4. *Resurfacing processes*, which shallow the curve
5. *Mapping and counting* (average and distortion), when geologic boundaries are ignored

The shape of the crater-production function must be determined over the largest possible diameter range. However, young units have been used for measurements of the small crater range and old units for large craters in order to derive statistically meaningful measurements from an unmodified cratering record. The shape of the curve may be distorted by considering large and small crater diameters separately, and this is reflected in the diversity of shapes of the various models. Nevertheless, this fact led to the idea that the projectile population may have varied with time (Fassett et al., 2012a,b; Head et al., 2010; Strom et al., 2005; Werner, 2008). These authors have cited various reasons for these apparent or real changes in the SFDs.

In the recent years, with Mars orbiter cameras (HiRISE on the NASA Mars Reconnaissance Orbiter, MOC on the NASA Global Surveyor mission, and HRSC on the ESA Mars Express) and Thermal Emission Imaging System (THEMIS on the NASA Mars Odyssey mission) showing craters as small as $D = 1$ m on various geologic formations of various scales, there has been increasing emphasis on the question of whether the small craters can be used to date the formation and evolution of young and small-scale features, such as formations with glacier-like morphology, debris aprons, landslide deposits, mantled deposits, and exhumed surfaces. Almost 10 years of Mars imaging accumulated sets of image pairs of the same area and allowed Malin et al. (2006) to collect information about 20 new craters that appeared in 21×10^6 km^2 of Martian surface between May 1999 and March 2006. Similar work has been repeated by Daubar et al. (2013) with HiRISE imagery. Both studies find that the crater formation is lower than extrapolated from the currently available crater-chronology models (Hartmann, 2005; Hartmann and Neukum, 2001). All original lunar crater SFD prototypes are not defined for this very small crater range, which can now be observed on the Moon and Mars. Crater scaling laws and the thin Martian atmosphere will modify the projectile–crater relation between the Moon and Mars significantly. Also, Ivanov (2001) pointed out that the cratering rate is varying with respect to the actual eccentricity of the Martian orbit, which is different at the moment compared to the average over the past 3 billions of years (**Table 3**). All these aspects have not been evaluated in detail, but (1) the results from the observed cratering rate at less than 10 m crater diameter and (2) the extrapolation from crater-chronology models found and calibrated for kilometer-sized craters give some additional confidence to the entire system of the terrestrial planet's surface age in comparison with the cratering statistics.

10.10.7.10 Effects of Target Properties

Explosion experiments on the Earth suggest that target properties may influence crater diameters as well as the shape, even for intermediate crater (see detailed discussions in **Section 10.10.3**). The same projectile can form differently sized craters depending on the target strength, and thus, the slope of the crater SFD may vary if the target is distinctly layered. If, for example, on Mars wind-blown material accumulates above lava plains, craters in the upper dusty layer are larger than in the more competent target material (lava). Due to the cumulative effect of cratering, the observed crater SFD function appears steeper. This mostly affects craters below 200 m in diameter (e.g., Dundas et al., 2010). However, the discrepancy between estimated asteroid and lunar crater SFD (see **Figure 17**) could indicate that this effect is relevant for much thicker layers and affect larger diameter ranges.

10.10.7.11 Secondary Cratering

The basic principle of crater dating of planetary surfaces is the assumption that older surfaces have higher crater densities per unit area than young surfaces. In reality, on a geologically active planet, many processes such as erosion and deposition may modify the crater record partially, making the dating (both absolute and relative) ambiguous in a specific situation. Not only uncertainties in cratering rates, scaling laws, and therefore the analytic description of the crater SFD exist, but also the ratio of crater formation rate from celestial small bodies (primary impacts) to cratering from *secondary* fragments ejected from primary craters is uncertain. The limited

observational constraints to determine the small crater range rate (**Section 10.10.6.3**) keep the discussion alive over the past 50 years (Block and Barlow, 2005; Fielder, 1962; Hartmann, 2005; Ivanov, 2006; König, 1977; McEwen et al., 2005; Shoemaker, 1965; Vickery, 1986; Werner et al., 2009).

Secondary craters on Earth found around large-scale chemical and nuclear detonation craters have been discussed by Roberts (1964). For the largest excavation events, those secondary craters reach diameters of ~40 m. A few reports about secondary craters around natural terrestrial impact craters are not convincing enough, leaving room for further studies (Poag, 1995, 1999). In all cases, secondary craters have been found not far from the source and assumed velocity of ejection is in the range of a few 100 m s^{-1} and below. However, tektite strewn fields on Earth and crater ejecta–rays spreading over half of the Moon (Fielder, 1962) and discovered on Mars in thermal IR imagery (Tornabene et al., 2006) suggest that portions of the ejecta can reach large distances, associated with crater clusters (Bierhaus et al., 2001, 2005; McEwen and Bierhaus, 2006).

10.10.7.11.1 SFD for secondary craters

Shoemaker (1965) proposed that secondary craters have a very steep slope SFD with a cumulative relation of frequency and diameter of $N \sim D^{-m}$ and $m \approx 4$ (in contrast to $m \leq 3$ for small primary craters; compare **Section 10.10.4.1**). Shoemaker (1965) gave two examples for the SFD of secondary craters. Their incremental size–frequency curves are concave and the local exponent m slowly decreases with the crater diameter. This is a typical behavior for SFD of rock fragments formed under pressure (grinding and cracking). Decades of engineering experience resulted in many forms of fragment SFD description, and one most commonly used SFD form is the Weibull distribution (Weibull, 1951). Its application for explosive rock fragmentation is reviewed in detail by Grady and Kipp (1987). The Weibull distribution in its cumulative form expresses the volume of fragments larger than a given size in a fragment population analyzed:

$$V(>x) = V_0 \exp\left[-\left(x/x^*\right)^n\right] \qquad [27]$$

where V_0 is the total volume of fragments, x^* expresses the characteristic size in a population of fragments, and n is the Weibull exponent. According to Grady and Kipp (1987), the Weibull exponent varies from about $n = 6$ for a few fragmentation acts to 1 for heavily comminuting processes, such as a long-term fragmentation in rock mills. For explosion fragments, n ranges typically from 1 to 3. The characteristic feature of the Weibull distribution is the *rollover* at smaller sizes – the distribution for fine fragments is much shallower than for the largest fragments. Ivanov (2006) demonstrated that it is a valid approximation for fragments ejected from the primary crater, which create the secondary craters. Hence, smaller members in a cluster of secondary craters probably are less numerous than it is widely suggested from the steep slope for larger

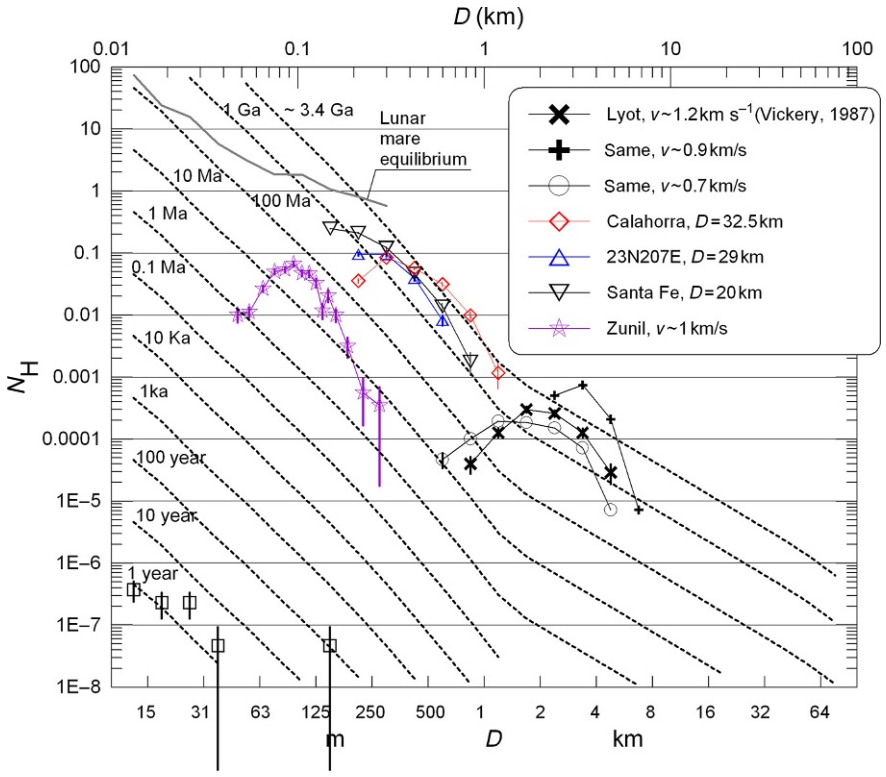

Figure 18 Secondary crater counts (Ivanov, 2006; Werner et al., 2006, 2009) show in incremental plots a deviation from the predicted crater SFD and are of bell-shaped behavior. In comparison, the first direct estimates of small impact crater-production rate on Mars (open squares with error bars; Malin et al., 2006) are shown.

fragments. The rollover character of the crater SFD in clusters is demonstrated by Ivanov (2006) for lunar and Martian secondary craters. The available SFDs for close and remote secondary craters on Mars are shown in **Figure 18** and include one of the highly debated cases, Zunil, a young rayed crater in the Cerberus Plains on Mars. As McEwen's numerical data for SFD of secondaries are unavailable to date, we use HRSC crater counts (Werner et al., 2006) in the area about 300 km west of Zunil, which suggests corresponding ejection or landing fragment velocity of about 1 km s^{-1}. It is interesting to note that fragments that created secondaries around the much larger Lyot crater (also Martian crater) in the same velocity range also have a *bell-shaped* SFD (Ivanov, 2006).

It has been speculated that secondary cratering could impede reproducible age determination (e.g., McEwen et al., 2005). However, one Zunil-sized primary crater probably forms on Mars every 1 Ma, on average. Consistent with this is that the secondary SFD measured in the HRSC image is well bracketed with the 1 and 10 Ma model-age isochrons. The secondary crater densities rise above the 1 Ma isochron at this distance from Zunil, but at larger distances, they drop below (according to McEwen's model). These facts suggest that the Hartmann derivative of isochrons lies closer to Martian realty on surfaces as young as a few Ma than suggest by McEwen et al. (2005). This test has been repeated for all craters on Mars, which appear young due to their prominent ejecta–ray system. All of these passed the test (Hartmann et al., 2010). A more general test, of course, is to try to take into account the total accumulation rate of secondaries from all sizes of primaries (not just Zunil-sized craters), which has been performed by Werner et al. (2009), where they conclude that the contribution of secondaries globally should be less than 10–15%. We note, however, that primary craters of $D < 3$ km are too small to launch large distance secondaries (Head et al., 2002). Issues were raised about the ratio of secondaries to primaries among different-sized craters (e.g., McEwen et al., 2005). It is usually accepted (Shoemaker, 1965) that the ratio is low in the *shallow branch* of the lunar SFD, at $D > 2$ km, and Werner et al. (2009) estimated that the contribution of *random distant background* secondary cratering to the smaller crater *steep branch* distribution segment can be only up to 10–15%. Uncertainties of the actual shape of the crater SFD remain. Yet dated returned samples from Mars do not exist, so arguments in the discussion about error bars in crater-retention age are mostly based on models.

10.10.7.12 Effects of Atmosphere and Geologic Processes

The effects of atmosphere are most obvious in the crater record of Venus (**Figure 14**), where craters smaller than a few kilometers in diameter are completely lacking because of the burnup in the atmosphere. While Mercury and the Moon have no atmosphere, Mars has one. For Mars, however, the significance at present is not well understood. Malin et al. (2006) documented that some of the newly formed impact events are clustered. Ivanov et al. (2011) used these clusters and those newly found in CTX and HiRISE imagery to determine breakup altitudes and effective meteoroid densities, which appear lower than expected. Therefore, they concluded that not only the target properties but also the projectile properties need to be considered, so that the crater–projectile scaling complexity is added.

Especially on Mars, where high-resolution imagery is available, the role of geologic modification needs to be considered, such as aeolian and seasonal processes related to frost and freezing. They modify the small-scale cratering record already within decades.

10.10.8 Conclusions

The exogenic dynamics of planets is a fast-developing system of knowledge, integrating facts and models from many fields of science from celestial mechanics to physics of shock waves. Visible on all planetary bodies, the scars of impact – impact craters – vividly illustrate that exchange among solid bodies is an active agent of the solar system and planetary surface evolution. Individual giant impacts appreciably change the heat balance of planets, producing *impact hot spots* for post-impact magmatic activity. SFDs of numerous small impacts, recorded in crater populations, create an opportunity to estimate not only the age of planetary surfaces but also the rates and efficiency of erosion and deposition processes through studies of degradation and losses of small craters. SFDs of craters can be compared with SFDs of asteroids and comets, resulting in observational constraints for the general solar system evolutionary history. Many topics of exogenic dynamics are still far from fully understood, and many problems are only qualitatively solved. Progress in the exogenic dynamics offers better understanding of planetary formation and evolution.

Acknowledgments

The authors are grateful to W. K. Hartmann for his contributions to the first edition of this chapter. Similarly, we like to thank G. Neukum for his fruitful discussions at many occasions. We acknowledge the efforts of Kai Wünnemann and an anonymous reviewer to improve the manuscript. SCW acknowledges support from the Research Council of Norway through its Centres of Excellence funding scheme, project number 223272 (CEED). BAI is supported by Program 22, Russian Academy of Sciences.

10.11.1 Introduction

Water is the second most abundant molecule in our solar system, following only molecular hydrogen. It plays an important role in many planetary processes and has significant importance for the habitability of a planetary body. Despite the importance of water, its complex physical behavior is still only partly understood.

This chapter provides an overview of the current knowledge of water and water-related processes on the terrestrial planets from a geophysical and a morphological point of view. Naturally, Mars plays a featured role here, as it is the only terrestrial planet where we have clear evidence for present and past widespread existence and activity of water on and close to the surface. In addition, strong evidence indicates the presence of water-ice deposits on the Moon and Mercury inside permanently shadowed craters close to the poles of the planet. Spectral evidence indicates widespread presence of water molecules across the lunar surface. As the focus of this chapter is on terrestrial planets, we will not discuss the icy moons of the giant planets, which will be dealt with in Chapter 10.18, or Pluto, which is discussed in Chapter 10.19.

This chapter is organized into six sections. Section 10.11.1 presents a general discussion of the geophysical constraints for the stability of ice and water focusing on the conditions found on the terrestrial planets. This is followed by a discussion of observational methods to detect the presence of water and ice. We then discuss water and ice on the terrestrial planets, starting with water on the surface of the terrestrial planets including a discussion of its morphological effects. From there, we move on to discuss water in the mantle and crust of terrestrial planets and discuss briefly the effects of water in the interior of terrestrial planets in Section 10.11.4. This topic is also covered in Chapter 10.08. Finally, a brief discussion on the evolution of water and climate on the terrestrial planets is included. For a more detailed discussion of the interactions between atmospheres and surfaces of terrestrial planets, we refer to Chapter 10.12. We conclude the chapter with a summary and outlook in Section 10.11.6. This includes a very brief discussion of necessary future measurements. For a more detailed discussion of planetary exploration strategies, we refer to Chapter 10.23.

All terrestrial planets are the topic of this chapter, but in much of the discussion, Mars will take center stage as it is the planet showing the most striking evidence of water activity in the past and even in the present.

10.11.1.1 Geophysical Constraints

10.11.1.1.1 Stability of water and ice

Water exists as a liquid at pressures above 611 hPa and temperatures above 273 K, the triple point of water. Under these conditions, the solid, liquid, and vapor phases coexist. Branching from the triple point are the phase transition curves for solid–liquid, liquid–vapor, and solid–vapor phase changes. Depending on the pressure, water can stay in liquid state up to more than 600 K. The phase diagram of water (Figure 1) reflects the complex behavior of the substance.

On planetary surfaces, temperatures are determined by the solar irradiance, which is a function of the solar luminosity (L) and the distance (D) as L/D^2. Thus, phase conditions for liquid water are dependent on the distance from the central star. Conservative estimates for distances at which water can be stable as a liquid on planetary surfaces in our solar system are between 0.95 and 1.37 AU (Kasting et al., 1993). Thus, of the terrestrial planets, only Mars (apart from Earth) has the potential for transient liquid water on the surface as its orbit is just at the outer edge of the estimate by Kasting et al. (1993). For the Moon, which is inside the distance limits but has no atmosphere, and for Mercury, only ice might be stable on or close to the surface within permanently shadowed regions. The present-day surface of Venus is too hot to support liquid water.

On Mars, with its thin atmosphere, liquid water might be a transient occurrence. If the total pressure of atmospheric gas exceeds 610 Pa, pure liquid water may be stable against boiling, but it is still unstable with respect to evaporation. The boiling point of a liquid is that temperature at which its saturation vapor pressure equals the total external pressure. This total pressure can be supplied in the case of Mars, for example, by CO_2, and does not refer to the partial pressure of water vapor. For example, at 283 K, the saturation vapor pressure of liquid water is $\sim$12 mbar. With these atmospheric conditions, liquid water would be stable against boiling even if the partial pressure of water in the atmosphere is less than the saturation vapor. Since the atmospheres of Mars and Earth are not saturated, liquid water is not stable on the surface of either planet with respect to evaporation. Stability of liquid water on the surface means therefore in general that liquid water, if it could form, would be stable against boiling or freezing but (most likely) unstable to evaporation. For more details, see the discussion by Haberle et al. (2001).

As pointed out by Richardson and Mischna (2005), boiling is only of major importance as a process because it leads to a much more rapid conversion of liquid to vapor than evaporation. Bubble development in the interior of the liquid is allowed and dynamically favored, if the saturation vapor pressure of the liquid exceeds the total atmospheric pressure. It enables the vaporization of the liquid to occur throughout the full volume of liquid. The rough surface created by boiling might also lead to a more effective heat exchange. In general, it can be summarized that liquid water might exist if surface pressures and temperatures fall between the melting point of ice and the boiling point of liquid water.

For an atmosphereless body like Mercury or the Moon, the stability of ice is determined purely by the sublimation rate as discussed recently by Andreas (2007). The standard equation for the sublimation (or evaporation) of ice (or pure water) in vacuum is given by Estermann (1955) as

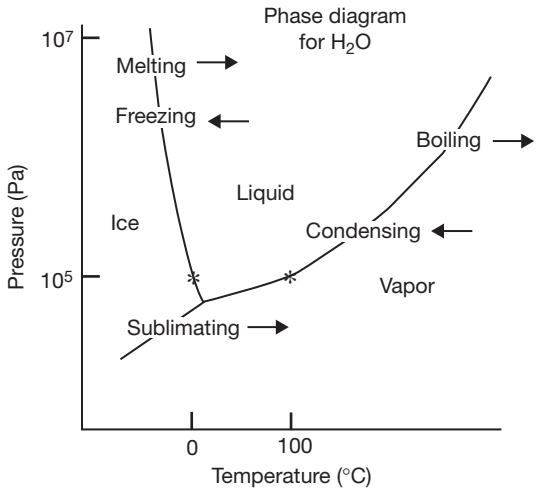

Figure 1 Phase diagram of water.

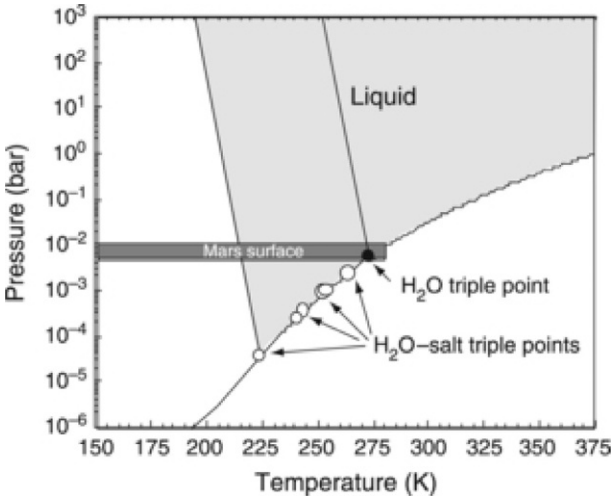

Figure 2 Phase diagram for a H_2O–$CaCl_2$ brine. Reproduced from Bodnar RJ (2001) PTX Phase equilibria in the H_2O–CO_2–salt system at Mars near-surface conditions. *Lunar and Planetary Science* XXXII: 1689 (CD-ROM).

$$S = p_{\mathrm{sat},i}(T)\left[\frac{M_\mathrm{w}}{2\pi RT}\right]^{1/2}$$

where S is a mass flux in kg m^{-2} s^{-1} and $p_{\mathrm{sat},i}(T)$ is the saturation pressure in hPa for an ice surface at temperature T (in Kelvin). M_w is the molecular weight of water and R the universal gas constant. Using the sublimation equation, it is straightforward to derive the temperature-dependent sublimation if the saturation vapor pressure curve is well known especially at low temperatures.

Murphy and Koop (2005) provided recently a new function for the temperature dependence:

$$p_{\mathrm{sat}}(T) = 0.01\exp\left(9.550426 - \frac{5723.265}{T} + 3.3068\ln T - 0.00728332\right)$$

The expression is valid for $T = 110$–273.15 K. $p_{\mathrm{sat}}(T)$ is in hPa, and T in K.

For a planet like Mars, the sublimation can be limited by the saturation of the atmosphere with water vapor. The saturation can be expressed in terms of relative humidity:

$$r_\mathrm{h} = \frac{\rho \cdot R_\mathrm{v} \cdot T}{p_{\mathrm{sat}}(T)}$$

where ρ is the water vapor density, T the temperature, p_{sat} the saturation pressure, and $R_\mathrm{v} = 461.5$ JK^{-1} kg^{-1}.

For Mars, the abundance of water vapor in the atmosphere *pr* is often given in precipitable microns, describing the amount of water if the whole atmospheric column would be condensed on the surface.

Assuming the simple case that water follows a scale height-dependent distribution, this can be converted to water vapor density using

$$\rho(t) = \frac{\rho_{H_2O} \times pr}{H(t) \times 100}$$

where ρ_{H_2O} is the density of water, *pr* the water abundance in precipitable microns, and $H(t)$ the scale height that can vary as a function of Martian seasons. One has to be cautious, however, because the vertical distribution of water in the Martian atmosphere is not readily describable only by a scale height. There are many instances where water does not follow a scale height or where there is an inversion and the number density increases with altitude.

Salinity does not influence the solid–vapor transition temperature, as salts are not incorporated into ice. However, it does influence the solid–liquid transition temperature. Addition of salt to water causes the triple point to migrate to lower temperatures and pressures (see **Figure 2**). Liquid water may exist in the form of salt-saturated solution (also called brines) at temperatures significantly below 273 K. Brines with a high content of $CaCl_2$ remain liquid up to 220–225 K (see, e.g., Brass, 1980; Kuzmin and Zabalueva, 1998). Haberle et al. (2001) had pointed out that while pure water could exist over 29% of the surface of Mars for 37 sols each year, a NaCl eutectic solution could remain liquid over most of the planet at some time of the year and up to 100 sols in some regions. As discussed before, this refers only to transient liquid water, as liquid water is stable nowhere on the Martian surface. The formation of eutectic solutions of $CaCl_2$, with its much lower eutectic temperature, would greatly increase the extent and duration of liquid on Mars. Sears and Chittenden (2005) showed recently that brine formation will increase the stability of water on Mars not only by extending the liquid temperature range but also by considerably decreasing the evaporation rate. At the eutectic temperature of NaCl brine, evaporation rates are ~30 times less than pure water; at the eutectic temperatures of $CaCl_2$, evaporation rates are slightly lower. In longer contact with the atmosphere, the water will still evaporate leaving behind evaporites. Such deposits have been suggested based on the geochemical studies by the Mars Exploration Rovers (MERs) (Christensen et al., 2003; Squyres et al., 2003). For a short time, brines could appear on the Martian surface or nearby even under present-day conditions and would be stable over longer time spans than pure liquid water.

10.11.1.1.2 Adsorption

Hydrogen bonds can form not only between water molecules but also between a water molecule and a silicate surface. The water molecules are typically bound in monolayers to the grain surface. There are a number of theories describing the amount of water that a certain material can hold. Following Jakosky (1985) with σ as the number of molecules bonded, we get

$$\sigma = \frac{Ap(1-\alpha)}{(2\pi MRT)^{1/2}}\tau_0 e^{Q/RT}$$

In this equation, α is the fraction of molecules striking the surface A, which do not stick, and it is assumed that the vibrating water molecules have a Maxwellian energy distribution. Q is the binding energy, R the gas constant, M the molecular weight, and T the temperature.

Defining $\theta = \sigma/\sigma_0$ as the fraction of monolayer of molecules present yields

$$\theta = \frac{kp}{1+kp}$$

where

$$k = \frac{A}{(2\pi MRT)^{1/2}}\frac{\tau}{\sigma_0}(1-\alpha)$$

These two equations form the Langmuir adsorption isotherm (Langmuir, 1915). This is the most simple approach because it limits adsorption to one monolayer. For most real materials, it fails, because they can adsorb more than one monolayer. A more realistic approach was proposed by Brunauer et al. (1938), termed the Brunauer–Emmett–Teller (BET) theory. Using a similar approach as discussed earlier, the isotherm can be expressed as

$$\theta = \frac{kx}{(1-x)(1-x+kx)}$$

where $x = P/P_s$ and P_s is the saturation pressure of the molecule. As adsorbed water molecules behave typically more like a liquid than a solid (quasiliquid), P_s is the saturation pressure with respect to the liquid.

These rather simplified theories of adsorption do not take into account a number of parameters, including grain-size distribution, ambient pressure, and temperature. Applying these theories to Mars, for example, has shown the need for measurements of the adsorption isotherms of real materials and realistic planetary conditions. Fanale and Cannon (1971, 1974) measured the adsorption of H_2O on basalt for $T = 250$–300 K and $P = 2$–2000 Pa. They found that $\sim 10^{-3}$ kg of water per kilogram was adsorbed. To extrapolate their measurement to Mars condition, usually a least squares fit of an empirical isotherm is used (Zent and Quinn, 1997):

$$\rho = \rho_s A_s \frac{\gamma P^{0.51}}{e^{\delta/T}}$$

This equation gives the adsorbed load of water per cubic meter of regolith. Here, ρ_s is the density of the regolith, A_s the specific surface area, $\gamma = 2.0487 \times 10^{-12}$ kg m^{-2} Pa^{-1}, and $\delta = -2679.8$ K.

Using this isotherm and assuming a specific surface area of 17 m^{2}g^{-1} (Ballou et al., 1978), it was predicted that the Martian regolith can hold about 2.1 kg m^{-3} of water and that formation of ground ice would be suppressed by this effective adsorption process (Flasar and Goody, 1976; Toon et al., 1980).

Zent and Quinn (1995) made the first measurements of adsorption of water onto palagonite and montmorillonite at conditions appropriate to Mars. The palagonite data fitted best to a Toth isotherm

$$\theta = K^*P/[1+(K^*P)^{\upsilon}]^{1/\upsilon}$$

and the montmorillonite data to a Freundlich isotherm

$$\theta = (K^*P)^{\upsilon}/[1+(K^*P)]^{\upsilon}$$

with $K^* = K_0 e^{\varepsilon/T}$ for both isotherms. For palagonite, the fitting parameters are $K_0 = 7.54 \times 10^{-9}$, $\varepsilon = 2697.2$, and $\upsilon = 0.4734$, and for montmorillonite, the fitting parameters are $K_0 = 2.207 \times 10^{-9}$, $\varepsilon = 4157.2$, and $\upsilon = 0.6593$.

With these new isotherms acquired under realistic conditions, Zent and Quinn (1995) found that adsorption is about an order of magnitude less efficient than previously thought and the formation of ground ice is not suppressed by adsorption. Zent et al. (2001) extended these studies to clays, namely, smectites. They discovered that they play no significant role for diurnal cycles of water, because the equilibration time is much longer than a Martian day and the abundances of adsorbed water are much smaller than predicted.

In a recent study, Jänchen et al. (2006) showed that microporous minerals (as nontronite, montmorillonite, chabazite, and clinoptilolite) might remain hydrated under present Martian atmospheric conditions and hold up to 2.5–25 wt% of water in their void volumes at a partial water vapor pressure of 0.001 mbar in a temperature range of 333–193 K. These results are in contradiction to the much lower values reported by Zent and Quinn (1997) and Zent et al. (2001). It should be however be noted that the measurements by Jänchen et al. (2006) have been performed at 257–333 K and have only been extrapolated to the Martian temperature range. This extrapolation might be a reason for the disagreement and demonstrates the importance of measurements under realistic Martian conditions.

10.11.2 Observational Evidence

10.11.2.1 Spectroscopy, Morphology, and Radar

10.11.2.1.1 Visual and infrared spectroscopic features of ice and bound water

H_2O is a bent polar molecule and has as such three fundamental vibration modes – a symmetrical stretch mode at 2.738 μm (ν_1), a bending mode at 6.270 μm (ν_2), and an asymmetrical stretch mode at 2.663 μm (ν_3). In the vapor phase, all absorptions predicted by group theory are observed. Phase changes into the liquid and solid phase change the spectral properties of water. In general, hydrogen bonds tend to broaden and intensify the O–H stretching features and shift them to longer wavelengths (Hamilton and Ibers, 1968). In liquid water, the fundamental vibration modes shift to $\nu_1 = 3.106$ μm, $\nu_2 = 6.079$ μm, and $\nu_3 = 2.903$ μm (Clark, 1999).

Water frost and ice are generally bright and spectrally flat in the visual wavelength range. They show various diagnostic

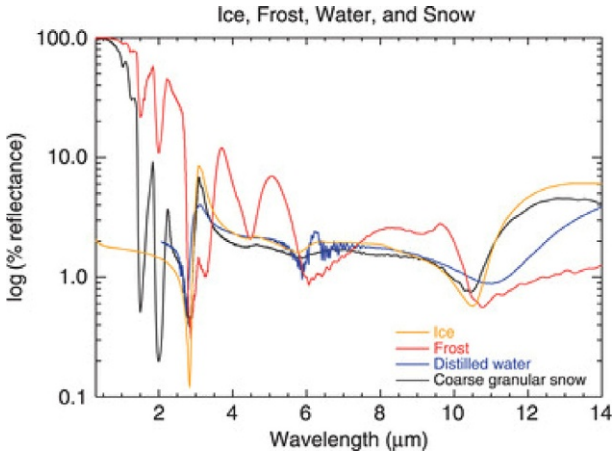

Figure 3 Measured reflectance spectra of different types of water deposits on planetary surface – water ice, frost, distilled water, and coarse granular snow. Data from the ASTER Spectral Library through the courtesy of the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California.

features in the ultraviolet (UV) and in the near- and mid-infrared (IR) (see **Figure 3**). Water ice has fundamental vibration modes at 3.2 and 6.1 μm and exhibits strong combination overtone bands centered near 1.5 and 2.0 μm. The fact that these bands are so strong makes them prone to saturation. Therefore, the weaker overtones observed at 1.26, 1.04 μm and shorter wavelengths can often provide more useful information (Clark, 1981; Roush et al., 1993). The unsaturated ice bands have distinctive positions, widths, and shapes different from the bands due to molecular water and OH^- absorptions on minerals as will be discussed later.

Many minerals can incorporate H_2O and/or OH^- in their structure. H_2O can also be absorbed on mineral surfaces, located in interlayer sites of smectite clays or trapped as fluid inclusions. All these forms are commonly found in terrestrial rocks as a result of weathering, hydrothermal alteration, or sedimentary precipitation. The near-IR region is ideally suited to search for water- or hydroxyl-bearing minerals (Farmer, 1974; Roush et al., 1993; Salisbury et al., 1991). Dominant in this region is a strong absorption feature around 3 μm. This feature is caused by an overlap of the symmetrical and antisymmetric stretching modes with the first overtone of the strong 6 μm bending mode. The feature is unfortunately not very sensitive to changes in the mineralogy; therefore, it is useful to identify the presence of water but less useful to constrain compositional information on the water-bearing mineral (Roush et al., 1993). Other features in this spectral region, although weaker, are more diagnostic. The region between 2.1 and 2.5 μm shows a group of sharp but weak bands. These are caused because of the stretching fundamental vibrations of cation OH^-, the 1.9 μm overtone of the H–O–H bending mode, and the 1.4 μm OH^- overtones in both H_2O and OH^- (Roush et al., 1993; Salisbury et al., 1991). The fine structure in this region can provide detailed information on the host minerals, because the combining spectral features are due to different physical processes. The 1.9 μm overtone, for example, is caused by adsorbed or bound water in a mineral, like interlayer H_2O in a smectite clay. The presence of the 1.4 μm overtone, combined with the absence of the 1.9 μm absorption feature, indicates the presence of OH^--bearing minerals.

10.11.2.1.2 Gamma-ray spectroscopy and neutron spectroscopy

Gamma-ray spectroscopy and neutron spectroscopy can be used to survey planetary bodies for hydrogen. The abundance of hydrogen is an indirect measurement of the abundance of H_2O or OH^- in the surface layer of a planetary body under certain assumptions. While the detection of hydrogen by these methods is, in contrast to optical spectroscopy, unambiguous, the conversion to water abundance is strongly model-dependent.

Galactic cosmic rays that penetrate the surface layer of a planetary body begin to lose energy immediately through a variety of mechanisms, mainly intranuclear cascades (Bertini, 1969). The secondary particles formed continue to lose energy by a variety of processes. The net result is that neutrons dominate the residual particle population below 100 MeV (Drake et al., 1988; Feldman et al., 1993) and gamma rays produced by the deexcitation of nuclei with characteristic energy spectra. On entering the surrounding material, the generated neutrons are moderated by elastic and inelastic collisions. The resulting spectrum below 10 keV has two distinct energy regimes, the epithermal and the thermal neutrons.

The cross section of hydrogen for the collision with neutrons is very high, and therefore, hydrogen is a very good neutron moderator. The epithermal neutron energy range (0.4–500 keV) is most sensitive for the detection and mapping of hydrogen (Feldman et al., 2002). Simultaneous measurements of the flux of fast, epithermal, and thermal neutrons emitted from a planetary surface allow constraining the amount of hydrogen as well as the vertical distribution in the subsurface. Deriving these constraints requires a multistep modeling approach, including the modeling of the neutron generation, the moderation in the subsurface, and propagation to orbit (Feldman et al., 1993). A parameterization of the neutron energy distribution based on altitude of the observation and depth below the surface has to be derived (Drake et al., 1988; Feldman and Drake, 1986). The model of the depth dependency includes assumptions about the soil composition, which add to the uncertainty of the obtained results.

The detection of hydrogen by gamma rays is based on the characteristic line at 2.2233 MeV generated by the neutron capture reaction (Reedy, 1978). Deriving the abundance and vertical distribution requires again a multistep modeling approach. This modeling again relies on assumptions about the soil composition and structure.

Gamma-ray spectroscopy and neutron spectroscopy allow detecting hydrogen buried in the subsurface. The penetration depths depend on the properties of the regolith and on the distance between detector and surface. Currently, flying instruments such as the gamma-ray spectrometer (GRS) suite on Mars Odyssey can detect hydrogen down to a burial depth of ~1 m (Feldman et al., 2004). This is an advantage over visual and IR spectroscopy, which can detect water only at the surface. The disadvantage of the technique is a model-dependent ambiguity between abundance and burial depths.

10.11.2.1.3 Morphology

The solid surface of planets and moons is shaped by both endogenic and exogenic processes (Greeley, 1985). The resulting surface morphology is due to a combination of these processes. Endogenic processes include tectonic and magmatic activities. The geologic action of water and ice belongs to the exogenic realm and can affect the surface morphology in several ways. Erosion, including transportation, tends to degrade the surface, while deposition of material leads to the formation of new sedimentary bodies. Erosional and depositional features result from the nature and intensity of weathering and erosional processes, which, in turn, are related to climatic and environmental conditions.

Information about the morphology of planetary surfaces comes mainly from spacecraft images, but radar data (e.g., the Magellan data for Venus) and recent highly resolved topographic data from laser altimeters (e.g., Mars Orbiter Laser Altimeter (MOLA) data for Mars) also contributed much to our knowledge of extraterrestrial landforms. The study of landforms is called geomorphology. It is not the intent of this chapter to give an overview of this discipline; instead, the reader is referred to classic textbooks, for example, Twidale (1976), Bloom (1991), Summerfield (1991), and Easterbrook (1999). Typically, processes related to water are classified depending on the environment: fluvial processes are related to running water, lacustrine and marine processes occur in lakes and seas, and glacial processes shape the surface by the action of ice. Water can also alter rocks and therefore change their physical properties, which in turn affects their susceptibility to other geologic processes.

A major problem of the interpretation of remotely sensed data lies in the distinction whether erosion and sedimentation are driven by water or another geologic agent like wind. For example, the sinuous rilles on the Moon were interpreted on the basis of Earth-based telescopic images and Lunar Orbiter photographs as erosional features carved by water by some early researchers (e.g., Urey, 1967). Zimbelman (2001) pointed out that the improvement in spatial resolution alone, as provided by Lunar Orbiter compared to Earth-based telescopic images, could not rule out several of the published hypotheses that are now known to be wrong. Only Apollo images in combination with in situ observations by astronauts together with laboratory investigations of returned samples revealed the volcanic origin of the rilles. Similarly, there is a long debate on Mars whether the huge outflow channels (see **Section 10.11.3.3**) were carved by water or another fluid like liquid CO_2, lava, or wind. It is therefore critical to test several hypotheses before coming to a final conclusion about the nature of morphological features.

The first and for a long time the strongest evidence that Mars has once experienced a warmer and wetter climate came from image data, starting with the Mariner 9 mission of 1971 (e.g., Masursky, 1973) and the Viking orbiter missions, and their morphological interpretation. Since water-related surface features often have a limited spatial extent and the minimum object size to be detected in images depends on the available image resolution (see Zimbelman (2001) for a discussion on image resolution and its role in the photogeologic interpretation), the recent advance of high- and very high-resolution images taken by the MGS, Mars Odyssey, Mars Express, and Mars Reconnaissance Orbiter (*MRO*) missions has greatly enhanced our ability to analyze small-scale morphologies.

Except Mars and Earth, no other terrestrial planet displays morphological features, which can be attributed to flowing water. Surface processes involving flowing water imply an atmosphere, so the lack of it is not surprising on the Moon and Mercury. Venus has an atmosphere, but at least in its current state, it contains no significant amounts of water vapor and it is too warm to allow liquid water or ice.

10.11.2.1.4 Radar

Radar techniques used for planetary exploration are typically ground-based radar, ground-penetrating radar (GPR) on orbiters or rovers, or synthetic aperture radar on orbiters.

Radar at frequencies commonly used for GPR in planetary exploration cannot unambiguously identify water. Dielectric-relaxation responses can uniquely identify water and ice, but these lie at frequencies of >10 GHz and <10 kHz, respectively, well above and below the GPR band, and above 10 GHz, the depth of investigation will be much less than 1 m.

At radar frequencies, rock and ice have representative dielectric constants of 5–10 and 3, respectively. In contrast, liquid water near freezing has a dielectric constant of 87 (Fletcher, 1970; Hasted, 1973; Heggy et al., 2001; Olhoeft, 1981). The dielectric constant of ice exhibits stronger temperature dependence than water, whereas rocks show almost no temperature effect. The strong difference in the dielectric constants for rock and water makes radar a favorable technique for detecting water, especially if low-frequency sounding (<10 kHz) is used that gives access to the dielectric-relaxation response (Grimm, 2002). This is however only true if water is confined in a larger volume – for example, in an aquifer. If water is dispersed in the pore space of a dry regolith, the contrast in the dielectric constant diminishes quickly. Assuming a soil–water mixture with a porosity of 5% yields a dielectric constant of 7–9 indistinguishable from dry rock (Shivola, 1996).

The small dielectric constant of ice allows a good penetration for radar signals. The difference from the typical dielectric values for rocks can result in detectable interfaces between pure ice and dry soil. Mixing of ice and water results in the same problem as described earlier for water–rock mixtures. Even large amounts of ice dispersed within the pore space are indistinguishable from dry rock and can therefore not be detected by GPR.

Ground-based radar observations of planetary surfaces assess the reflective properties of the surface and the near-surface material. Deposits of frozen volatiles on the surface, especially water ice, have a much lower transmission loss than silicate rocks. They produce therefore a higher average radar reflectivity than silicate rocks. This is however not a unique identification because the nature of the surface, especially the spatial-scale roughness of the radar wavelengths, can significantly influence the reflective properties of the surface. The polarization properties of the surface can provide another indication for the existence of ice on or near the surface. Ice-containing surface tends to show a smaller degree of depolarization of the radar signal than dry rock surface. The higher reflectivity and the smaller depolarization effect are due to the details of the multiple scattering at a semitransparent surface (Hapke and Blewett, 1991).

10.11.3 Water on the Surface

If we focus on the surface and near-surface region of terrestrial planets, there are several possible reservoirs for water: in the regolith as ice or adsorbed, on the surface as ice, or as standing or flowing body of water.

There are direct spectroscopic observations of water ice on Mars' polar caps as recently recorded by visible and IR mineralogical mapping spectrometer (OMEGA; Observatoire pour la Minéralogie, l'Eau, les Glaces et l'Activité) and planetary Fourier spectrometer (PFS) on Mars Express (Bibring et al., 2004b; Hansen et al., 2005) and evidence for its existence today in permanently shadowed regions around the poles of Mercury and the Moon (Butler et al., 1993; Feldman et al., 1998; Harmon and Slade, 1992; Nozette et al., 1996). So far, no direct evidence for liquid water at present time has been found on any terrestrial planet besides Earth. Mars, however, shows evidence that it had in its past large standing and flowing bodies of water. There are also indirect indications for the existence of larger amounts of water in the very early history of Venus.

10.11.3.1 Valley Networks

Valley networks, first detected in Mariner 9 imagery (Masursky, 1973), resemble terrestrial drainage patterns in plan view. More than 1000 individual valley networks were observed on Mars, and their similarity to terrestrial fluvial landforms implies that they were formed by water. They are the most striking morphological evidence that water once flowed across the Martian surface. Nearly all valley networks are located in the heavily cratered highlands, which led to the assumption that they were formed early in Martian history. Later studies used age determinations based on crater statistics and conformed that the majority of valleys were formed at the transition from the Late Noachian to the Early Hesperian epochs (~3.8–3.5 Ga). Although it is commonly accepted that water formed the valley networks, there is a long and ongoing debate about the process (e.g., the relative roles of groundwater versus surface runoff), the source of the water (precipitation as rain or snow versus groundwater or ground ice), and the implications for the climate of early Mars (i.e., 'warm and wet' vs. 'cold and wet'). While the valley networks seem to suggest that liquid water flowed once over the Martian surface for extended periods of time, atmospheric evolution and climate models have problems to explain how a dense, warm atmosphere with a sufficient greenhouse effect could have existed on early Mars (e.g., Fastook et al., 2012; Kasting, 1991; Lammer et al., 2013).

10.11.3.1.1 Morphology and formation processes

Importantly, the term valley network does not describe a river or stream channel. A valley may form by different processes, whereas a river channel is the actual conduit through which liquid water flows. Only relatively few interior river channels on Mars have been observed in high-resolution images (e.g., Irwin et al., 2005b; Malin and Carr, 1999), because they can be easily destroyed by erosion or infilled by sedimentation over long timescales. If their three-dimensional geometry can be resolved, flow models can be applied to constrain the amount of water flowing through these channels per time unit (ranging from a few hundred to a few thousand cubic meters per second, assuming bank-full flow) (Irwin et al., 2005b). Nevertheless, due to their morphological characteristics, most valley networks or systems on Mars are thought to be of fluvial origin.

Valley networks can reach lengths from <5 km to nearly 1000 km and widths from <1 km to nearly 10 km (Mars Channel Working Group, 1983). Some large valley systems, also sometimes termed longitudinal valley systems (examples are Nirgal, Nanedi, Bahram, and Al Qahira Valles), are several hundred kilometers long and several kilometers wide. They exhibit upper reaches with short theater-headed tributaries and a broad, flat-floored main valley with only a few tributaries. On the other hand, small valley systems show a larger morphological variety. Many of them display a dendritic pattern in which tributaries converge downstream. More detailed descriptions about fluvial valley morphology are given in, for example, Baker et al. (1992), Carr (1996), Gulick (2001), and Ansan and Mangold (2013).

Some of the larger or longitudinal valley systems show morphological characteristics (e.g., an abrupt headward termination, prominent structural control, low junction angles, a relatively constant valley width downstream (Goldspiel et al., 1993), and rectangular cross sections with flat floors) that resemble that of terrestrial sapping valleys, which are often situated in layered sedimentary rocks (Howard and Kochel, 1988; Laity and Malin, 1985). Laity and Malin (1985, p. 203) defined sapping process as

> The process that leads to the undermining and collapse of valley head and side walls by weakening or removal of basal support as a result of enhanced weathering and erosion by concentrated fluid flow at a site of seepage.

An origin of Martian longitudinal valleys by groundwater seepage (Goldspiel and Squyres, 2000) would not necessarily require warm and wet surface conditions, and therefore, the problem that atmospheric and climate models do not predict a strong greenhouse effect on early Mars would be less severe. However, groundwater seepage also requires recharge of aquifers by precipitation. Moreover, it has been questioned if sapping alone has enough erosive power to remove the weathered and collapsed sediment in order to continue the retreat of the headwall (Craddock and Howard, 2002; Lamb et al., 2006). Hence, groundwater sapping was probably not the only process involved, and surface runoff may have played an important role, too (Baker et al., 1992; Craddock and Howard, 2002).

The smaller, dendritic valley networks (**Figure 4**) are even less likely to be formed by groundwater seepage alone. Some morphometric properties (e.g., bifurcation ratios, start of branches at high elevations where groundwater emergence is unlikely) support the view that valley network formation required an active water cycle and that surface runoff, either from rain or from snowmelt, was a dominant factor (Ansan and Mangold, 2013). Moreover, whereas studies based on low-resolution data concluded that drainage densities are very low when compared to terrestrial valleys (Carr and Chuang, 1997) and that only some valley systems on volcanoes have comparable drainage densities to fluvial networks on Earth (Gulick and Baker, 1989), measurements based on

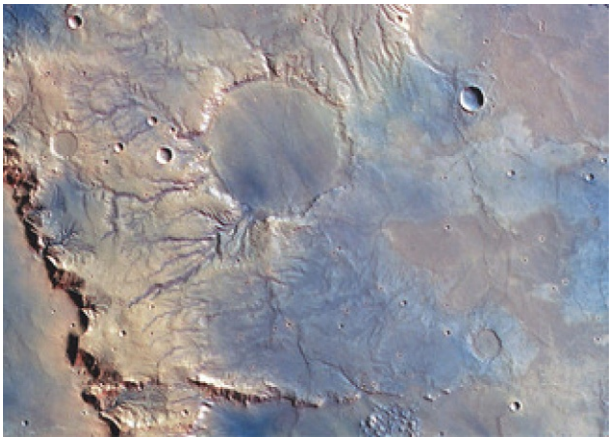

Figure 4 Dendritic valley networks on Mars. The large crater in the center of the image has a diameter of 45 km (false-color HRSC image h00532_0000 at 60° E and 12.5° S). copyright: ESA/DLR/FU Berlin.

higher-resolution imagery data and topographic data have demonstrated that drainage densities on Mars can reach the lower bounds of terrestrial values (Ansan and Mangold, 2006, 2013; Hynek and Phillips, 2003; Hynek et al., 2010; Irwin and Howard, 2002; Stepinski and Stepinski, 2005). Nevertheless, it is still unclear what exactly the climatic conditions were during their formation. Some characteristics of the valley networks, such as their still relatively low drainage densities (Erkeling et al., 2010; Hynek et al., 2010; Luo and Stepinski, 2006; Stepinski and Coradetti, 2004) and other morphometric properties, for example, a paucity of crater rim exit breaches or the shape of longitudinal valley profiles (e.g., Barnhart et al., 2009; Penido et al., 2013), suggest that Martian valley networks are immature as compared to terrestrial drainage patterns and do not indicate an Earth-like climate on Mars that would have been sustained over prolonged periods of time (reviews by Irwin et al. (2008) and Carr (2012)).

10.11.3.1.2 Ages

Most of the valley networks are located in the oldest terrains of the southern highlands, which led to the assumption that they were formed early in Martian history (Carr and Clow, 1981; Pieri, 1976). The age of a larger number of small valley networks was determined by superposition relationships on geologic units. Scott and Dohm (1992) analyzed the transection relationships of about 400 valley networks on geologic units. They derived maximum stratigraphic ages for most valleys between the Noachian and the Early Hesperian. They suggest that possibly 30% of all valleys might be Early Hesperian in age or even younger. Carr (1995) analyzed more than 800 valley networks with the same method and derived that ~92% have Noachian, ~4% Hesperian, and ~4% Amazonian maximum ages. However, these studies suggest that most valley networks were formed early in the Martian history, primarily in the Noachian and Early Hesperian. Carr (1996) pointed out that the cratered highland valley networks are probably mostly Noachian in age and Hesperian-aged ones primarily occur where there is substantial local relief, such as in the Valles Marineris region and along the dichotomy boundary. Most Amazonian-aged valleys are located on volcanoes (Carr, 1995; Gulick and Baker, 1990; Scott and Dohm, 1992). Age determinations by crater counts are complicated due to the small areas of valley floors and subsequent obliteration of craters by infilling processes, such as eolian deposition and mass wasting. The age of some larger valley systems has been determined by crater counts on channel floors (Masursky et al., 1977) and by the so-called buffered crater-counting technique, which takes into account that younger craters hit the valley rims. The problem of small counting areas can be overcome using a so-called buffered crater-counting technique, which takes into account that younger craters hit the valley rims. Applying this method, Fassett and Head (2008a,b) confirmed previous notions that most valley networks are Late Noachian or Early Hesperian in age. Based on global mapping of valley networks, Hoke and Hynek (2009) and Hynek et al. (2010) also concluded that valley networks formed mostly between ~3.8 and 3.6 Ga. This period in the Martian history may have been a peak time of extensive fluvial denudation (Harrison and Grimm, 2005; Howard et al., 2005; Irwin et al., 2005a), since only limited direct observational evidence is left from possible earlier episodes of fluvial degradation (although the degradation state of craters points to significant erosion even before that time).

10.11.3.1.3 Source of water and climate

As pointed out by Craddock and Howard (2002), groundwater flow, recharge, and erosion are closely related to precipitation and surface runoff on Earth. Although sapping is an efficient process in loose sediments, there is no clear evidence from recent studies on Earth that groundwater processes cause significant erosion in resistant rock such as basalt (Lamb et al., 2006). Due to bedrock strength, enormous discharges of water would have been necessary to erode the Martian valley networks (Howard and Kochel, 1988). Estimates of water volumes required for the formation of the valley networks indicate that the aquifers contained about 100–1000 times less water than needed to erode the valleys (Gulick, 2001). A recharge of the drainage areas was therefore necessary (Craddock and Howard, 2002; Goldspiel and Squyres, 2000; Grant, 2000; Gulick, 2001; Howard and Kochel, 1988). The simplest recharge mechanism is by precipitation and subsequent groundwater sapping and/or surface runoff, which would require higher atmospheric temperatures and pressures and point to a warmer and wetter climate on early Mars (e.g., Baker et al., 1991; Carr, 1996; Craddock and Howard, 2002). Phillips et al. (2001) suggested a release of carbon dioxide and water from Tharsis magmas, which may have sustained a warmer climate for the formation of valley networks around or after the end of the Noachian epoch.

Models of valley network formation under dry and cold climatic conditions include the melting of dusty snowpacks by insolation (Clow, 1987), basal melting of snowpacks (Carr and Head, 2003), or melting of snowpacks by internal heat (Zent, 1999). Clifford (1987) proposed an aquifer recharge by basal melting of the south polar cap. However, this model is not consistent with the observation that the elevation of many valley heads is higher than the base of the south polar cap (Carr, 2002). Another suggested recharge model is the global hydrothermal circulation model of Clifford (1993), in which upward vapor flow driven by the

geothermal heat gradient might form an icy permafrost layer. Subsequent melting of permafrost by geothermal heating might cause groundwater sapping (e.g., Squyres and Kasting, 1994). A formation mechanism by snow or ice melt and runoff may specifically apply to valleys of Hesperian and Amazonian age (Fassett et al., 2010; Howard and Moore, 2011).

The genesis of the younger valleys on volcanoes might have been different from valley networks in the highlands. Gulick (2001) suggested that a hydrothermal system associated to magmatic intrusions replenishes itself. Basal melting of a summit snowpack triggered by the heat flux of magmatic intrusions was also proposed for the formation of fluvial valleys on volcanoes (Fassett and Head, 2006).

10.11.3.2 Fluvial and Lacustrine Sedimentary Processes

10.11.3.2.1 The orbiter view

Paleolakes with their morphological characteristics like delta-like deposits, wave-cut terraces, shorelines, and evaporites support the hypothesis of past standing bodies of water on Mars (Cabrol et al., 1996; De Hon, 1992; Forsythe and Zimbelman, 1995; Grin and Cabrol, 1997; Hauber et al., 2009; Newsom et al., 1996; Ori and Mosangini, 1998; Ori et al., 2000; Wharton et al., 1995). More than 200 candidate paleolakes were identified on a global scale in impact craters on Mars, based on fluvial network inflows and morphological lacustrine characteristics (Cabrol and Grin, 1999; Fassett and Head, 2008b; Goudge et al., 2012). In addition to lacustrine sedimentary deposits, a large number of alluvial fans have been identified (Kraal et al., 2008a; Moore and Howard, 2005). Using stratigraphic relationships derived from geologic maps and crater-counting techniques, Cabrol and Grin (2001) estimated most of the paleolakes to be active in the Hesperian, although it has to be noted that the small areas of the deposits may bias the crater-counting results toward younger ages. Nevertheless, a large number of lakes and alluvial fans might have been active even later during the Amazonian, often associated with outflow channels or other short-lived aqueous activity (Cabrol and Grin, 2001; Di Achille et al., 2007; Grant and Wilson, 2011; Hauber et al., 2013). Cabrol and Grin (2001) found little evidence for Noachian lacustrine activity. This apparently contradicts the notion from valley network studies that fluvial activity peaked at the end of the Noachian. Cabrol and Grin (2001) suggested that evidence for it might have been lost due to erosion and major resurfacing episodes later in the Martian history.

Recent image and topographic data allowed detailed analyses of paleolakes and their associated delta and fan deposits and enable reconstructing local hydrologic conditions that help to understand the Martian climatic history. A detailed study of the Tyras Vallis delta deposit in the Xanthe Terra region revealed a complex crater lake history with changing lake levels and water supplies between the Late Noachian and the Hesperian (Di Achille et al., 2006a). Deltaic, coastal, and lacustrine environments occurred during the Hesperian in the Holden crater, followed by glacial processes in Amazonian (Pondrelli et al., 2005). Sedimentary deposits in the Coprates Catena have been interpreted as an alluvial fan (Di Achille et al., 2006b) or delta deposit (Weitz et al., 2006). A particularly well-studied example of deltaic deposits occurs in the Eberswalde crater (**Figure 5**). It shows evidence for channelized and meandering flow indicating persistent flow conditions and formation of intracrater layered sedimentary sequences within fluvial and perhaps lacustrine environments (Malin and Edgett, 2003; Moore et al., 2003). The morphology of this deposit has been interpreted as a fan delta (Bhattacharya et al., 2005; Irwin et al., 2005a; Pondrelli et al., 2008) or alluvial fan (Jerolmack et al., 2004; Malin and Edgett, 2003).

The morphology of deltas and feeder channels has been used to reconstruct the formative processes by modeling and experimental work. These results indicate that the formation of deltas can occur over geologically very short timescales (~years to thousands of years) (Hoke et al., 2014; Kleinhans et al., 2010; Kraal et al., 2008b), eliminating the need to invoke extended periods of a warm and wet climate. However, the presumption of these studies is that, during the epoch of their formation, the deltas were deposited without significant hiatuses or lengthy periods of aridity; if activity on these features was intermittent, the timescale of formation may have been much longer. These results are consistent with the notion of delta formation by local, not global, conditions (Hauber et al., 2013) that may include impacts, volcanism, and transient episodes of warming that were perhaps triggered by orbital or obliquity variations (Mangold et al., 2012). Using laboratory experiments of crater lakes, De Villiers et al. (2013) could show that the water level behavior controls delta morphology: Stepped, retrograding deltas form during water level rise, whereas prograding deltas form during periods of constant water level.

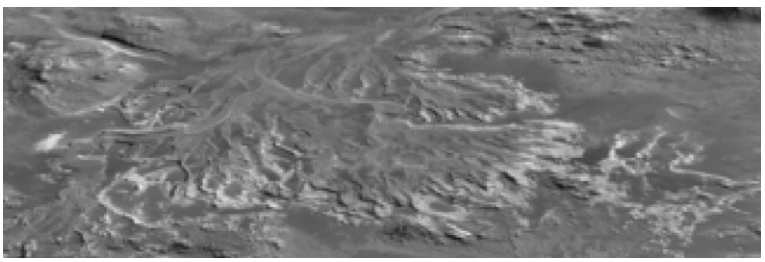

Figure 5 The Eberswalde crater hosts the best-known example of a deltaic structure on Mars. Evidence for channelized and meandering flow indicates persistent flow conditions and formation of intracrater layered sedimentary sequences within fluvial and perhaps lacustrine environments (Malin and Edgett, 2003). The image is a perspective view from the east, and the image width is about 20 km (MOC image mosaic draped over topography derived from HRSC stereo images). HRSC image copyright: ESA/DLR/FU Berlin.

10.11.3.2.2 The view of the rovers

Aqueous processes have also been inferred from morphological observations by the MER rover, Opportunity, in Meridiani Planum (Squyres et al., 2004). The layered rocks consist of sandstones, which show several sedimentary structures like cross-bedding, festoon cross-lamination, resistant fracture fills, and polygonal forms (Grotzinger et al., 2005). Although eolian processes probably dominated the overall environment, these structures, together with geochemical and mineralogical evidence (see **Section 10.11.4.2**), indicate that abundant acidic groundwater was present, that acidic and oxidizing conditions prevailed, and that inundations led to episodic shallow subaqueous flows of liquid water (Squyres et al., 2006). Several terrestrial analogues, ancient and modern, have been proposed to illustrate the paleoenvironment in Meridiani Planum. A summary is given by Benison and Bowen (2006), who favored ephemeral acid saline lakes in SW Australia as the best-known Earth analogue. There, shallow lakes and adjacent groundwater have low pH values (1.5–4) and minerals are precipitated that are also found in Meridiani Planum (gypsum, halite, iron oxides, and jarosite). Flooding, evaporation, desiccation, and winds dominate the environment (Benison and Bowen, 2006). Recently, the Curiosity rover of the Mars Science Laboratory (MSL) mission has investigated in situ fluvial conglomerates as parts of an alluvial fan complex within Gale crater (Williams et al., 2013).

10.11.3.3 Outflow Channels

Outflow channels, first detected in images of the Mariner 9 spacecraft (Masursky, 1973), are the most spectacular examples of Martian surface features formed by the erosive power of water. Their dimensions are much larger than those of other fluvial landforms on Mars as, for example, valley networks (**Section 10.11.3.1**). The largest outflow channels can reach lengths of thousands of kilometers, widths of tens to hundreds of kilometers, and depths of more than 1 km. They are not uniformly spread over the Martian surface, but cluster in a few distinct regions, in particular around the Chryse Planitia basin in the eastern vicinity of the huge magmatectonic center of Tharsis (**Figure 6(b)**: circum-Chryse outflow channels). Other concentrations occur in Elysium Planitia, in the eastern Hellas region, and on the southern margin of Amazonis Planitia. Outflow channels formed episodically in several stages over a significant part of the geologic history of Mars, beginning in the Late Noachian. The main activity seems to have been in the Hesperian period, with lesser stages continuing well into the Amazonian period (see Basilevsky et al., 2006; Table IV of Clifford and Parker, 2001; Greeley and Guest, 1987; Lanz, 2004; Neukum and Hiller, 1981; Scott and Tanaka, 1986; Warner et al., 2010; Werner, 2006). Two outflow channels in the Elysium region, Marte Vallis and the Athabasca Valles, even show evidence for some of the youngest fluvial activity on Mars (Burr, 2003; Burr et al., 2002a,b; Werner et al., 2003).

Outflow channels are important in at least two aspects for the Martian history: first, their enormous sizes strongly indicate that large volumes of liquid water or water ice once flowed across the surface of Mars. Secondly, outflow channels would have been the most obvious pathways for water that filled the northern lowlands to form an ancient Martian ocean (Baker et al., 1991; see also **Section 10.11.3.4**).

10.11.3.3.1 Morphology

Outflow channels start full size at discrete sources. These sources may be fractures (e.g., at Athabasca or Mangala Valles; **Figure 7**: Mangala), but most commonly, they are located in the so-called chaotic terrains (**Figure 6(d)**: Aromatum Chaos (chaotic terrains)). Large blocks of plateau material and intermediate depressions, often arranged in a 'chaotic' geometry, characterize these zones. They seem to have formed by the collapse of plateau material that, where undisturbed, currently forms the surroundings of the chaotic terrains. The most characteristic landforms associated with outflow channels themselves are streamlined or 'teardrop-shaped' islands, which were clearly carved by a fluid medium and indicate the flow direction (**Figure 7**: Mangala). The overall pattern of outflow channels is often anabranching (**Figure 6(b)** and **6(c)**: outflow channels in MOLA). Other surface features typically observed at the floors of outflow channels are bedforms like scour marks, grooves, cataracts, and possible sinkholes ('kolks') (Baker, 1982), testifying that the outflow channels are true river channels (as opposed to valleys; see discussion in Carr, 1996). Outflow channels have only few tributaries and maintain a more or less constant width downstream. More detailed descriptions of the channel morphologies are given by Baker (1982), Baker and Nummedal (1978), and Baker et al. (1992). It was recognized early in the interpretation of spacecraft images that the collective association of these landforms bears a striking similarity to the so-called Channeled Scabland in the northwestern US (Baker, 1978, 1982, 2009; Baker and Kochel, 1979; Baker and Milton, 1974) (**Figure 6(a)**: Landsat). J Harlen Bretz interpreted these giant erosion features in a series of pioneering studies early in the twentieth century as results of the catastrophic drainage of ice-dammed lakes during the latest glaciation in the Pleistocene (e.g., Bretz, 1923). Their significance extends well beyond the Channeled Scabland in that they helped to understand that catastrophic events must not be neglected in the deciphering of the Earth's geologic record ('uniformitarianism' vs. 'catastrophism'; for a comprehensive modern view on this debate, see Baker and Nummedal (1978)). Similar 'spillways' have later been interpreted by means of modern spacecraft data in Siberia (Manych spillway and Turgay spillway; e.g., Baker et al., 1993; Grosswald, 1998).

The cataclysmal flood hypothesis is, however, not without difficulties, as pointed out by Baker et al. (1992). First, under current climatic conditions, water is not stable. Since the floods were probably very short-lived, this does not seem to be a major problem. Second, there are no obvious fluvial deposits like deltas at the termini of the channels. The third problem is that the source areas, which mostly are chaotic terrains, are relatively small when compared to the amount of water that probably carved the outflow channels. This discrepancy might be explained by the headward migration of the source areas as more and more terrains collapse in the subsequent stages of flooding (Baker, 1982).

10.11.3.3.2 Morphometry/discharge

Many attempts have been made to estimate the peak drainage in the outflow channels from the geometry of the

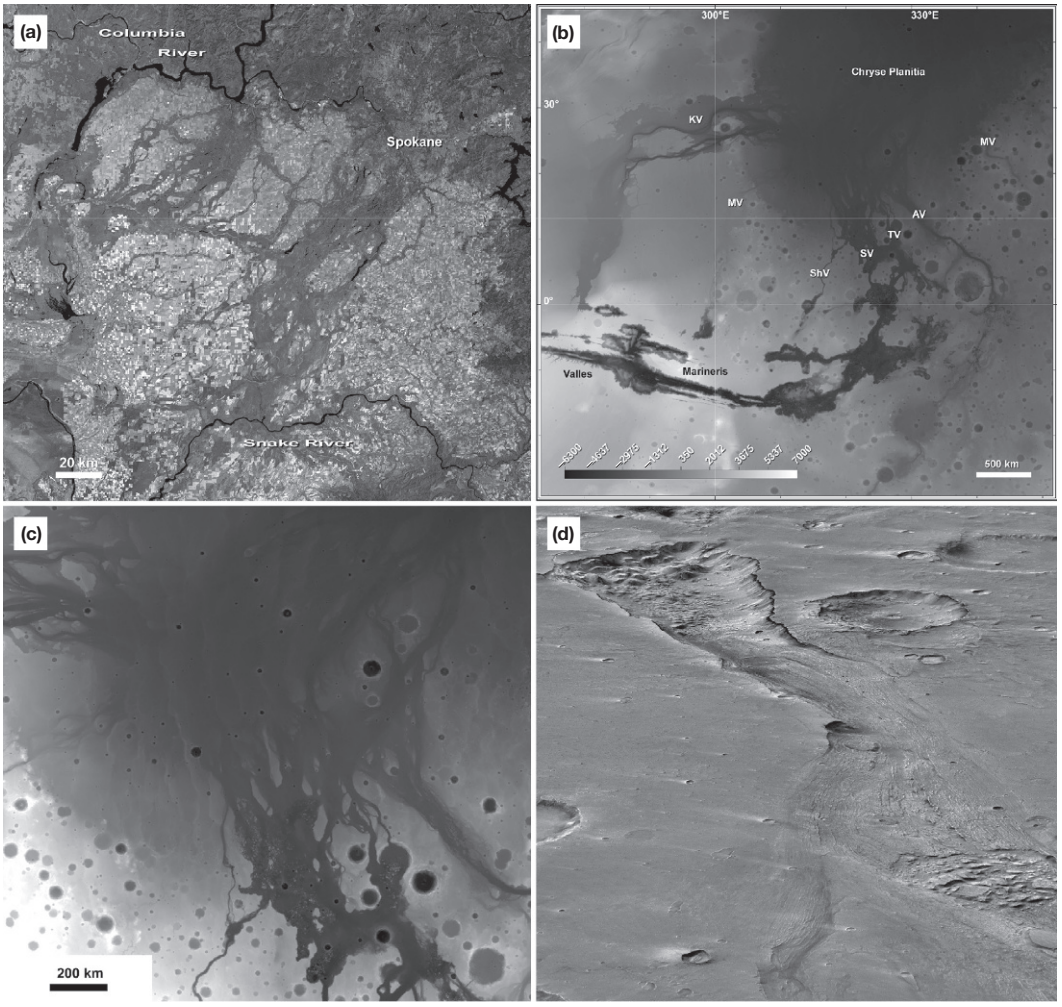

Figure 6 Outflow channels are the most dramatic geomorphic evidence for the flow of liquid water or ice on the Martian surface. They were interpreted as the erosional products of catastrophic floods on the basis of the comparison to terrestrial analogues. (a) The Channeled Scablands in Washington State (the United States) formed when an ice-dammed lake drained in a huge flood toward the Pacific Ocean (Bretz, 1923). The channel floors can be recognized as dark areas and form an anastomosing pattern (Landsat mosaic; north is up). (b) Outflow channel on Mars. The largest channels debouch into the topographic low of the Chryse Planitia basin (KV, Kasei Vallis; MV, Maja Vallis; ShV, Shalbatana Vallis; SV, Simud Vallis; TV, Tiu Vallis; AV, Ares Vallis). The image is a gridded digital elevation model derived from MOLA altimetry data (see scale bar for elevations). (c) Detail from (b), showing the anastomosing nature of the downstream parts of some channels. Note the similarity to the terrestrial analogue shown in (a), but also note the difference in scale. (d) Perspective view of an outflow channel. The source in the left background is a typical chaotic terrain, Aromatum Chaos, and the outflow channel, Ravi Vallis, extends from there to the right foreground, displaying a grooved channel floor (HRSC image mosaic draped over MOLA topography; the diameter of the large crater is about 26 km). copyright: ESA/DLR/FU Berlin.

paleochannels. The first and for a long time the most accepted approach was the application of modified versions of the empirically determined Manning equation (Manning, 1891), which predicts flow velocities in terrestrial channels. In two outstanding papers, Komar (1979, 1980) pioneered studies of this kind and found values in the range of 10^7–$10^8 m^3 s^{-1}$ (for Maja, Ares, and Tiu Valles, assuming a flow depth of 100 m). Even higher values of up to 10^9 $m^3 s^{-1}$ have been reported for Kasei Vallis, the largest outflow channel on Mars (Baker, 2001; Robinson and Tanaka, 1990). Williams et al. (2000) used improved topographic data from the MOLA instrument and reported values between 8×10^4 and 2×10^7 $m^3 s^{-1}$ for channels of the Kasei Vallis system. It has to be emphasized, however, that Komar (1979, 1980) was aware of the shortcomings of this approach (see discussions in Kleinhans, 2005; Wilson et al., 2004). More recently, Wilson et al. (2004) derived a new value for the Manning n coefficient and found that previous analyses based on modified versions of the original Manning equation overestimated the water flow velocities by a factor of up to 2.5. They recommended that their improved value for the Manning n coefficient should be used or, preferably, that a modern form of the Manning equation or the Darcy–Weisbach equation be used for future studies. In an up-to-date review of water flow and sediment transport models, Kleinhans (2005) also recommended the use of the Darcy–Weisbach equation and gave ranges of flow discharges for large outflow channels like Ares or Kasei Vallis in the order of 10^2–$10^3 \times 10^6$ $m^3 s^{-1}$. Discharges within the same order of magnitude were found by Burr et al. (2002a) for the Athabasca Valles ($1–2 \times 10^6$ m^3 s^{-1}), Ghatan et al. (2005) for Mangala Valles ($\sim 5 \times 10^6$ m^3 s^{-1}),

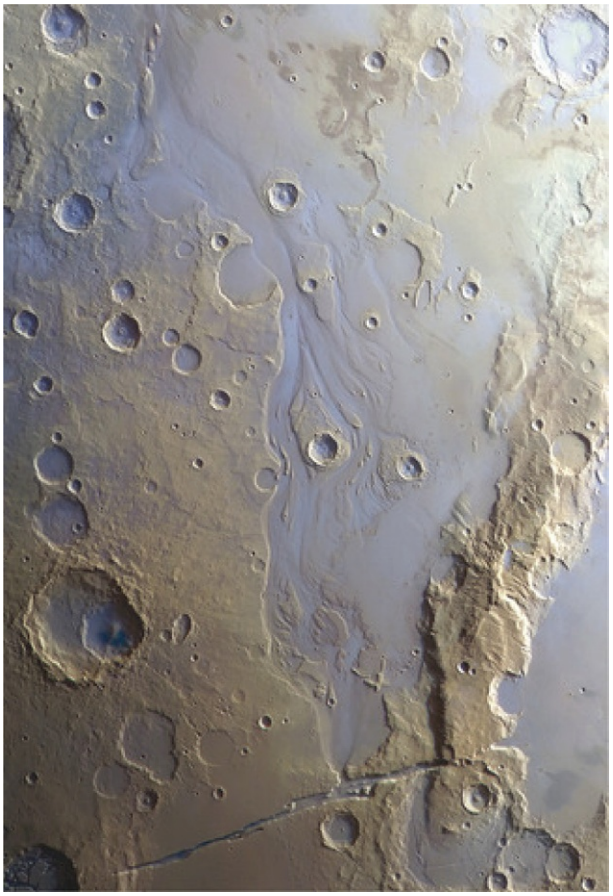

Figure 7 Mangala Vallis, a typical outflow channel on Mars. The channel originates at a tectonic fracture at the bottom center of the image and flowed toward north (top of image), eroding streamlined islands. False-color HRSC image 0644 (image width is about 370 km). copyright: ESA/DLR/FU Berlin.

Coleman (2004) for Ravi Vallis ($1–35 \times 10^6$ m^3 s^{-1}), and Leask et al. (2006a), also for Ravi Vallis (between <1 and 30×10^6 m^3 s^{-1}). Leask et al. (2006a) calculated the duration of the flooding event from the volume of the eroded material, from plausible assumptions on the sediment-carrying capability of water, the minimum total volume of water involved, and the crustal erosion rate. They obtained a duration of 2–10 weeks, comparable with a duration of 1–3 months for the flooding in the Mangala Valles, as reported by Ghatan et al. (2005). The total amount of water required to erode the outflow channels may have corresponded to a global equivalent water layer of 500–1000 m thickness (e.g., Carr, 1986), but this estimate is subject to considerable uncertainties.

10.11.3.3.3 Formation

Many fluid media have been proposed to explain the formation of outflow channels, for example, wind (Cutts and Blasius, 1981), lava (e.g., Carr, 1974; Leverington, 2004, 2011), liquid hydrocarbons (Yung and Pinto, 1978), and liquid CO_2 (Hoffman, 2000a; Milton, 1974; Tanaka et al., 2001); the dissociation of methane hydrate (Max and Clifford, 2001); or liquefaction and/or debris flows (Nummedal, 1978; Nummedal and Prior, 1981; Rodriguez et al., 2006; Tanaka, 1997, 1999) (for a more complete list, see Carr (1996) and references therein). However, the consensus among many researchers is that only liquid water and water ice are physically plausible candidates in the Martian environment (e.g., Baker, 2001; Carr, 1996; Coleman, 2003, 2005), although it has been argued that lava can also be an efficient erosive agent (e.g., Keszthelyi et al., 2014). While the collective assemblage of outflow channel landforms suggests, by analogy with the terrestrial Channeled Scabland, cataclysmal release of liquid water as the formation mechanism, it has to be emphasized that water ice can also explain some of the properties of outflow channels (Lucchitta, 1982, 2001).

How could huge volumes of water be released in short time on the Martian surface? Most researchers think that a pressurized aquifer at depth, covered by an impermeable crustal zone of ground ice (the cryosphere; Clifford, 1993; Lasue et al., 2013a,b), was tapped, and the artesian release of that pressurized water led to the catastrophic drainage of the aquifer, collapse of the surface to form chaotic terrains, and outflow channel formation (e.g., Baker and Kochel, 1979; Baker et al., 1991; Carr, 1979; Masursky et al., 1986; Theilig and Greeley, 1979). Some chaotic terrains are completely enclosed and do not have a surface connection to an outflow channel. On the other hand, there are zones of surface subsidence between some chaotic terrains and outflow channels (e.g., between Ganges Chasma and Shalbatana Vallis) (e.g., Cabrol et al., 1997). Both observations indicate that channelized subsurface flow of water is an important factor in the mobilization of the water masses responsible for outflow channel generation (Carr, 1995). Rodriguez et al. (2003) suggested that extensive cavernous systems, triggered by intrusive magmatism into permafrost, served as pathways for the migration of water that finally emerged into the outflow channels.

Several processes have been invoked to break the thick permafrost zone or cryosphere above a pressurized aquifer, including magmatic intrusions (e.g., Greeley and Spudis, 1981; Mars Channel Working Group, 1983; Masursky et al., 1977, 1986; Mouginis-Mark et al., 1984; Rodriguez et al., 2003), and in particular dikes (e.g., Head et al., 2003b) and sills (Leask et al., 2006b), and tectonism (e.g., Cabrol et al., 1997). Manga (2004) showed for the case of the recent flooding at Cerberus Fossae that large subsurface aquifers with permeabilities comparable to those of young basaltic aquifers on Earth can discharge enough water to account for the estimated 10^6 m^3 s^{-1} (Burr et al., 2002a), without the need for unusual physics or material properties. An alternative way to release water in large amounts might have been the catastrophic drainage of ice-covered lakes in the Valles Marineris area or in the chaotic terrains (e.g., McCauley, 1978; Robinson and Tanaka, 1990). Outflow channels often show evidence for multiple stages of flooding, which requires recharging of the aquifer(s). This could have taken place by basal melting of the topographically high-lying south polar cap (Clifford and Parker, 2001), supplying a globally connected aquifer with water, or by precipitation on the elevated Tharsis bulge in times of higher obliquity (Harrison and Grimm, 2004).

10.11.3.4 Oceans

The Earth is topographically divided in two main regions on a global scale, the high continents and the low-lying,

water-covered ocean floors. Mars is also topographically divided in two main regions on a global scale, the southern highlands and the northern lowlands. The lowlands north of the dichotomy boundary would represent the largest drainage basin on Mars (Banerdt and Vidal, 2001; Smith et al., 2001), and most of the largest erosional features on Mars, the outflow channels (see **Section 10.11.3.3**), debouch into them. Not surprisingly, perhaps, a variety of studies investigated the possibility of an ancient large body of standing water in the lowlands.

10.11.3.4.1 Models involving oceans

Oceans as water reservoirs from which the atmosphere could be replenished constitute major elements in some models of the evolution of the Martian hydrology. Perhaps, one of the most influential was a conceptual scheme outlined by Baker et al. (1991). Overall, this model suggests that the climate since the end of the Noachian was mainly cold and dry, in agreement with the very low erosion rates since then (e.g., Golombek and Bridges, 2000; Golombek et al., 2006). However, short episodes of enhanced hydrologic activity were triggered by volcanism in Tharsis and subsequent cataclysmal outbursts of water that was transported down the outflow channels and finally ponded in the lowlands as oceans, called 'Oceanus Borealis.' The release of the greenhouse gases, H_2O and CO_2, would have created a short-lived denser atmosphere and an active and dynamic hydrologic cycle, which involves precipitation and channel formation (e.g., on areas of high elevations like Alba Patera). In colder regions, glacial landforms would result from snowfall and glaciation. When the released water finally was trapped as ground ice or water, the hydrologic activity would have stopped. The short phases of enhanced hydrologic activities would also have been responsible for the formation of a variety of geomorphic features on Mars, which were otherwise hard to explain. Among these were possible glacial features in the southern hemisphere (Kargel and Strom, 1992) and young, Amazonian-aged valley networks on some volcanoes (Gulick and Baker, 1989, 1990). It has to be noted, however, that recently other possibilities to provide the water for the formation of these young valley networks have been investigated, like the melting of snow (e.g., Fassett and Head, 2006) that was deposited during periods of higher obliquity and enhanced precipitation in lower latitudes.

Most studies proposing an ocean explained it as the consequence of water release through the giant outflow channels. Therefore, its age was commonly assumed to be roughly coeval with outflow channel activity, that is, Hesperian (~3.7–3.3 Ga) or even Early to Middle Amazonian (~3.3–0.6 Ga) in age. In contrast, a recent theory of the hydrologic evolution of Mars postulates the existence of an ocean in the first billion years of the planet's history: Clifford and Parker (2001) investigated the hydraulic conditions that were necessary to explain the outflow channel formation in the Late Hesperian by the catastrophic release of groundwater from confined aquifers. They found that a several-kilometer-thick cryosphere would have been required to support an elevated groundwater table at or above the source region of the outflow channels. In the Noachian, when the climate might have been warmer and the global heat flux was several times higher, the cryosphere would have been too thin to prevent the water from accumulating in the regions of the lowest geopotential. According to Clifford and Parker (2001), the inevitable consequence would have been the formation of a primordial ocean in the Noachian, which might have covered a third of the planet's surface.

10.11.3.4.2 Assessment of geomorphic evidence

One of the first studies that speculated about the existence of an ocean was by Jöns (1984, 1985). He described possible sediments and mudflows (Jöns, 1984) and concluded that the northern lowlands might have hosted an ancient mud ocean fed by mass-wasting processes (Jöns, 1985, 1986). At about the same time, McGill (1985) and Lucchitta et al. (1986) mapped polygonal patterns in the northern lowlands and found a spatial association with the terminations of the big outflow channels. Lucchitta et al. (1986) suggested that the polygons developed in sedimentary layers and concluded that these might have been deposited by outflow channel discharge in an ancient ocean, which could have been covered by ice. Later, but still on the basis of Viking orbiter images with a resolution of typically 60–100 m per pixel, Parker (1989) and Parker et al. (1993) made an attempt to map shorelines around the northern lowlands. They suggested two possible sets of shorelines, an outer set called 'contact 1' and an inner set ('contact 2'). Based on their mapping and a discussion on possibly involved water volumes, Parker et al. (1993) proposed that the northern lowlands have been occupied by an ocean fed by outflow channel activity, the shorelines representing highstands of the water level. For a long time, the shoreline maps by Parker (1989) and Parker et al. (1993) were the foundation of most studies speculating about northern Martian oceans. Later, Edgett and Parker (1997), Clifford and Parker (2001), and Webb (2004) reported on additional shorelines, some of them requiring significant volumes of water to fill the outlined depressions.

In these studies, the outflow channels would have been the pathways for the water filling the hypothesized ancient oceans. Therefore, the plausibility of the ocean hypothesis depends critically on the relationship between the outflow channels and the northern lowlands as the natural sink for their water.

The morphological expression of six major outflow channels disappears in the downstream direction at about the same elevation around Chryse Planitia. Ivanov and Head (2001) noted that this fact might suggest a common base level and would be in agreement with large lakes or oceans in the lowlands in the Hesperian or in the Early Amazonian, the main periods of outflow channel activity (see **Section 10.11.3.3**). Similarly, there are no deltaic deposits observed below one of the shorelines proposed by Parker et al. (1993), which would be consistent with a global-scale base level (i.e., an ocean) (Di Achille and Hynek, 2010). The Vastitas Borealis Formation (VBF), which covers Lower Hesperian ridged plains in the lowlands, is interpreted to be an eroded residue of ice-rich sedimentary deposits, which were emplaced by the floods carving the outflow channels (e.g., Head et al., 2002; Kreslavsky and Head, 2002; Tanaka et al., 2001). The very similar ages of the outflow channels and the VBF support this idea. Further support comes from the approximately identical volumes of the material eroded by the outflow channels and the VBF (Carr and Head, 2003). The dielectric properties of the uppermost crust in the northern lowlands are consistent with

ice-rich material or low-density sediments, which have been interpreted as the remnants of a Late Hesperian-aged (~3 Ga) ocean (Mouginot et al., 2012) fed by the outflow channels.

Polygonal terrain in Utopia, previously suggested to be of sedimentary origin (Lucchitta et al., 1986), was interpreted to be a tectonic consequence of flexural rebound of the crust after removing the load of a former ocean (Hiesinger and Head, 2000). Boyce et al. (2005) examined the morphometry of impact craters in the northern lowlands with MOLA data. A population of Hesperian-aged craters with a low depth-to-diameter relationship seems to be filled by material of the VBF. Boyce et al. (2005) concluded that the crater filling is the result of burial from an ice-rich mantle. They used the extent of this crater population as an indicator of the areal extent of the VBF and the possible limits of an ancient ocean in the Late Hesperian or Early Amazonian.

10.11.3.4.3 Tests of ocean hypotheses

More recent data from the MGS mission (Albee et al., 2001) allowed to test the ocean hypothesis. MOLA data showed that the northern lowlands were extremely smooth and level at scales of a few hundred meters to a few kilometers (Aharonson et al., 1998; Kreslavsky and Head, 1999; Smith et al., 1999). Indeed, they can be compared to the smoothest terrestrial surfaces like the abyssal plains (Smith et al., 1999). Head et al. (1998) and Head et al. (1999) used MOLA data to compare the smoothness of the surface within and outside of the mapped shorelines of Parker et al. (1989). The surface is rougher at all scales from several hundred meters to tens of kilometers outside of contact 1 than between contacts 1 and 2, and similarly, the surface within contact 2 is smoother at all scales than outside contact 2. They also sampled the elevations along the shorelines and found that elevations of contact 1 span almost 11 km, a value that is clearly inconsistent with any plausible equipotential surface in the past. Contact 2 still has an elevation range of ~4.7 km, but the major deviations from an equipotential surface occur in Arabia and Elysium (>1 km downward deflection of the mapped features from an equipotential surface) and in Tharsis (>2 km upward deflection), both being regions where vertical tectonic movements might have occurred after the formation of the shorelines. Head et al. (1999) concluded that MOLA data are consistent with hypotheses of oceans in the Martian past. However, several objections can be raised. First, it seems questionable whether postshoreline downward flexure in Arabia or uplift in Tharsis could really have reached these values in the order of kilometers. Although Clifford and Parker (2001) admitted that errors in the original, Viking-based identification of shorelines by Parker et al. (1989) might have contributed to the wide range of elevations, significant tectonic forces would have been required after outflow channel activity and shoreline formation in the Late Hesperian or even later. Second, detailed analyses of the suggested shoreline features have not shown morphological evidence in very high-resolution MOC images. Malin and Edgett (1999) investigated MOC images crossing the proposed shorelines at several locations and found no evidence for coastal landforms. This result was challenged by Clifford and Parker (2001) who insisted that some of the features shown by Malin and Edgett (1999) against shorelines are indeed evidence in favor of shorelines. However, Carr and Head (2003) in their assessment of the observational evidence for oceans also could not confirm the existence of coastal landforms. While most studies tried to find geomorphic evidence in the form of wave-cut erosional landforms or interior sedimentary features, Ghatan and Zimbelman (2006) searched the shorelines mapped by Parker et al. (1993) and Webb (2004) for coastal constructional landforms but found almost none. Based on this paucity of geomorphic evidence for shorelines, Ghatan and Zimbelman (2006) did not exclude the possibility of a northern ocean, but put constraints on its nature. For example, the water flowing down the outflow channels could have ponded in smaller lakes and not in a global-scale ocean. Such ponds and lakes had already been mapped by Scott et al. (1995) on the basis of Viking orbiter images, but a test of their existence, for example, by examining their potential shorelines using higher-resolution post-Viking data, has not been performed yet. It has to be noted, however, that the detection of shorelines in satellite imagery is difficult even on Earth and that erosion over possibly billions of years would have obscured any such features. Moreover, an ocean would likely freeze very rapidly (Baker, 2001; Carr, 1983; Kreslavsky and Head, 2002) before any significant coastal erosion by wind-generated waves could start.

If there were major bodies of standing water on ancient Mars, it would be expected that sedimentation of carbon dioxide derived from the atmosphere would have led to carbonate formation (e.g., Catling, 1999). Although minor amounts of carbonates have been detected from orbital and in situ measurements (Ehlmann et al., 2008; Morris et al., 2010) and some carbonate-bearing phases are present in the Martian meteorite ALH84001 (Borg et al., 1999), the sparse mineralogical evidence for carbonates has always been a major argument against long-lived oceans and lakes on Mars. The thermal emission system (TES) on board of Global Surveyor did not show spectral signatures of carbonates (Christensen et al., 2001a; Stockstill et al., 2005). Only small amounts are distributed in the Martian dust (Bandfield et al., 2003). The OMEGA imaging spectrometer confirmed the results, reporting no carbonates above the instrument's detection limit (Bibring et al., 2005). Moreover, the identification of olivine, a mineral that is easily destroyed by chemical weathering, might argue against long-lived reservoirs of liquid water at the surface of Mars. It has to be noted, however, that the lack of carbonates does not necessarily exclude the possibility of oceans on ancient Mars. Even minor amounts of sulfur dioxide would produce acidic waters and prevent the formation of carbonates, instead leading to sulfate deposition (Fairén et al., 2004; Lane et al., 2004). Calcium sulfates have indeed been found in orbital data by Gendrin et al. (2005) and Langevin et al. (2005a) and in situ by the MER or Opportunity in Meridiani Planum (Farrand et al., 2013) and by the MSL rover Curiosity in Gale crater (Vaniman et al., 2014).

While the ocean hypothesis is attractive to explain several observations related to the hydrologic evolution of Mars, the existence of an ocean is yet to be proven. Meanwhile, many key questions are still open (summarized by Ghatan and Zimbelman (2006)): Was there a Noachian ocean as proposed by Clifford and Parker (2001)? Was there a genetic relationship between outflow channel discharge and water ponding as an ocean in the northern lowlands during the Hesperian? Was ocean formation a repeated phenomenon (Baker et al., 1991)? Was an ocean liquid, or did it freeze rapidly and then

sublimate? It seems questionable if new remote-sensing data can answer these questions. So far, the Mars Advanced Radar for Subsurface and Ionosphere Sounding (MARSIS) on Mars Express did not reveal the existence of massive ice deposits beneath the surface of the northern plains, a result that, if confirmed, argues against the evolutionary model outlined by Clifford and Parker (2001). Given the old age of the hypothesized oceans and the susceptibility of coastal landforms to erosion, the search for coastlines with imaging and topographic data is considered to be difficult. Even if the images of the High Resolution Imaging Science Experiment (HiRISE) camera with a lateral resolution of 30 cm per pixel (McEwen et al., 2007a,b) do not show any unequivocal evidence, this result does not disprove an ocean. Perhaps, the best chances to reach more definitive results will involve lander experiments (e.g., with GPR experiments) and sample return missions.

10.11.3.5 Glacial, Permafrost, and Ground-Ice Features

10.11.3.5.1 Glacial landforms

Glacial processes on Earth produce a wide variety of landforms at different scales (e.g., Benn and Evans, 1998; Bennett and Glasser, 1996; Embleton and King, 1975; Evans, 2003; Hambrey, 1994; Menzies, 1995; Sugden and John, 1976). Examples of glacial erosional features include striated rock surfaces at small scales, roches moutonées at intermediate scales, and cirques, troughs, and fjords at large scales. Well-known glacial depositional features are, for example, moraines and till deposits. As part of a glacial system, not only the processes at the glacier surface boundary but also those landforms produced by fluvial discharge from glacier melting are of importance.

The surface of Mars has probably been a cold environment over most of the planet's history (e.g., Bibring et al., 2006; Carr, 1996; Solomon et al., 2005). This and the fact that water, although in unknown quantity, is assumed to have been present at the surface throughout most of this time raise the possibility that glaciers have formed on the Martian surface and that glacial surface features are still observable today.

Mariner and Viking images showed landforms that were indeed interpreted as glacial in origin, but the number of studies was limited. Williams (1978) and Lucchitta (1981) described landforms resembling recessional moraines at the western and northwestern flanks of the large Tharsis shield volcanoes, which are also shown as possible glacial deposits on the global-scale map by Scott and Tanaka (1986). The morphology of some outflow channels is also indicative of glacial action (Lucchitta, 1982, 2001) (see **Section 10.11.3.5**), and both flood and glacial processes may have simultaneously or sequentially shaped them (Costard and Baker, 2001).

Intriguing evidence for glacial processes reported in the Viking era includes esker-like and moraine-like landforms in both hemispheres (Kargel and Strom, 1992). Kargel et al. (1995) reported an assemblage of features in the northern plains that resemble terrestrial glacial landforms, including moraines, tunnel valleys, and possible eskers.

These landforms were recognized to be relatively young (Kargel and Strom, 1992). Since glaciers need to be recharged by precipitation and a water cycle, their formation late in the Martian history would require a major climate change on Mars relatively recently. The scenario of Baker et al. (1991) accounted for this problem in postulating the episodic formation of oceans by outflow channel activity (see **Section 10.11.3.3**), which then triggered short-lived episodes of a warmer climate with precipitation. It has to be noted, however, that the interpretation of these features as being glacial was partly met with skepticism (Carr, 1996), since the low amount of erosion in the Amazonian (e.g., Golombek and Bridges, 2000; Golombek et al., 2006) seems to contradict major climate excursions late in the Martian history.

Images with higher spatial resolution (MOC, THEMIS-VIS, and HRSC) revealed more details of the moraine-like features. Head and Marchant (2003), Shean et al. (2005), and Milkovich et al. (2006) investigated the structures on the northwestern flanks of the Tharsis Montes (Arsia, Pavonis, and Ascraeus Montes) and Olympus Mons (**Figure 8**) and found an assemblage of landforms that they interpreted as the result of cold-based glaciation, in analogy with cold-based glaciers in Antarctica, which are frozen to the ground and do not move by sliding on the ground, but by internal deformation. Bed erosion at cold-based glaciers is limited due to the fact that ice usually does not reach its melting temperature. Hauber et al. (2005) detected possible glacial features at the northwestern flank of Hecates Tholus, where previously no glacial features had been identified. Additional evidence for midlatitude glaciation was described by Head et al. (2005, 2006).

A particular type of ice-related morphology is hypothesized by some authors to exist near the Martian equator in Elysium Planitia. Rafts of darker material seem to have flown on a brighter matrix. In places, the dark material obviously broke into smaller pieces. On the basis of its overall similarity to terrestrial shelf ice, Brakenridge (1993) suggested that quite recent surface water releases filled a topographic depression, that ice floes formed almost immediately, and that either a grounded ice or an ice-covered sea still persists. Later, the area was revisited by Murray et al. (2005), who analyzed HRSC images and basically came to the same conclusions. The massive water release required to fill the roughly North Sea-sized

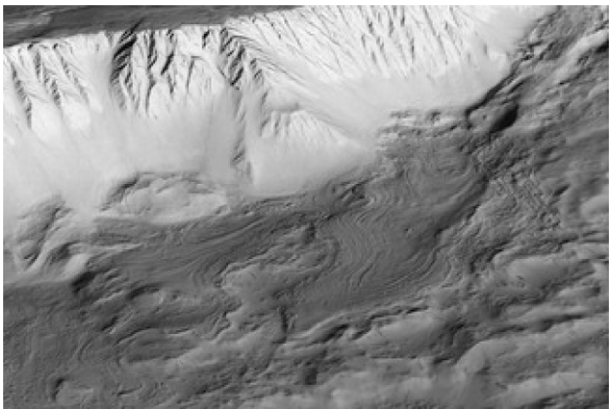

Figure 8 Lobate deposits at the foot of the western scarp of Olympus Mons. Such deposits were interpreted as possible glacial landforms by Lucchitta (1981). Milkovich et al. (2006) ascribed their origin to episodes of increased obliquity during the Late Amazonian period of Mars. Perspective view derived from HRSC stereo images (orbit 2091). copyright: ESA/DLR/FU Berlin.

basin would imply a large underground reservoir. It seems possible that water was transported through the Athabasca Valles, a young outflow channel, toward Elysium Planitia. It must be noted, however, that the pack ice theory for the platy landforms in Elysium Planitia is highly contentious. An origin by flowing lava, which cools at the surface and builds a solidified upper crust that can break in a way similar to pack ice, also seems to be possible (Keszthelyi et al., 2004), and recent very high-resolution images revealed textural details that resemble lava coils only found in terrestrial lava lakes (Ryan and Christensen, 2012).

10.11.3.5.2 Permafrost and ground-ice landforms

Permafrost on Earth is defined as soil or rock that remains below 0 °C for two or more consecutive years, regardless of the water content. Following this definition, Mars may well be regarded as a permafrost planet. Beneath a thin surficial layer, which is affected by the diurnal temperature wave, all of its upper crust can be considered to have temperatures below 0 °C. Ground ice on Earth is ice in frozen ground. Both permafrost and ground ice belong to the realm of the periglacial zone. The term periglacial was first introduced by Lozinski (1909), and in 1910, the concept of a 'periglacial zone' was established to describe climatic and geomorphic phenomena occurring peripheral to the Pleistocene ice sheets (e.g., Huggett, 2003). The term 'periglacial' is nowadays used in a wider sense, and periglacial areas are not restricted anymore to any location or time; it is generally qualitatively used to define areas of cold-climate environments where permafrost might be present although it is not a prerequisite (e.g., Washburn, 1979). Permafrost and ground ice produce a wide variety of landforms on Earth (e.g., Embleton and King, 1975; French, 1996; Jahn, 1975; Washburn, 1979; Yershov, 1998).

In the Viking era, permafrost and ground ice-related landforms on Mars were reported more frequently than glacial ones. Early reports noted the morphological similarity of many Martian landforms to terrestrial analogues of the periglacial zone (Carr and Schaber, 1977; Lucchitta, 1981; Rossbacher and Judson, 1981). The advent of higher-resolution images and detailed global topography obtained through the MGS spacecraft (Albee et al., 1998) spurred a large number of studies analyzing landforms on Mars reminiscent of terrestrial periglacial landforms.

10.11.3.5.2.1 Lobate debris aprons, lineated valley fill, and concentric crater fill

Mass wasting phenomena that display similarities to terrestrial rock glaciers were first described in detail by Squyres (1978) and Squyres (1979). He subdivided them on the basis of their morphology into lobate debris aprons (**Figure 9**), lineated valley fill, and concentric crater fill. Lobate debris aprons are characterized by a convex-upward topography and a steep and distinct flow front, strongly suggesting plastic deformation and flow. They can also show lineations on their surfaces, which can be both parallel and perpendicular to the flow direction. Where lobate debris aprons are confined by valley walls, their surfaces are deformed into contractional lineations parallel to the confining walls. Material with this specific surface texture is called lineated valley fill (**Figure 10(a)** and **10(b)**). Lobate debris aprons and lineated valley fill are best developed

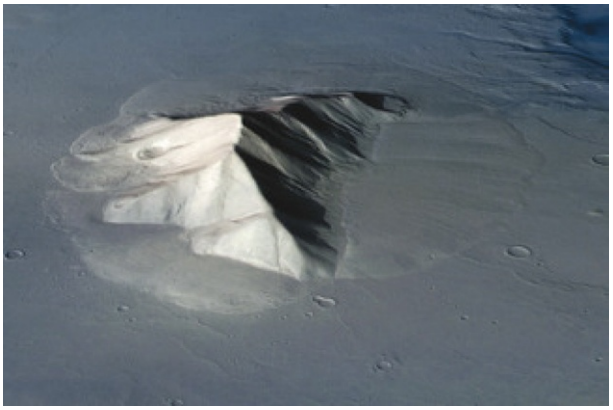

Figure 9 Lobate debris apron surrounding a mountain in the southern midlatitudes (~41° S, 103° E) on Mars. The morphology of the apron suggests viscous flow. Such deposits have been compared to terrestrial rock glaciers. Perspective false-color view of HRSC image 0451. The diameter of the debris apron is about 50 km (north is down, toward the viewer). copyright: ESA/DLR/FU Berlin.

where mesas and valleys with steep walls are found, in particular at the steep scarps of the dichotomy boundary. Concentric crater fill is found in the interior of many craters, where ridges and troughs show a concentric pattern that can also show lobate flow fronts toward the crater center. All these types of landforms show evidence for plastic deformation and resemble terrestrial rock glaciers (Lucchitta, 1984; Squyres, 1978, 1979, 1989), which are mixtures of rock and ice (Barsch, 1996; Wahrhaftig and Cox, 1959). Whalley and Azizi (2003) gave a comprehensive review on the terminology and problems related to the identification of rock glaciers on Mars.

Several hypotheses try to explain the origin of the ice in these debris flows. Water ice could have formed by direct condensation of ice from the atmosphere (Squyres, 1978) or by snow precipitation (Squyres, 1989). It could also accumulate by water vapor diffusion down into the regolith and subsequent condensation (Mellon and Jakosky, 1995). Finally, groundwater may seep into debris and create interstitial ice (Lucchitta, 1984; Mangold and Allemand, 2001; Squyres, 1989). The elastic particles in the lobate debris aprons might come from rock falls that accumulated at the base of scarps (Colaprete and Jakosky, 1998; Squyres, 1978) or, alternatively, from landslides (Lucchitta, 1984; Mangold and Allemand, 2001).

It has been demonstrated by Squyres (1978) on the basis of photoclinometry and by Mangold and Allemand (2001) and Li et al. (2005) on the basis of MOLA topographic profiles that the cross-sectional shape of lobate debris aprons can be approximated by the flow law of polycrystalline ice (Glen, 1955) and the flow relation of ice (Paterson, 1994; Vialov, 1958). Colaprete and Jakosky (1998) modeled flow of ice under Martian conditions and found that flow rates are very low. To create lobate debris aprons of the observed size, they showed that temperatures 20 to 40 K higher than present average midlatitude temperatures (~210 K), ice contents exceeding 80%, and net accumulation rates of $\geq$1 cm per year are required.

Lobate debris aprons, lineated valley fill, and concentric crater fill are young landforms. Crater counts yield low crater densities, and absolute ages of $<$100 Ma have been derived

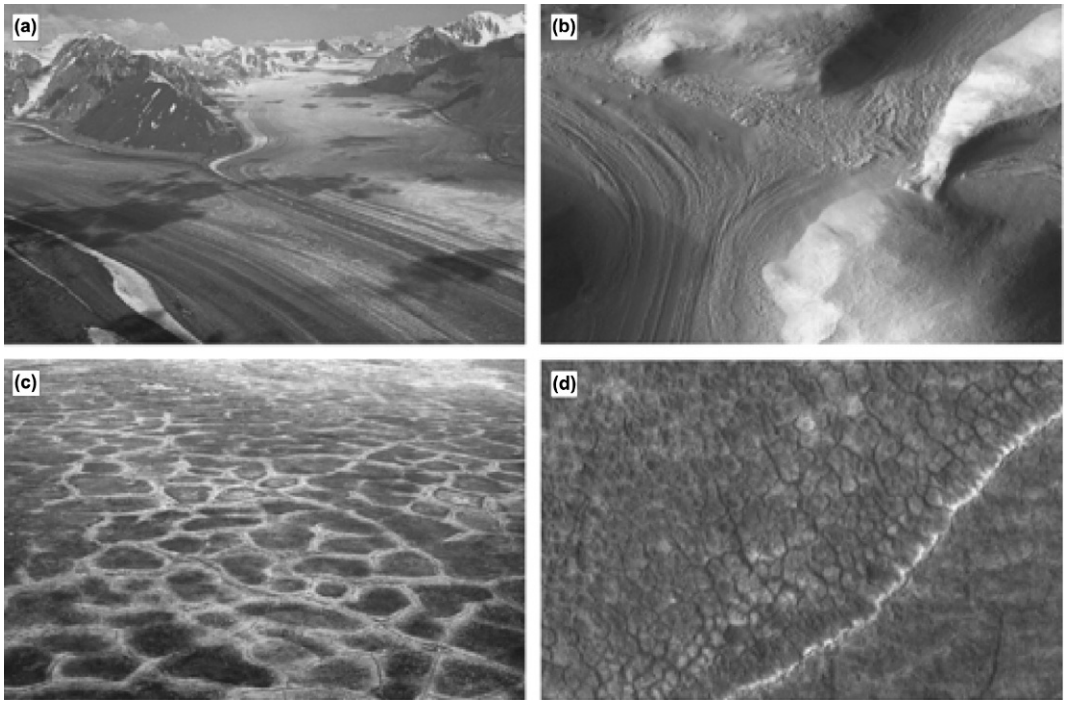

Figure 10 Comparisons between cold-climate landforms on Earth (left) and Mars (right). (a) Glaciers fusing together in the Yukon region (Canada; image courtesy Marli Miller, University of Oregon; image source: Earth Science World Image Bank). (b) Convergent flow features on Mars, probably the result of the flow of rock glacier-like material (MOC image SP245006). (c) Ice-wedge polygons in terrestrial permafrost terrain (Yukon, Canada; image courtesy Agriculture and Agri-Food Canada). (d) Patterned ground (polygons) on Mars. The diameter of the smaller polygons is <10 m and comparable to the size of ice-wedge polygons on Earth (HiRISE image TRA_000856_2265). Image credit NASA/JPL/University of Arizona.

(e.g., Berman et al., 2003; Head et al., 2005; Li et al., 2005; Mangold, 2003; Squyres, 1978). However, morphometric evidence for former lobate debris that were flooded by lava flows or debris flows (e.g., lahars) more than 1 Ga ago suggests that much older rock glaciers existed equatorward of 30°, indicating a paleoclimate allowing ground ice to be stable at that latitudes (Hauber et al., 2008). Indeed, a recent study concluded that widespread glaciation on the northern midlatitudes spanned a range of at least 600 Ma and ended roughly 100 Ma (Fassett et al., 2014).

10.11.3.5.2.2 Terrain softening

At many locations, the Martian topography exhibits a rounded and subdued appearance when compared to undegraded terrain. The effect can be observed in particular at impact craters, which have rounded rims and convex-upward inner wall slopes. This phenomenon was termed 'terrain softening' by Squyres and Carr (1986) and mapped on a global scale. They found that this topographic softening affects terrain in the 30°–60° latitude belts. It affects all sorts of topographic features (Squyres, 1989) and was attributed to the viscous relaxation of the topography due to the creep of a deformable and ice-rich regolith. While the mapping of Squyres and Carr (1986) was done qualitatively on the basis of Viking orbiter images, Jankowski and Squyres (1992) quantified the effect of terrain softening by examining the resulting topography by means of photoclinometry. Theoretical modeling suggests that the thickness of the deformable layer is limited to about 1 km (Jankowski and Squyres, 1992). The effect of viscous creep facilitated by ground ice was also suggested to explain the fact that rocky debris slopes are well below the angle of repose at higher latitudes (Perron et al., 2003).

It has to be noted, however, that mantling deposits can also subdue the topographic signature of the surface. Soderblom et al. (1973) observed a mantling deposit with a similar extent than the terrain softening mapped by Squyres and Carr (1986). They attributed it to dust deposits from the polar regions. The effects of terrain softening and mantling can be discriminated because mantling processes tend to leave sharp topographic crests like crater rims unaffected, whereas terrain softening affects them strongly. In addition, mantling deposits remove small topographic features, while relaxation processes leave them due to insufficient stresses (Squyres et al., 1992).

MOLA data revealed that the global surface roughness displays a latitudinal trend (Kreslavsky and Head, 2000): at latitudes >30–50° in both hemispheres, Mars seems to be smoother at short base lengths than at lower latitudes. This observation is in agreement with the mapping of Squyres and Carr (1986). Kreslavsky and Head (2000) suggested that this trend might be the result of a high-latitude mantling deposit that is several meters thick. Independently, it was found that images taken through the MOC show a very particular texture at certain locations. They reveal a dissected surficial layer or mantle, which suggests the degradation of an originally volatile-rich material (Carr, 2001; Malin and Edgett, 2001; Mustard et al., 2001). Poleward of about 70°, the entire surface appears to be mantled, so that the surface looks very smooth and lacks sharp topographic gradients.

Mustard et al. (2001) suggested that the mantle was deposited as airfall dust and cemented by atmospherically derived ice. There are very few fresh impact craters superimposed on this surface, suggesting that it formed and degraded very recently. Global mapping showed that the mantle seems to be degraded in two latitude belts between 30° and 60° in both latitudes (Mustard et al., 2001). These authors explicitly considered the idea of modern Martian ice ages operating at Milankovitch timescales, triggered by changes in insolation driven by variations in Mars' orbital parameters.

On a global scale, Milliken et al. (2003) mapped the occurrence of young gullies (Malin and Edgett, 2000) (see **Section 10.11.3.8**), viscous flow features (e.g., Squyres and Carr, 1986), and the dissected terrain described by Mustard et al. (2001). Milliken et al. (2003) found a latitudinal concentration of these landforms at midlatitudes with a spatial clustering at latitudes of ~40° in both hemispheres. They suggested that this correlation might be caused by the deposition, deformation, and removal of ice-rich materials at midlatitudes in the Amazonian.

10.11.3.5.2.3 Thermokarst

Thermokarst landforms develop as a result from the thawing of ice-rich permafrost or the melting of massive ice. Typical examples are thermokarst lakes, alases (large depression of the ground surface produced by thawing of a large area of very thick and exceedingly ice-rich permafrost), and thermokarst mounds (hummocks remaining after melting of the ice wedges surrounding an ice-wedge polygon) (van Everdingen, 2005). On Mars, irregularly shaped depressions, mainly in the outflow channels (Costard and Baker, 2001; Theilig and Greeley, 1979), and in the northern plains (Bun Tseung and Soare, 2006; Costard and Kargel, 1995; Morgenstern et al., 2007; Séjourné et al., 2011; Ulrich et al., 2010) and southern hemisphere (Lefort et al., 2010; Zanetti et al., 2010) have been interpreted as thermokarst features.

A fluvial-induced mechanism of thermokarst on Mars has been proposed by Costard et al. (1999). It is based on analogy to huge terrestrial outflow channel-like streams in Siberia during snowmelt in spring, where the high water discharge transfers heat from the flow of water to the frozen ground and triggers ground thawing and thermal erosion. Costard et al. (1999) suggested that relatively warm floods on Mars might have enlarged outflow channels by a combination of thermal and mechanical erosion along frozen river banks.

10.11.3.5.2.4 Patterned ground

A variety of landforms on Mars resemble terrestrial patterned ground. On Earth, this category of landforms includes polygons, circles, stripes, and nets (e.g., French, 1996; Washburn, 1979). Polygons, a common surface phenomenon in terrestrial permafrost areas (e.g., Lachenbruch, 1962), are the most frequently observed periglacial-like features on Mars. Viking orbiter images showed several examples; however, most of them had sizes that were an order of magnitude larger than their possible terrestrial analogues (Rossbacher and Judson, 1981). For example, giant polygons in Utopia Planitia with diameters of 20 km are probably too large to have originated by thermal cracking (Pechmann, 1980) and might instead be the product of fracturing of a sedimentary or volcanic layer due to cooling or desiccation shrinkage plus differential compaction over a rough buried surface (McGill, 1986) or the result of tectonic uplift (Hiesinger and Head, 2000).

Possible periglacial landforms were described in more detail on the basis of post-Viking data with a much higher spatial resolution. Small-scale polygons (**Figure 10(c)** and **10(d)**) could now be analyzed morphometrically, and MOC images revealed that their size distribution is often much more like that of terrestrial ice-wedge polygons than it was thought before (Kuzmin and Zabalueva, 2003; Seibert and Kargel, 2001; Yoshikawa, 2003). Recent images with a resolution of less than 1 m, obtained by the HiRISE camera on board the MRO (McEwen et al., 2007a,b), show that the diameters of polygons in Utopia Planitia are in the order of 10 m, which corresponds exactly to the diameters of their terrestrial counterparts. Global-scale mapping using MOC images showed that the polygons are concentrated in two latitudinal belts poleward of 55° (Mangold, 2005) and correlate to the distribution of ground ice detected by the neutron spectrometer aboard Mars Odyssey (Mangold et al., 2004a,b). However, the absence of polygonal fracture patterns in the north polar area and a high abundance of these landforms near the south polar cap suggest formation processes connected to seasonal deposition of CO_2 ice. Seasonal changes in polygon patterns were observed by van Gasselt et al. (2005) on the basis of multitemporal MOC images of a trough on the south polar cap. They ascribed these changes to contraction-crack processes in a thin layer of water ice beneath the seasonal CO_2 ice cover.

10.11.3.5.2.5 Pingos and frost mounds

Pingos on Earth are perennial frost mounds consisting of a core of massive ice, produced primarily by injection of water (Mackay, 1973, 1979; Porsild, 1938; Washburn, 1979). The identification of pingos in Viking orbiter images has been ambiguous due to the relatively low image resolution (Lucchitta, 1981, 1985; Rossbacher and Judson, 1981). Higher-resolution MOC images allow a closer inspection of candidate topographic features, and several authors cite evidence for pingos at diverse locations like Gusev crater (Cabrol et al., 2000), Athabasca Valles (Burr et al., 2005), and the Cerberus Plains (Page and Murray, 2006), all at equatorial latitudes, and in the midlatitude region of Utopia Planitia (Soare et al., 2005).

10.11.3.6 Polar Caps

The inventory and the seasonal change of the water and carbon dioxide reservoir in the polar regions of Mars play an important role in understanding the evolution of the planet and its current state.

Viking data showed that the residual polar caps consist of H_2O ice. The north polar cap loses a seasonal cover of CO_2 ice annually and the residual consists of H_2O ice (Farmer et al., 1976; Kieffer et al., 1976) The south polar cap partly retains its CO_2 cover (Kieffer, 1979; Paige et al., 1990). This survival of the CO_2 ice veneer on the south polar cap was explained with a lower concentration of dust and therefore higher albedo (James et al., 1992). However, it was unknown if the residual CO_2 ice is underlain by H_2O ice (Thomas et al., 1992) The layered deposits in both polar regions have been assumed to

consist of H_2O ice (Cutts, 1973; Herkenhoff and Murray, 1990).

Except for some spatially unresolved 10–50 μm IRIS spectra (Paige et al., 1990) and TES spectra (Kieffer et al., 2000), the spectral characteristics of the residual ice caps had not been published from any mission before Mars Express. The OMEGA (Bibring et al., 2004a) and PFS (Hansen et al., 2005) instruments on Mars Express independently detected and mapped spectral signatures of water ice on the southern polar cap of Mars. As expected, OMEGA identified the 1.5 and 2.0 μm spectral signatures of water ice over extended parts of the polar cap. In the bright region, the water ice is seen as a small admixture to CO_2 ice, whereas at the edge of the bright cap, pure water ice with a dust admixture was seen. Surprisingly, OMEGA detected also extended deposits of water ice in large areas tens of kilometers away from the polar cap. PFS – using a much higher spectral resolution but without contiguous coverage – observed a similar distribution of ice; however, there is a significant disagreement in the amount of water ice (Hansen et al., 2005). While OMEGA measurements indicate a H_2O/CO_2 ratio of 15%, the PFS measurements indicate not more than several tens of parts per million by mass. The disagreement is most likely due to different modeling assumptions. While Bibring et al. (2004a) assumed a molecular mixture of H_2O and CO_2, the analysis by Hansen et al. (2005) is based on a discrete condensation and therefore a heterogeneous mixture. Due to the spectral range used by the instruments, they are inherently limited to probing the upper few millimeters of the surface and allow no conclusion about the bulk composition.

Studies of the evolution of the northern polar cap indicate that observed brightness variations are due to changes in the grain size of the water ice (Langevin et al., 2005b). In early summer, seasonal water-ice frost with grain sizes <100 μm sublimates and larger grains ($\sim$1 mm) of the permanent ice cap dominate the optical near-IR spectral properties of the water ice.

Global neutron mapping of Mars at various spectral ranges obtained by the HEND instrument on MGS allowed to constrain the content of water ice and adsorbed and bound water in the upper 1–2 m of the Martian surface. The data returned by HEND showed huge regions of permafrost present both north of 55° N and south of 60° S. As discussed earlier, the measurement of one energy range of neutron flux alone is not sufficient to derive the water-ice content and distribution. However, combining data from neutrons with different energies and 2.2 MeV flux (Boynton et al., 2002; Feldman et al., 2002; Mitrofanov et al., 2002) indicates that a soil model consisting of a layer with water ice overlain by a layer of drier soil is in best agreement with the available data. The lower ice-rich layer contains between 50 and 75 wt% water, with a higher abundance of water ice in the shallow subsurface at northern polar latitudes than in the south (Mitrofanov et al., 2003). These ground-ice deposits extend over $\sim$15% of the surface of Mars and are therefore a substantial water reservoir.

Previous compositional and stratigraphic interpretations of the polar cap deposits have been based on imaging, spectral, thermal, and topographic measurements. With the MARSIS on Mars Express, it was possible to study the internal structure of the caps for the first time. In an early MARSIS orbit, 1855, the

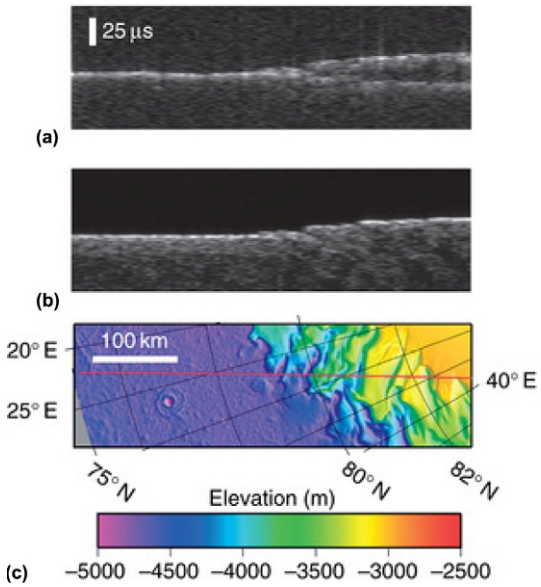

Figure 11 (a) MARSIS data in radargram format for orbit 1855 as it crossed the margin of the NPLD. (b) Simulated MARSIS data if echoes are only from the surface (nadir and off-nadir clutter). (c) MOLA topography along the ground track (red line); elevation is relative to mean planetary radius. MARSIS data at 5 MHz show a split of the strong return into two as the ground track reaches the NPLD (higher terrain to the right). Maximum time delay to the second reflector is 21 μs, equivalent to 1.8 km depth in water ice. Reproduced from Picardi G, Plaut JJ, Biccari D, et al. (2005) Radar soundings of the subsurface of Mars. *Science* 310: 1925–1928.

northern polar layered deposits were briefly observed in the longitude range from 10° to 40° E (Picardi et al., 2005). The radargrams show the surface reflection splitting into a pair of strong reflectors as the ground track passes from the northern plains onto the layered deposits (**Figure 11**). An analysis of the signal taking into account the effect of surface topography as a source for clutter indicates that the second reflector is below the surface. The derived dielectric properties for the overlaying material indicate a fairly pure water ice with $\sim$2% impurities and a bulk temperature of 240 K.

The delay time of the second reflection allows estimating the thickness of the overlying material. The results indicate that basal reflector is approximately level with the surrounding plains. This excludes a significant downward deflection of the plains due to the load of the polar cap. A deflection of <500 m as indicated by the accuracy of the MARSIS measurements would put a lower limit of at least 150 km on the elastic thickness of the lithosphere (Johnson et al., 2000; Phillips et al., 2008).

10.11.3.7 Large Debris Flows

A large variety of gravity-driven flow or mass movement processes that involve water and sediments have been termed debris flows (see reviews by Coussot and Meunier (1996) and Iverson (1997)). Several landforms on Mars have been interpreted as the products of erosion and sedimentation by debris flows. While the small-scale gullies and the rock glacier-like features are discussed elsewhere in this chapter

(see Sections 10.11.3.8 and 10.11.3.5), here, we give a short overview of possible large-scale debris flow processes on Mars. Debris flows were invoked several times to explain the complex assemblages of collapsed surface regions and the huge outflow channels. For example, a debris flow mechanism was proposed to account for the formation of the chaotic terrains and the outflow channels debouching into Chryse Planitia (Nummedal and Prior, 1981). Huge smooth deposits on the floor of some outflow channels and extending into Chryse Planitia have been interpreted to be debris flows (Tanaka, 1997, 1999).

Large flow-like deposits northwest of the Elysium volcanic rise might have been emplaced as lahars (Christiansen, 1989; Russell and Head, 2003). Lahars are debris flows originating at volcanoes, often triggered by the melting of ice (glaciers and ground ice) by volcanic heat (e.g., Vallance, 2000). Water was also proposed to be a constituent in Martian landslides, mainly in Valles Marineris (Lucchitta, 1979, 1987). It has to be noted, however, that the presence of water in Martian landslides is still under debate, and a dry origin for the landslides in the Valles Marineris also seems possible (McEwen et al., 1989), a view that was recently confirmed by lab-scale dry granular flow experiments (Lajeunesse et al., 2006) and comparative studies with landslides on Earth (Soukhovitskaya and Manga, 2006).

It should be mentioned that interpreting debris flow features and deriving implications on their water content and emplacement mechanisms are not without problems on Mars. The strong and possible long-term modification of landforms on Mars by cold-climate processes often hinders the identification of their original nature (Van Gasselt et al., 2007).

10.11.3.8 Gullies

The discovery of gullies on Mars was one of the most exciting findings of the MGS mission because most gullies are pristine and not superposed by impact craters, which is a sign of their formation in recent geologic timescales. Because of their small scale, they were first detected in high-resolution MOC images (Malin and Edgett, 2000). The morphology of these features indicates the involvement of a fluid medium, most probably water, in their formation. As a consequence, the gullies are important for the Martian history because they may attest to very recent hydrologic activity on Mars.

10.11.3.8.1 Morphology and Occurrence

Gullies on Mars resemble terrestrial features formed by a combination of processes including overland and debris flow, which vary in water content and sediment supply (Figure 12). The Martian features show three typical morphological attributes that can be divided into (1) head alcove (source region), (2) channel (transport zone), and (3) debris apron (deposition zone) (Malin and Edgett, 2000). Gully sizes range in lengths from a few hundred meters to some kilometers and widths from some meters to several tens of meters. Morphological characteristics of the gullies such as anastomosing, braided, and sinuous channels with multiple

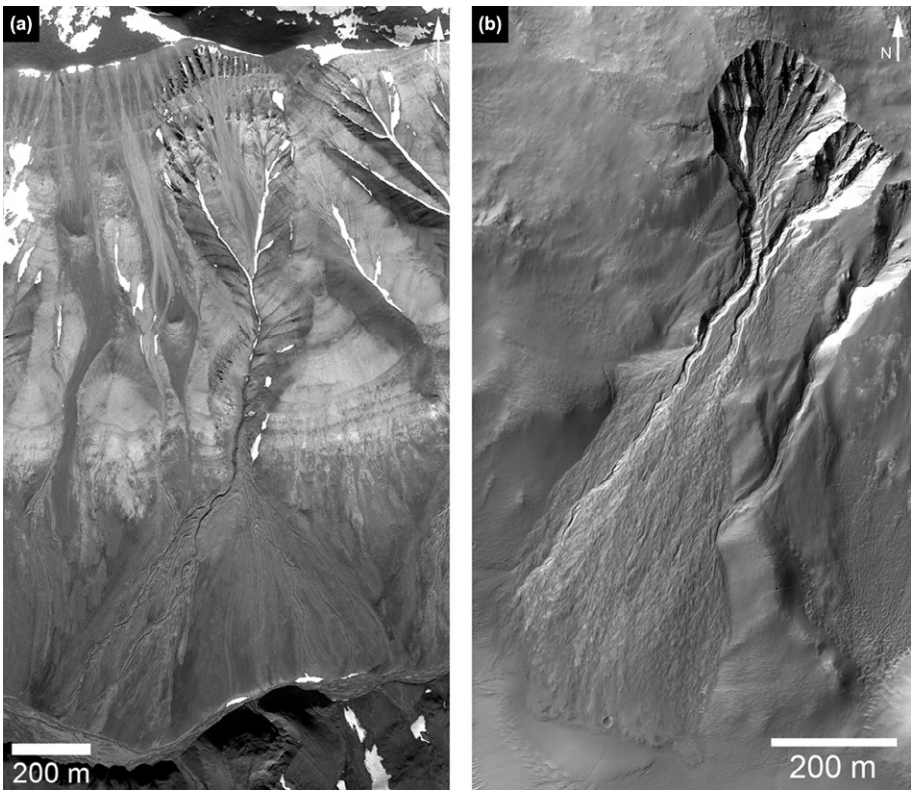

Figure 12 (a) Gully on Svalbard and (b) Mars. (a) High Resolution Stereo Camera (HRSC-AX) aerial image at 78.3° N and 15.8° E; 20 cm per pixel. terraces, point bars, and cutbanks (e.g., Dickson and Head, 2009; Malin and Edgett, 2000; McEwen et al., 2007a,b) suggest that fluvial processes were involved in their formation. Modeling of Martian gully systems suggests that debris flows are the dominant process for gully formation on Mars (Conway et al., 2011; Mangold et al., 2010), and some Martian gullies show morphological evidence such as lateral ridges (levees) along channels, debris lobes or snouts, and debris plugs (Lanza et al., 2010; Levy et al., 2010; Mangold et al., 2010; Reiss et al., 2011). However, most gullies do not show clear evidence for debris flow processes possibly because debris flow characteristics were eroded or obscured by dust or fluvial processes were the dominant process in gully formation on Mars.

Gullies on Mars are tied to steep terrains. Most of them occur on crater slopes and, less frequently, on trough and valley slopes. Other locations include slopes of crater central peaks, isolated knobs, and dunes. The global distribution is limited to midlatitudes and high latitudes poleward of ~30° in both hemispheres but most frequently in the 30°–50° latitude bands (Balme et al., 2006; Bridges and Lackner, 2006; Dickson et al, 2007; Heldmann and Mellon, 2004; Heldmann et al., 2007; Kneissl et al., 2010; Malin and Edgett, 2001; Milliken et al., 2003). Gullies are much more common in the southern hemisphere. This asymmetry is probably due to the less cratered and smooth terrain in the northern hemisphere in contrast to the heavily cratered southern highlands with a high amount of steep slopes (Malin and Edgett, 2001). Global studies showed a preferred poleward-facing slope orientation of gullies (e.g., Malin and Edgett, 2000).

10.11.3.8.2 Formation

The formation mechanism for gullies is controversially debated since their discovery. The morphology of the gullies suggests that they are formed by a mass-wasting process behaving like a fluid. The fluid medium as well as the source of it is still discussed. Hoffman (2000b), Hoffman (2002), and Musselwhite et al. (2001) suggested that carbon dioxide from surface snow or the subsurface can carve the channels by gas-lubricated flows with entrainment of clastic debris. Additionally, Jöns (2002) suggested that the decomposition of CO_2 hydrates can deliver sufficient amounts of liquid water for the erosional processes. These theories seem unlikely because neither CO_2 nor CO_2 hydrates can accumulate in significant quantities in the subsurface and the morphology of possible gas-supported flows is not consistent with the observed gully morphology (Stewart and Nimmo, 2002). Granular flows are suggested by Treiman (2003) and Shinbrot et al. (2004), but dry mass movements cannot form the observed characteristic morphologies. However, there are a broad variety of different gully morphologies, and some Martian features may resemble dry mass movement features on the Moon (Bart, 2007). The most likely medium to explain the gully morphology is liquid water. Two main theories depending on the source of water exist. The water is suggested to be released from the subsurface or deposited from the atmosphere and melted by insolation. Malin and Edgett (2000) proposed a model in which a shallow subsurface reservoir of liquid water is protected against evaporation by an ice barrier. Sudden release of liquid water and subsequent debris flows occur when the icy plug is ruptured (Malin and Edgett, 2000). Gilmore and Phillips (2002) favored melting of near-surface ice that percolates through a permeable surface layer and subsequent seepage at the base of an impermeable layer in the subsurface. Others suggest that geothermal heating melts subsurface ice (Gaidos, 2001; Hartmann, 2001; Mellon and Phillips, 2001). Atmospheric-dependent models suggest that the water ice is deposited out of the atmosphere and melted by insolation during periods of high-obliquity phases of Mars. Costard et al. (2002) suggested accumulation of ice within the regolith and melting of this near-surface ice by insolation during periods of high obliquity. In this model, the near-surface ice is protected against evaporation by seasonally deposited CO_2 frost. Lee et al. (2001) and Christensen (2003) proposed a model in which water ice is deposited as snow during high-obliquity periods and melted at low obliquity. Here, melting occurs beneath the snow cover sheltering the liquid water against evaporation (Christensen, 2003). Head et al. (2008) proposed a top-down melting of residual ice and snow after the last glaciation.

The morphological characteristics of gullies, their limited global distribution in midlatitudes and high latitudes, and their preferred orientation on poleward-facing slopes are in agreement with water being involved in gully formation. The model of atmospherically derived ice or snow deposits is consistent with other morphological observations of a deposited dust–ice mantle and viscous flow features in the midlatitudes (Milliken et al., 2003; Mustard et al., 2001). Several gullies also emanate from the dust–ice mantle (e.g., Arfstrom and Hartmann, 2005; Aston et al., 2011; Berman et al., 2005; Bleamaster and Crown, 2005; Christensen, 2003; Raack et al., 2012), suggesting that melting from the dust–ice mantle formed these gullies. The formation of an ice-rich mantle, viscous flow features, and gullies are possibly all related to recent ice ages within the last few million years on Mars. According to this theory, water ice was removed from the poles and transported and deposited as a dust–ice mantle to midlatitudes during higher obliquities, which desiccated during lower obliquities (Head et al., 2003a). Modeling results indicate that centimeters of snow can be seasonally deposited and melted in midlatitude regions on Mars under high-obliquity (>35°) conditions in the past (e.g., Mischna et al., 2003; Williams et al., 2009).

10.11.3.8.3 Age

The gullies are suggested to be formed geologically recently. Estimates that the gullies could be < 1 Ma years old are based on their pristine appearance, their stratigraphic relationships to young surface features, and the lack of superimposed impact craters (Malin and Edgett, 2000). Other age estimations assume that the gullies were formed under different climatic conditions than today and correlate their activity to obliquity variations in the last few million years (e.g., Christensen, 2003; Costard et al., 2002; Head et al., 2003a; Lee et al., 2001). Crater counts on dunes superposed by gully deposits in Nirgal Vallis indicate that the gullies were formed within the last 3 Ma, possibly within the last 300 ka (Reiss et al., 2004). Schon et al. (2009) dated a crater with 0.6–2.4 Ma (best fit 1.25 Ma) that produced secondary craters superposing gully sedimentary fans. Although most of the gullies appear morphologically

pristine, there is observational evidence of older gullies that are degraded (filled channels, eroded aprons, and cut by fissures) or cratered (e.g., McEwen et al., 2007a,b; Morgan et al., 2010a,b; Reiss et al., 2009). These older examples indicate that not all gullies are young and their formation occurred at least episodically over a longer timescale (Morgan et al., 2010a,b, 2011; Reiss et al., 2009).

10.11.3.8.4 Dune gullies

Gullies have also been found in several places on slopes of midlatitude dark dunes in the southern hemisphere that can be classified into two main morphologies (Reiss et al., 2007):

(1) Long sinuous channels, with a constant width from the source region to their termini; lateral ridges (levees) along the channels; and debris snouts at their termini (lack of sedimentary fan), also called 'linear dune gullies' (Védie et al., 2008) (**Figure 13(a)**).
(2) Dune gullies with an alcove, channel, and sedimentary fan resembling the typical morphology of midlatitude slope gullies elsewhere on Mars, also called 'ACA (alcove–channel–apron) dune gullies' (Dundas et al., 2012) (**Figure 13(b)**). Linear dune gullies occur on several slopes of midlatitude dark dunes (e.g., Costard et al., 2002; Mangold et al., 2003; Reiss and Jaumann, 2003). Based on their morphological characteristics, flow rheology, and laboratory simulations, they were interpreted to be formed by debris flow (mudflows and slurry flows) with the involvement of about >10% by volume of liquid water (Jouannic et al., 2012; Mangold et al., 2003; Miyamoto et al., 2004; Reiss and Jaumann, 2003; Reiss et al., 2010; Védie et al., 2008). An alternative formation mechanism carving the channels by mass movements of CO_2 blocks was proposed by Dundas et al. (2012) and Diniega et al. (2013). ACA dune gullies were interpreted to be formed by H_2O- or CO_2-related processes (Reiss et al., 2007) and recently more to be caused by CO_2 processes (Diniega et al., 2010; Dundas et al., 2012), see **Section 10.11.3.8.5**.

10.11.3.8.5 Present-day activity

Bright sedimentary deposits (**Figure 13(c)**) were observed to form under present-day conditions at gully sites and interpreted to be caused by flows involving liquid water (Malin et al., 2006). Based on analogue studies, Hugenholtz (2008) proposed that the bright deposits on Mars might be formed by vaporization of CO_2–ice small amounts of H_2O–ice lubricating fine-grained material. The following studies did not rule out the presence of liquid water, but indicate that dry flows can form all the morphological characteristics of the bright deposits (Kolb et al., 2010; Pelletier et al., 2008). Multitemporal image analysis showed that the bright deposits do not change their tone or shape (Kolb et al., 2010; McEwen et al., 2007a,b), which would be expected when the bright deposits would contain water or ice (Williams et al., 2007). In addition, ice or hydrated minerals could not be detected with hyperspectral data (McEwen et al., 2007a,b). However, spectral analysis of bright deposits left by former mudflows in the Atacama Desert showed no hydrated minerals suggesting that liquid water cannot be ruled out as a possible formation hypothesis for the bright gully deposits (Heldmann et al., 2010).

Recently, new multitemporal observations revealed modifications of several gully channels and aprons including widening of channel segments, possible channel incision, and new dark deposits on the aprons (Dundas et al., 2010, 2012). The changes occur in the winter seasons and are interpreted to be caused by CO_2 frost and some by dry granular flows (Dundas et al., 2010, 2012). Present-day activity of dune gullies was also observed. ACA dune gullies show morphological changes of alcove and channel widening and new depositions on aprons (Diniega et al., 2010; Dundas et al., 2012). Based on the seasonal behavior of the ACA dune gully activities, their formation is suggested to be triggered by CO_2-driven processes (Diniega et al., 2010; Dundas et al., 2012). Reiss et al. (2010) observed present-day activity of linear dune gullies where a small ~2 m wide channel grew by incision into the dune several tens of meters in length in two subsequent years. The activity was interpreted to be caused by melting of small amounts of H_2O–ice triggering slurry flows of sand mixed with liquid water based on seasonal spectral data and modeled surface temperatures (Reiss et al., 2010).

10.11.3.9 Recurring Slope Lineae

Recurring slope lineae (RSL) are narrow (up to 5 m wide), relatively dark-toned features on steep (>25°) equator-facing slopes in the southern hemisphere between 48° and 32° S latitude (**Figure 14**) (McEwen et al., 2011). They appear and lengthen in late spring and summer and slowly fade and disappear during autumn and winter (McEwen et al., 2011). Their seasonal behavior, latitudinal occurrence, preferred slope orientation, and small size suggest that these features could result from brine flows (McEwen et al., 2011). Terrestrial analogue studies in Antarctica combined with a groundwater flow model used for the Martian and terrestrial RSL analogues support the hypothesis that RSL form through the downslope flow of liquids (Levy, 2012). Chevrier and Rivera-Valentin (2012) used a combination of thermodynamic and kinetic numerical models to investigate if the RSL can be formed by melting of brines. Their model results reproduced well the seasonality and preferred slope orientations (Chevrier and Rivera-Valentin, 2012).

10.11.4 Water in Mantle and Crust

Looking at the terrestrial planets today, Mars is the only planet on which surface water has been detected directly in the form of ice at the polar caps (Bibring et al., 2004a; Hansen et al., 2005). There is also evidence for large amounts of ground ice in the circumpolar areas (Feldman et al., 2004). Recent radar observations by the MARSIS instrument on Mars Express (Picardi et al., 2005) and theoretical modeling indicate the existence of ground-ice deposits extending to midlatitudes and low latitudes (Helbert et al., 2005). For Mercury (Butler et al., 1993 and Harmon and Slade, 1992) as well as for the Moon (Feldman et al., 1998; Nozette et al., 1996), there are indications for the existence of ice deposits in the regolith in permanently shadowed areas in the polar regions (see

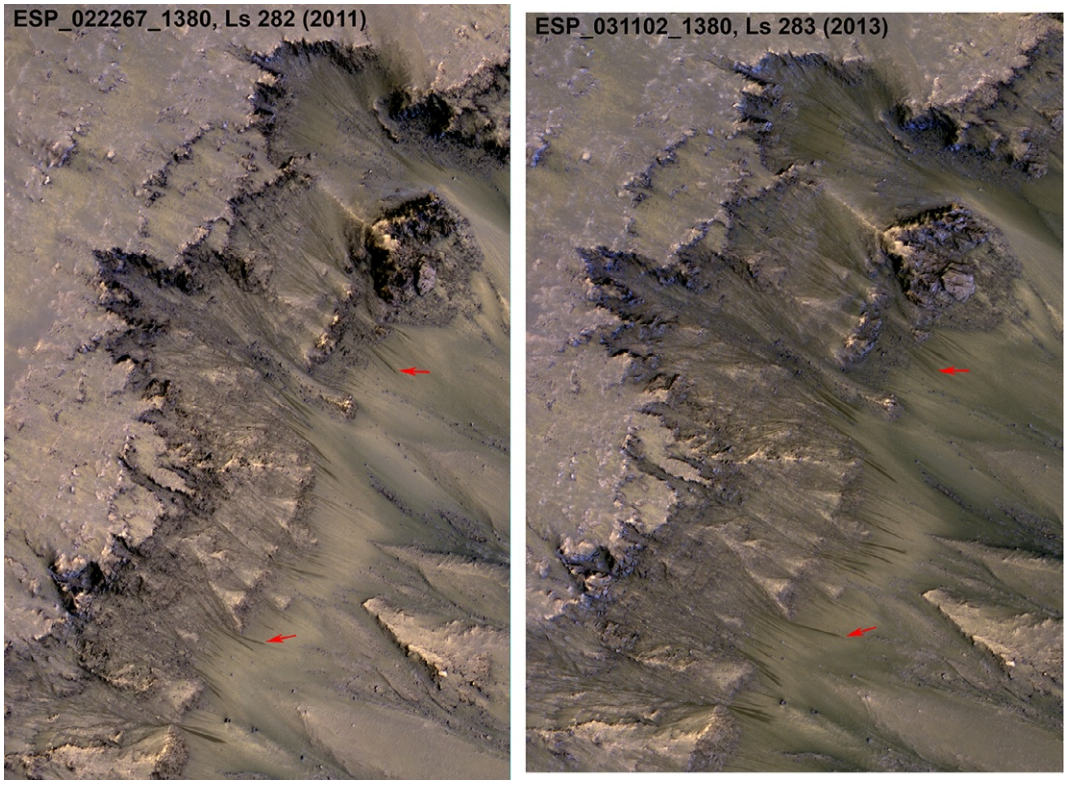

Figure 14 Seasonal changes of recurring slope lineae (RSL) in Palikir Crater at 41.6° S and 202.3° E during one martin year. Image credit: NASA/JPL/University of Arizona.

Section 10.11.4.1.1). These deposits are still subject to debate and await confirmation by future missions. The present-day conditions clearly exclude the existence of liquid water or ice on the surface of Venus.

10.11.4.1 Regolith

10.11.4.1.1 Moon and Mercury

The rotation axis of the Moon has an inclination of only 1.6° resulting in areas near the poles, primarily the floors and lower interior walls of impact craters, that are permanently shadowed from the Sun. It was suggested very early (Arnold, 1979; Watson et al., 1961) that temperatures within these permanently shadowed regions near the lunar poles were sufficiently low that water would be stable to sublimation for the lifetime of the Moon. Meteoroids and comets were proposed as source for the water. A number of follow-up studies refined this idea (Butler, 1997; Butler et al., 1993; Vasavada et al., 1999). The first tentative observation indicating possible ice at the lunar south pole was reported by Clementine from bistatic radar observations of very low spatial resolution (Nozette et al., 1996). The 13 cm wavelength telemetry system of the Clementine orbiter was used as a transmitter and one of the 70 m NASA/Deep Space Network antennas to receive the echo. The signal received from the pass over the south pole showed a lower depolarization as the other passes indicate the presence of a low-loss volume scatterer, possibly water ice. A follow-up analysis by Nozette et al. (2001) suggested a body of ~ 10 km^2 of ice in the Earth-facing lower part of Shackleton crater. However, analysis of Arecibo radar data (Stacey et al., 1997) and a reanalysis of the Clementine data (Simpson and Tyler, 1999) have raised questions regarding this conclusion. An independent indication for possible ice deposits at the poles of the Moon was provided by an analysis of Lunar Prospector (LP) neutron data. These data showed enhanced abundances of hydrogen, existing at both poles of the Moon (Feldman et al., 1998, 2000). The spatial resolution of the LP measurements was not sufficiently good to prove a one-to-one correspondence of the signal to the permanently shaded craters near both poles (Bussey et al., 1999; Margot et al., 1999). However, it was possible to show that an association was plausible. Using models of neutron emission from assumed water-ice deposits filling the largest three craters in the neighborhood of the south pole, a water-ice abundance of $1.5 \pm 0.8\%$ by mass was derived. The result is however not a proof for the existence of water ice, because the measurement of hydrogen is independent of its chemical association. Recent high-spatial-resolution Earth-based radar observations using the 13 cm radar imaging with the Arecibo radar system showed no evidence for characteristic changes in the depolarization in Shackleton crater or anywhere else near the south pole of the Moon (Campbell et al., 2006). These results in combination with the LP results implied a low likelihood for a thick ice deposit within the crater but rather favor ice being dispersed within the regolith.

The distribution of hydrogen across the region is consistent with buried water ice from cometary impacts, hydrogen implantation from the solar wind, and/or other as yet unknown sources.

IR spectroscopic measurements of the lunar surface from three different spacecraft published in 2009 provide unambiguous evidence for the presence of hydroxyl (OH) or water on the surface of the Moon. The Moon Mineralogy Mapper (M3) on Chandrayaan-1 detected absorption features near 2.8–3.0 μm on the surface of the Moon (Pieters et al., 2009). Based on the general lack of correlation of this feature in sunlit M3 data with neutron spectrometer H abundance data, Pieters et al. (2009) suggested that the formation and retention of OH and H_2O is an ongoing surficial process. OH/H_2O production processes may feed polar cold traps. The Deep Impact spacecraft found the entire surface to be hydrated during some portions of the day (Sunshine et al., 2009). OH and H_2O absorptions in the near-IR were strongest near the north pole and are consistent with <0.5 wt% H_2O. Hydration varied with temperature, rather than cumulative solar radiation, but no inherent absorptivity differences with composition were observed. However, comparisons between data collected one week (a quarter lunar day) apart show a dynamic process with diurnal changes in hydration that were greater for mare basalts ($\sim$70%) than for highlands ($\sim$50%). This hydration loss and return to steady state occurred entirely between local morning and evening, requiring a ready daytime source of water group ions, which is consistent with a solar wind origin. Finally, looking at data from the Visual and IR Mapping Spectrometer on Cassini during its flyby of the Moon in 1999, Clark (2009) observed a broad absorption at 3 μm due to adsorbed water and near 2.8 μm attributed to hydroxyl in the sunlit surface on the Moon. The amounts of water indicated in the spectra depend on the type of mixing and the grain sizes in the rocks and soils but could be 10–1000 ppm and locally higher. Water in the polar regions may be water that has migrated to the colder environments there. Trace hydroxyl is observed in the anorthositic highlands at lower latitudes.

The Lunar Crater Observation and Sensing Satellite (LCROSS) mission was designed to detect hydrogen-bearing volatiles directly (Colaprete et al., 2010). On 9 October 2009, a spent Centaur rocket struck the persistently shadowed region within the lunar south pole crater Cabeus, ejecting debris, dust, and vapor. A second 'shepherding' spacecraft, which carried nine instruments, including cameras, spectrometers, and a radiometer, observed this material. Near-IR absorbance attributed to water vapor and ice and UV emissions attributable to hydroxyl radicals support the presence of water in the debris. The maximum total water vapor and water ice within the instrument field of view was 155 ± 12 kg. Given the estimated total excavated mass of regolith that reached sunlight, and hence was observable, the concentration of water ice in the regolith at the LCROSS impact site is estimated to be $5.6 \pm 2.9\%$ by mass. In addition to water, spectral bands of a number of other volatile compounds were observed, including light hydrocarbons, sulfur-bearing species, and carbon dioxide.

Neutron flux measurements of the Moon's south polar region from the Lunar Exploration Neutron Detector (LEND) (Mitrofanov et al., 2010) on the Lunar Reconnaissance Orbiter spacecraft were used to select the optimal impact site for LCROSS. LEND data show several regions where the epithermal neutron flux from the surface is suppressed, which is indicative of enhanced hydrogen content. These regions are not spatially coincident with permanently shadowed regions of the Moon. The LCROSS impact site inside the Cabeus crater demonstrates the highest hydrogen concentration in the lunar south polar region, corresponding to an estimated content of

0.5–4.0% water ice by weight, depending on the thickness of any overlying dry regolith layer.

The same arguments made for the Moon are valid for Mercury as well. Thermal modeling (Ingersoll et al., 1992; Paige et al., 1992, 2013) showed that ice can remain stable over geologic timescales in permanently shadowed areas near the poles of Mercury. This was confirmed by Earth-based radar observation discovering probable ice deposits at the poles of Mercury (Harmon and Slade, 1992; Slade et al., 1992). The radar echoes from Mercury's poles were interpreted as reflections from water ice on the basis of their similarity to the unusual properties of radar echoes from the icy Galilean satellites of Jupiter (Campbell et al., 1978). Higher-spatial-resolution radar images (see **Figure 15**), obtained by Harmon et al. (2001), confirmed all the original polar features and revealed many additional features, including several at latitudes as low as 72–75° N and several from craters <10 km in diameter. All of the new features located on the Mariner-imaged side of the planet could be matched with known craters or other shaded areas. Moses et al. (1999) showed by extrapolating the current terrestrial influx of interplanetary dust particles to that at Mercury that continual micrometeorite bombardment of Mercury over the last 3.5 billion years could have resulted in the delivery of $(3–60) \times 10^{13}$ kg of water ice to the permanently shaded regions at Mercury's poles. This would result in an average ice thickness of 0.8–20 m. Erosional processes like solar wind sputtering and micrometeorite bombardment would remove about half of this ice in the same time span. The resulting amount of ice is in general agreement with the proposed amount of $\sim$2–20 m based on radar imaging if the additional influx by comets and asteroids is taken into account. Butler et al. (1993) discussed the notion that water originating away from the poles would behave as individual, randomly moving molecules, some of which could migrate to the poles and become cold-trapped there.

Observations by the NASA MESSENGER spacecraft confirmed this notion (Lawrence et al., 2013). The neutron spectrometer on the MESSENGER spacecraft shows decreases in the flux of epithermal and fast neutrons from Mercury's north polar region that are consistent with the presence of water ice in permanently shadowed regions. The neutron data indicate that Mercury's radar-bright polar deposits contain, on average, a hydrogen-rich layer more than tens of centimeters thick beneath a surficial layer 10–20 cm thick that is less rich in hydrogen. The buried layer must be nearly pure water ice. The upper layer contains <25 wt% water-equivalent hydrogen. The total mass of water at Mercury's poles is inferred to be 2×10^{16}–10^{18} g and is consistent with delivery by comets or volatile-rich asteroids. This discovery was independently confirmed by measurements from the laser altimeter on the MESSENGER spacecraft (Neumann et al., 2013). Measurements of surface reflectance of permanently shadowed areas near Mercury's north pole reveal regions of anomalously dark and bright deposits at 1064 nm wavelength. These reflectance anomalies are concentrated on poleward-facing slopes and are spatially collocated with areas of high radar backscatter postulated to be the result of near-surface water ice. Correlation of observed reflectance with modeled temperatures indicates that the optically bright regions are consistent with surface water ice, whereas dark regions are consistent with a surface layer of complex organic material that likely overlies buried ice and provides thermal insulation.

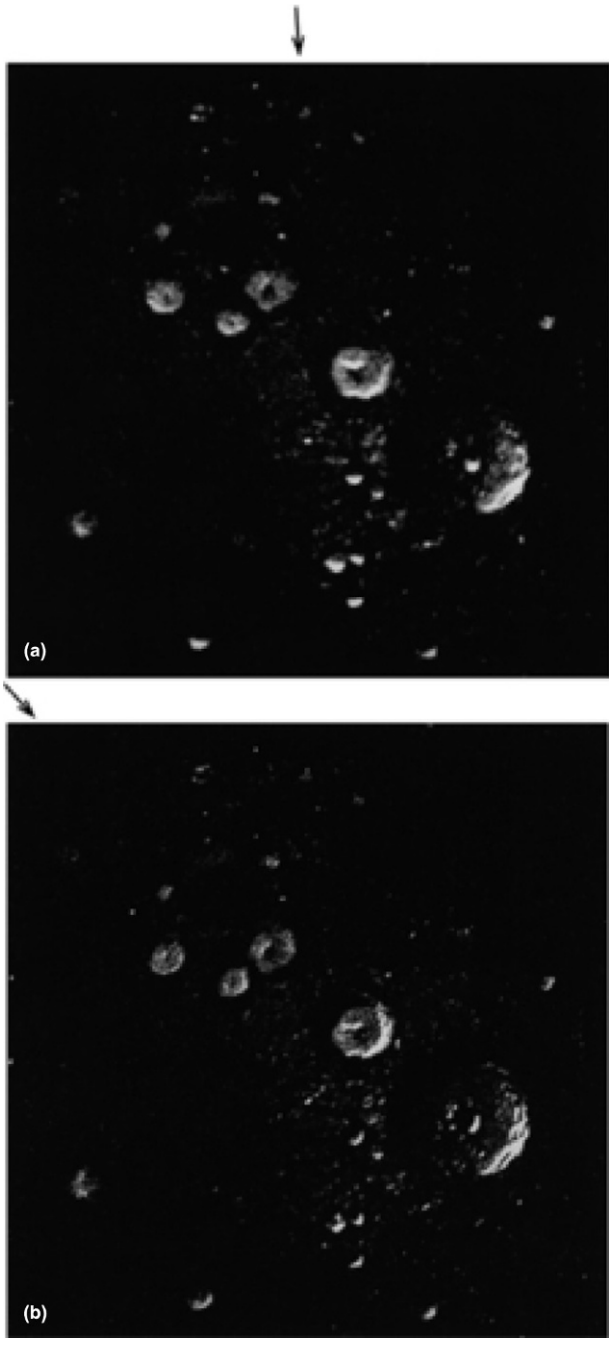

Figure 15 Radar images of the deposit close to the pole of Mercury. Lighter shades correspond to higher echo strength. The radar illumination directions are indicated (arrows). Surface resolution is 3 km in (a) and 1.5 km in (b). Reproduced from Harmon JK, Perillat PJ, and Slade MA (2001) High-resolution radar imaging of Mercury's North Pole. *Icarus* 149: 1–15.

10.11.4.1.2 Mars

The stability of water ice on the surface of Mars is governed by the balance between sublimation and deposition and mainly a function of the atmospheric temperature and water vapor

abundance. For subsurface water-ice deposits in the regolith, the situation is more complex, because the exchange rate with the atmosphere is controlled by the physical properties of the regolith. In principle, two end-member situations can be identified. One extreme scenario is that the subsurface ice is disconnected from the atmosphere by an impermeable layer of material. The other extreme would be a free exchange of water vapor between the subsurface ice deposit and the atmosphere. While the regolith would protect the subsurface ice deposit from temperature variation, ground ice and atmospheric vapor would eventually reach equilibrium (Flasar and Goody, 1976; Mellon and Jakosky; 1993; Schorghofer and Aharonson, 2005). Between these two extremes, there are a variety of other possibilities. Helbert et al. (2005) proposed, for example, that the retreating ground ice forms a sublimation till, which limits the vapor transport to the atmosphere, thereby stabilizing the ice.

The wide range of assumptions on the interaction between subsurface ice and the atmosphere lead to a disagreement about the stability of proposed ground-ice deposits especially at midlatitudes and low latitudes. The calculations by Farmer and Doms (1979), Mellon and Jakosky (1993), and Mellon and Jakosky (1995) show that water ice must be unstable at shallow depths for latitudes $<65°$. Schorghofer and Aharonson (2005) took into account seasonal variations of air moisture in their model and found that the ice can be stable under some conditions, in particular, at low thermal inertia. In the model by Helbert et al. (2005), subsurface ice is metastable at these depths: it disappears, but slowly over geologically significant timescales. On Mars, the variation of climate over the history of the planet plays an important role in the distribution and amount of ice in the regolith.

Impact cratering into ice-rich (and possibly fluid) target material is suggested to form a specific layered ejecta morphology on Mars termed rampart crater, which is not observed on other terrestrial planets. Models suggest that the target material must contain at least 15–20% ice for the formation of a layered ejecta blanket (Stewart et al., 2001; Woronow, 1981). The ejecta are characterized by 'lobate'- or 'fluidized'-like structures, which terminate in distal ramparts (**Figure 16**). A summary of different layered ejecta morphologies is given in Barlow et al. (2000). Although most researchers suggest impacts into volatile-rich target material for their formation (e.g., Carr et al., 1977; Head and Roth, 1976; Mouginis-Mark, 1979), atmospheric processes might also cause or contribute to it (e.g., Barnouin-Jha and Schultz, 1998; Schultz, 1992; Schultz and Gault, 1979). For a summary of models, morphological constraints, laboratory experiments, and discussion about the two formation theories, see the reviews by Barlow (2005) and Kuzmin (2005).

Rampart craters are found in all geologic units and at all altitudes and latitudes (Allen, 1979; Barlow and Bradley, 1990; Costard, 1989; Kuzmin et al., 1988; Mouginis-Mark, 1979). In a given area, a certain minimum diameter exists for rampart craters, called the onset diameter (Boyce and Witbeck, 1980; Kuzmin, 1980). Geographic mapping revealed that the onset diameter decreases toward higher latitudes (Costard, 1989; Kuzmin et al., 1988; Mouginis-Mark, 1979). Rampart crater diameters in equatorial regions are typically 4–7 km versus 1–2 km at high latitudes (50° latitude) (Squyres et al., 1992).

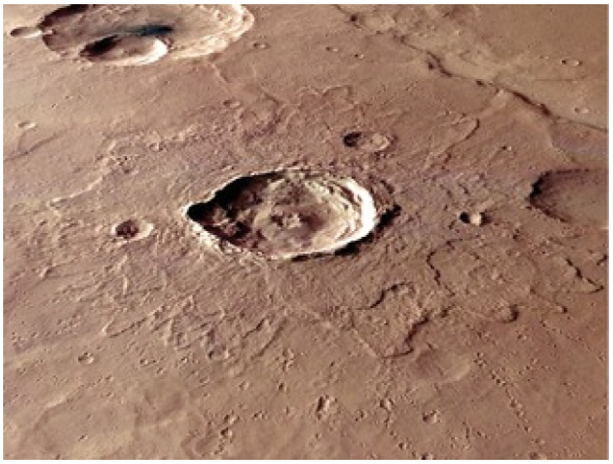

Figure 16 Perspective color view of a rampart crater (diameter = 9.5 km) in southern Arabia Terra, Mars (HRSC orbit 2956_0000 at 16.5° E and 15.2° N). copyright: ESA/DLR/FU Berlin.

Based on the physics of the impact process and using a relationship between the onset diameter and the crater's excavation depth, Kuzmin et al. (1989) derived global depths of the boundary between a desiccated regolith layer and an ice-bearing regolith layer. The results indicate a possible boundary in ~300 to ~400 m near the equator and ~100 m at 50° latitudes (Kuzmin, 2005). Barlow et al. (2001) showed that the onset diameter varies regionally near the equator, indicating shallower ground-ice depths in these regions. Reiss et al. (2005) found regionally equatorial onset diameters of rampart craters as small as 1 km, equal to those at high latitudes. However, the layered ejecta blankets are highly degraded, indicating a formation in the early history of Mars and possible shallow ground-ice depths at these times (Reiss et al., 2005). Rampart craters may have formed over a significant time interval and the onset diameter records the ground-ice depth at the time of the impact (Squyres et al., 1992). Possible changes with time might be detectable. Barlow (2004) analyzed characteristics of layered ejecta in equatorial regions and found no major variations in volatile concentrations at depths >1 km. Based on absolute age determinations by crater counts on the layered ejecta of rampart craters in equatorial regions and in comparison with the onset diameter, Reiss et al. (2006) suggested a decrease of the ground-ice table at depths <1 km in these regions.

10.11.4.2 Mineralogy

Minerals are the basic rock-forming constituents of planetary surfaces. As such, their investigation can provide valuable information about the aqueous history of a planet. The most interesting minerals in this respect are hydrated minerals, that is, minerals that include water (H_2O) or hydroxyl (OH) in their mineral structures. Examples of hydrated minerals are iron hydroxides, carbonates, sulfates, phyllosilicates, and zeolites. The only terrestrial planets that have been found to have hydrated minerals at their surfaces are the Earth and Mars. Some asteroids also possess OH- and/or H_2O-bearing minerals (Rivkin et al., 2002), for example, Vesta (Hasegawa et al., 2003),

but these are not further discussed here. On the other hand, there is no evidence for water-containing minerals on the Moon (Lucey et al., 2006), or on Venus, although on Venus too little of the mineralogy is known to make a firm statement. It is not in the scope of this chapter to discuss hydrated minerals on Earth. Summaries of Martian surface mineralogy, including potential hydrated minerals, are given by Soderblom (1992), Roush et al. (1993), Bell (1996), and Bibring and Erard (2001). Bish et al. (2003) discussed the stability of hydrous minerals on Mars, Bishop (2005) gave a recent but still pre-MER and pre-MEX overview of the properties of hydrated minerals on Mars, and a review of the several forms of hydration that can exist on the Martian surface is presented by Jouglet et al. (2006). Over the last decade, the results obtained by spectrometers in orbit (OMEGA and CRISM) and in situ on board the MER and MSL rovers have dramatically changed the picture for Mars, and some of the most relevant results are presented in the succeeding text.

10.11.4.2.1 Methods

Typically, the composition of Martian surface materials has been analyzed on the basis of Earth-based spectroscopic (e.g., McCord and Adams, 1969), in situ chemical (e.g., Clark et al., 1977; Rieder et al., 1997; Wänke et al., 2001), and in situ magnetic (e.g., Hargraves et al., 1977) data (see Bell, 2008). Reflectance spectroscopy is a particularly powerful tool to infer the mineralogy of planetary surfaces (e.g., Burns, 1970), but only few instruments were operated in orbit around Mars. The near-IR spectrometer (IRS) aboard Mariner 6 and Mariner 7 (Calvin, 1997) and imaging spectrometer for Mars (ISM) aboard Phobos-2 (Bibring et al., 1989 and Murchie et al., 1993) detected a broad and deep 3 μm absorption band in each spectrum. The strength and shape of the 3 μm band are influenced by all forms of hydration. Unfortunately, the ISM acquired only a very limited number of observations before the Phobos 2 mission failed at an early stage. The most recent near-IR imaging spectrometers in orbit around Mars are OMEGA on board Mars Express (Bibring et al., 2004b) and the Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) on board the MRO (Murchie et al., 2009). The Thermal Emission Spectrometer (TES) on board the MGS Mission (Christensen et al., 1992) and the THEMIS instrument on board the Mars Odyssey mission (Christensen et al., 2004a) both acquired spectra at longer wavelengths in the thermal emission range.

The MERs, Spirit and Opportunity, have several instruments that can provide mineralogical information (Squyres et al., 2003). The panoramic camera (Bell et al., 2003) and the miniature thermal emission spectrometer (Christensen et al., 2003) provide multispectral data and can still be considered to be 'remote-sensing' experiments, despite their very close range to the observed targets. The Mössbauer spectrometer (Klingelhöfer et al., 2003) and the alpha particle x-ray spectrometer (APXS) (Rieder et al., 2003), which provides geochemical rather than mineralogical information, take their measurements in direct contact with the target materials. A variety of hydrated minerals have been identified on Mars (see succeeding text; e.g., Bibring et al., 2006; Carter et al., 2013; Ehlmann et al., 2013).

10.11.4.2.2 Basalt and dust

Overall, the surface of Mars consists of a mixture of relatively pristine mafic materials (i.e., basalt consisting of pyroxenes and olivine) and highly oxidized secondary materials (Bell, 1996). Mössbauer and APXS data collected by the MERs show that the ubiquitous, oxidized bright red dust, which is responsible for the red color of Mars, consists of ferric oxides and includes nanocrystalline phases (e.g., Goetz et al., 2005). It is an alteration product, probably of a primary material with basaltic chemistry, but the presence of olivine in the dust, which is quickly weathered in the presence of water, suggests that water did not play a significant role in its production (Goetz et al., 2005). This is also confirmed by orbital observations with the OMEGA instrument. It found evidence for widely distributed anhydrous ferric oxides in high-albedo regions (Bibring et al., 2006), which might consist of nanocrystalline red hematite (α-FeO) and maghemite (γ-FeO). Therefore, both rover and orbiter data point to the formation of the Martian dust that occurred under a dry climate. Nevertheless, recent observations by the Curiosity rover show that dust contains a significant amount of H (Lasue et al., 2013a,b; Meslin et al., 2013), which may account for much of the hydrogen detected by the GRS from orbit (Feldman et al., 2004).

10.11.4.2.3 Hematite

Spectra taken with TES show evidence for gray, coarse-grained (>10 μm) crystalline hematite in three limited regions, Aram Chaos, Meridiani Planum, and, to a lesser degree, Valles Marineris (**Figure 17**) (Christensen et al., 2000, 2001b). Hematite is not a hydrated mineral, but it is thought to have formed via aqueous processes. Although several mechanisms exist to form this variety of hematite, Christensen et al. (2001b) favored chemical precipitation from Fe-rich aqueous fluids under either ambient or hydrothermal conditions (see also Catling and Moore, 2003). Such a process would have required substantial amounts of liquid water. From a morphological perspective, this appears plausible, since all three hematite deposits detected with TES are located in sedimentary settings.

Figure 17 Hematite in Meridiani Planum as mapped with the TES (e.g., Christensen et al., 2000). The hematite-rich areas (marked in red) have probably experienced long-lasting aqueous processes and were selected as landing site for one of the MERs. Image credit: NASA Planetary Photojournal, PIA02056.

Actually, the hematite deposit in Meridiani Planum was considered to be such strong evidence for past surface or near-surface water that one of the MERs, Opportunity, was sent there to explore its details (Golombek et al., 2003).

Indeed, the findings of the rover confirmed the presence of hematite in Meridiani Planum. Over the entire region, small millimeter-sized spherules (called 'blueberries' by the rover team) are embedded in the sandstones, which form the layered outcrops in Meridiani Planum. These spherules were found to consist of hematite, based on the observations of the Mössbauer and Mini-TES instruments (e.g., Christensen et al., 2004c; Klingelhöfer et al., 2004). Their accumulation in topographic depressions as a result of weathering is responsible for the detection of hematite from orbit.

10.11.4.2.4 Phyllosilicates

Phyllosilicates form a large group of minerals that includes, among others, micas, smectites, and kaolinites. Their basic characteristic feature is the layered structure, and their formation can take place at the surface (e.g., in soils or sediment) or subsurface (diagenesis and hydrothermal alteration) (e.g., Meunier, 2005). Some of them, for example, smectites, form as alteration products of volcanic material. Therefore, their presence on Mars has been considered possible and even likely on theoretical grounds (e.g., Bishop, 2005). Several studies suggested the existence of phyllosilicates on Mars based on in situ Viking lander analyses (Toulmin et al., 1977), the identification of smectites in laboratory analyses of shergottite, nakhlite, and chassigny (SNC) meteorites (e.g., Bridges et al., 2001), and spectroscopic measurements (e.g., Bishop et al., 1995; Clark et al., 1990; Wyatt and McSween, 2002). The general opinion, however, confirmed by the detection of sulfates in orbiter and rover measurements, was that the Martian mineralogy was dominated by acid sulfate processes, which prohibit the formation of clay minerals (see the comment by Newsom (2005)). Nevertheless, phyllosilicates were identified on Mars in near-IR spectra taken with the OMEGA spectrometer (Bibring et al., 2005). Clay minerals such as smectites were first identified from orbit in two major outcrops in the area of Mawrth Vallis and Nili Fossae and in several smaller-sized areas (Poulet et al., 2005). The phyllosilicate-rich materials were located in ancient (Noachian) regions, but their surfaces do not show large abundances of impact craters and, therefore, must have been exposed relatively recently. Later orbital observations added thousands of phyllosilicate-bearing surface materials (e.g., Carter et al., 2013; Ehlmann et al., 2013; Mustard et al., 2008), and even though most of them were found in ancient surfaces, some phyllosilicate formation appears to have continued into the Hesperian (Thollot et al., 2012).

Phyllosilicates have also been found in Gusev crater at the base of the Columbia Hills. Measurements of the Mössbauer and APXS spectrometers indicate the presence of members of the kaolinite, serpentine, chlorite, and septechlorite groups (Wang et al., 2006). The detection of Al-rich phyllosilicates suggests a mildly acidic past environment and an open hydrologic system with good drainage conditions (Wang et al., 2006). When both Fe/Mg- and Al-rich phyllosilicates are found together, the common stratigraphic relationship is that Al phyllosilicates overlie Fe/Mg phyllosilicates. This has been interpreted as a surface weathering sequence (e.g., Le Deit et al., 2012). On the other hand, it appears likely that no single process can explain all phyllosilicate outcrops on Mars, and multiple phyllosilicate-forming processes operated in diverse chemical environments, varying over space and time (Ehlmann et al., 2013).

10.11.4.2.5 Sulfates

Sulfates are salts of sulfuric acid and often contain water molecules. They are particularly useful to constrain the climatic evolution, since some sulfates can be transformed to other sulfates that have a different water content. While this reaction is sometimes reversible, it is irreversible for others. As an example, kieserite ($MgSO_4 \cdot H_2O$) can easily be hydrated and converts to hexahydrite ($MgSO_4 \cdot 6H_2O$) and epsomite ($MgSO_4 \cdot 7H_2O$). When these minerals are desiccated, they do not convert back to kieserite, but to an amorphous phase (Vaniman et al., 2004). The presence of kieserite at certain locations on Mars (see succeeding text) indicates, therefore, that the climate probably never experienced obliquity-driven periods of hydration and desiccation in these regions (Vaniman et al., 2004).

The presence of sulfates on Mars has been discussed for a long time. Theoretical considerations, partly based on terrestrial analogue materials, suggested that Mars might host sulfates, and, for example, Burns (1987) predicted that jarosite might be the result of the interaction of groundwater with iron sulfides. Viking lander measurements indicated a high sulfur content in the Martian soil, and Toulmin et al. (1977) proposed that sulfates might be the corresponding minerals. The SNC meteorites, which are thought to be samples of the Martian crust (e.g., Bogard and Johnson, 1983), contain sulfates (e.g., McSween, 1994), and spectroscopic observations also hinted toward sulfates (e.g., Blaney and McCord, 1995; Pollack et al., 1990).

Major sulfate deposits have been found with OMEGA in the Valles Marineris and Terra Meridiani (Gendrin et al., 2005) and the north polar region (Langevin et al., 2005a). In Valles Marineris, they are associated with layered deposits (**Figure 18**), and in the north polar region, they occur within a huge field of dark dunes. The MER confirmed the presence of sulfates and identified the Fe sulfate jarosite, predicted to exist on Mars by Burns (1987), in Meridiani Planum (Klingelhöfer et al., 2004). Most recently, the rover Curiosity identified Ca-sulfates in Gale crater, pointing to a more clement environment than the Fe and Mg sulfates found elsewhere (Nachon et al., 2013).

10.11.4.2.6 Carbonates

A warmer and denser greenhouse atmosphere on early Mars, as suggested by the geomorphic record of fluvial and lacustrine processes (see **Section 10.11.3.1**), would raise the question where the greenhouse gases have disappeared since then. A plausible way to remove CO_2 from the atmosphere would be the formation of carbonates, and the search for carbonates on Mars has been the subject of many investigations (Bibring et al., 2005; Christensen et al., 2001a). In fact, carbonates were identified in SNC meteorites (e.g., Bridges et al., 2001) and in surface materials both from orbit and in situ (Ehlmann et al., 2008; Morris et al., 2010), but the amount is limited and cannot account for the fate of a possibly denser CO_2 atmosphere on early Mars.

10.11.4.2.7 Opaline silica

Opaline silica ($SiO_2 \cdot nH_2O$) occurs at several locations on Mars (Milliken et al., 2008; Skok et al., 2010) and may have been precipitated in hydrothermal or lacustrine evaporitic environments. On Earth, it rarely persists more than a few million years. The persistence of opaline silica on Mars over much longer geologic timescales (billions of years) therefore may indicate that water was not present for extended periods of time after its original formation (Tosca and Knoll, 2009).

10.11.4.2.8 Chlorides

Chlorides have been identified in many locations in the southern highlands of Mars (Osterloo et al., 2008). The most likely formation process is via ponding and evaporation of surface water from runoff or groundwater upwelling (Osterloo et al., 2010; Ruesch et al., 2012).

10.11.4.2.9 Zeolites

Zeolites are common alteration products of basaltic ashes and palagonitic material on Earth, and they have been proposed as potential water-containing minerals on Mars. Spectral evidence for zeolites in the Martian dust has been presented by Ruff (2004) and possibly by Christensen et al. (2004b) in Mini-TES data taken in Gusev crater. Zeolites can easily be hydrated and dehydrated, and experimental studies have suggested that zeolites, if present on Mars, could undergo a diurnal cycle of hydration and dehydration with possible impact on the atmosphere (Bish et al., 2003), but Tokano and Bish (2005) showed that the diurnal atmospheric water cycle on Mars is unlikely to be affected by zeolites.

10.11.4.3 Geophysical Consequences

Based on experiments performed on dry peridotite systems, water is capable of lowering the melting temperature of mantle material by as much as 500 K. The resulting melting curve for the water-saturated system has a negative *P*–*T* gradient at low pressures, which becomes positive with increasing depth and therefore pressure. An amount as small as 0.1% of water would enable some partial melt to be formed, even if it would be impossible in the dry system. The amount of partial melting increases with increasing depth (Cattermole, 1989). Therefore, the effect of water on the solidus behavior can have a significant influence on the mantle of terrestrial planets. This is discussed in greater details in **Chapter 10.09**.

Small amounts of dissolved volatiles can have important effects on the density, viscosity, and crystallization of melts and magmas. Changing these properties influences the mechanical behavior of magmas, the differentiation, and the eruption style. The solubility of water in magmas depends on parameters like temperature, pressure, the presence of other volatiles (Williams and McBirney, 1979), and the presence of exchangeable cations, that is, those that are not in tetrahedral coordination sites (Burnham, 1979). A decrease in temperature and an increase in pressure both tend to increase the solubility of water in magma, and an increasing abundance of other volatiles decreases it (Cas and Wright, 1988). Consequently, the water contents of magmas vary widely (**Table 1**). In general, water is more soluble in highly differentiated magmas than in basaltic ones. For example, magmas from subduction zones are water-rich, because sediments and secondary altered basalts provide water sources. It seems possible that a significant fraction of the water in magmas is added in crustal magma chambers (Kyser and O'Neil, 1984). It is, however, difficult to determine the original content of H_2O, in particular the amount of water injected into the stratosphere (Schmincke, 2000).

Mierdel et al. (2007) showed recently that the asthenosphere of Earth coincides with a zone where the water solubility in mantle minerals has a pronounced minimum. The minimum is due to a sharp decrease of water solubility in aluminous orthopyroxene with depth, whereas the water solubility in olivine continuously increases with pressure. Melting in the asthenosphere may therefore be related not to volatile enrichment but to a minimum in water solubility, which causes excess water to form a hydrous silicate melt.

Dissolved water can change the density of magma and thereby influence, for example, the buoyancy. In an experiment with H_2O dissolved in a melt of albite composition ($NaAlSi_3O_8$), a partial molar volume of 14–20% $cm^3\,mol^{-1}$ has been measured for a temperature range from 750 to 950 °C. Indirect estimates for the partial molar volume of

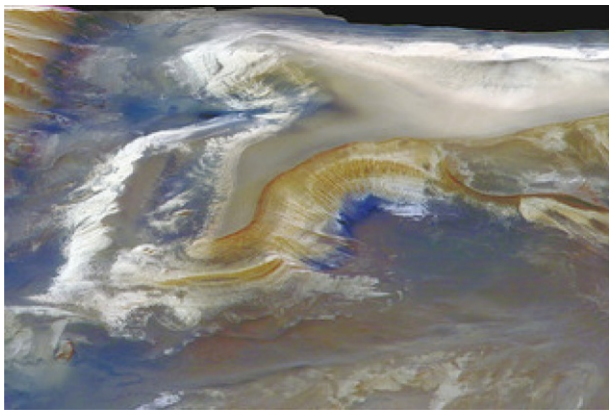

Figure 18 Layered deposit in Valles Marineris, Mars. The flank surfaces of this mountain were found to contain sulfates, based on spectra taken with the OMEGA instrument (Gendrin et al., 2005). The sulfates seem to be associated with bright layers of unknown origin. The image is a false-color perspective view, based on HRSC stereo data (image width is about 70 km, and the height of the mountain is more than 4 km). copyright: ESA/DLR/FU Berlin.

Table 1 Approximate H_2O contents in magmas

Magma content	*H_2O content (wt%)*
MORB (tholeiites) Schmincke (2000)	0.1–0.2
Island tholeiites	0.3–0.6
Alkali basalts	0.8–1.5
Subduction-zone basalts	2–3
Basanites and nephelinites	1.5–2
Andesites and dazites (island arcs)	1–2
Andesites and dazites (active continental margins)	2–4
Rhyolites	Up to ~7

MORB, mid-ocean ridge basalts.

Source: Fisher RV and Schmincke H-U (1984) *Pyroclastic Rocks*, 472 pp. Berlin, Germany: Springer; Aoki K, Ishiwaka K, and Kanisawa S (1981) Fluorine geochemistry of basaltic rocks from continental and oceanic regions and petrogenetic application. *Contributions to Mineralogy and Petrology* 76: 53–59.

water in rhyolitic or basaltic melts based on solubility data are generally at the lower end of the measurements for the albite melt (Hamilton and Oxtoby, 1986). Using the molecular weight of 18 g mol^{-1} for H_2O with the partial molar volume of $\sim$14 cm^{3}mol^{-1}, the addition of dissolved water generates a component with a density of slightly >1 g cm^{-3} compared to $\sim$2.7 and $\sim$2.3 g cm^{-3} for the anhydrous basaltic and rhyolitic melt, respectively (Wallace and Anderson, 2000). The addition of water decreases effectively the density of the melt. As an example, adding 6% dissolved water to a rhyolitic melt decreases the density by about 5%.

The viscous behavior of melts is also discussed in **Chapter 10.09**. In general, silicate melts exhibit Newtonian behavior, which means the rate of shear in the liquid is linearly proportional to the magnitude of applied shear stress. The viscosity increases rapidly with decreasing temperature. The viscosity is strongly dependent on the melt composition; with increasing SiO_2 content, the viscosity also increases. The difference in viscosity between a low-temperature rhyolitic melt and a high-temperature basaltic melt can be as much as eight orders of magnitude.

Adding dissolved water to a melt decreases the viscosity (e.g., Murase, 1962). The most likely cause is H_2O weakening or breaking apart (depolymerizing) the Si=O=Si bridges in the aluminosilicate framework of the melt (Wallace and Anderson, 2000). H_2O has a nonlinear effect on melt viscosity (Hess and Dingwell, 1996). A proportion of 0–3% of water strongly reduces the viscosity. Adding 3 wt% of water to a dry siliceous melt can decrease the viscosity by five orders of magnitude, while adding more than 3% of water has very little additional effect on the viscosity. For $<3\%$ H_2O, the water can dissolve in OH^- groups that bond to the aluminosilicate framework, thereby decreasing the viscosity very effectively. For higher amounts of water, the saturation for OH^- groups is reached and additional water is dissolved as H_2O, having little effect on the aluminosilicate bonds; therefore, little additional change in the viscosity is observed.

Water is the most important volatile species controlling the acceleration and mass eruption rate of eruption columns. Pyroclastic explosive eruptions are mainly caused by the volumetric expansion of magmatic H_2O and the resulting fragmentation of magma. This effect is substantial, as an example given by Sparks et al. (1997) makes clear: a volume of 1 m^3 rhyolitic magma at 900 °C and a H_2O content of 5 wt% will expand to a 670 m^3 of degassed mixture of water vapor and magma at 1 atm (1000 mbar) surface pressure. For small masses of up to 10–15 wt% added surface water, the formation of an eruption column in an explosive event will be promoted (Koyaguchi and Woods, 1996). On the other hand, water contents that exceed 20–30 wt% result in a dense, wet, and cold mixture, which requires a greater initial velocity to produce a buoyant column (Woods, 1995).

10.11.5 Evolution of Water and Climate

Of the terrestrial planets besides Earth, only Venus and Mars might have experienced in the past episodes in which a water-rich climate might have been possible.

Venus is at present an extremely dry and hot planet. The atmospheric water content is $\sim$30 ppmv (e.g., see de Bergh et al. (1995) and the H_2O measurements tabulated in Fegley et al. (1997)) yielding a water partial pressure of $\sim$3 mbar at the surface of Venus. For comparison, the Earth's average surface temperature is 288 K and its troposphere is much wetter with a water vapor content up to $\sim$4% (see Chapter 1.19 in Volume 1 of the *Treatise on Geochemistry* by Fegley). There are indications suggesting that Venus had more water in its past. This is based on the high deuterium/hydrogen (D/H) ratio of $(2.5\pm0.5)\times10^{-2}$ in atmospheric water vapor reported by Donahue et al. (1997). It is 160 ± 32 times higher than the D/H ratio of 1.56 ± 10^{-4} in standard mean ocean water on Earth (Lodders and Fegley, 1998). One possible scenario to explain this ratio is enrichment by isotope fractionation. Hydrogen preferentially escapes through physical processes such as evaporation or diffusion, thus enriching the deuterium concentration (e.g., see Criss, 1999). The study of the D/H ratio by Donahue et al. (1982) (Donahue et al., 1997, and references therein) concluded that Venus once must have had the equivalent of at least a 4 m deep global ocean and may have had as much as a 530 m deep global ocean. This interpretation of the D/H ratio is complicated by the fact that some interplanetary dust particles, meteorites, and comets also have a higher D/H ratio (Irvine et al., 2000). Therefore, Venus might have accreted from material with a different D/H ratio than Earth. Further clues might be derived in the future by studying the surface mineralogy. While the extreme volcanic activity of Venus has most likely erased all morphological evidence for a water-rich past, there might be traces of hydrate minerals left as indications for a water-rich past (Johnson and Fegley, 2000).

If the D/H ratio is due to a water-rich past of the planet, Venus must have lost a large amount of water during its history. Rabette et al. (2002) proposed for Earth a scenario in which an increase in sea surface temperatures above 27 °C leads to strong evaporation loading the atmosphere with a critical amount of water vapor. If enough water vapor enters the troposphere, a runaway greenhouse effect is initiated, causing even more water loss through evaporation from the ocean.

The ASPERA-4 instrument on Venus Express is studying the current oxygen and hydrogen escape rate from Venus that allows providing constraints on such escape models. Recent studies by Lammer et al. (2006) indicated that on Venus, the most relevant atmospheric escape processes of oxygen involve ions and are caused by the interaction with the solar wind. For the loss of hot H* atoms produced by photochemical reactions in the Venusian atmosphere, Gröller et al. (2010) found an average loss rate of about 3.8×10^{25}s^{-1} This is about two times lower than the estimated H^+-ion outflow from Venus' nightside due to acceleration upward along magnetic field lines of ionospheric holes (Hartle and Grebowsky, 1993) in the order of about 7×10^{25}s^{-1}. The loss rate for solar wind pickup of H^+ and O^+ ions is about 1×10^{25} and 1.6×10^{25}s^{-1}, respectively. Pickup of H_2^+ and He^+ ions is negligible compared to the loss rates of atomic hydrogen and oxygen ions. Additional loss rates are found from detached plasma clouds that yield a loss of about 5×10^{24}–1×10^{25}s^{-1} O^+ ions, in agreement with the results of a two-dimensional global hybrid simulation of Terada et al. (2002) indicating that Venus loses O^+ ions in the order of about $10^{25}\times O^+$ due to the Kelvin–Helmholtz

instability. Heavy O atoms can only escape as neutrals by atmospheric sputtering in an order of about $6 \times 10^{24} s^{-1}$ (Luhmann and Kozyra, 1991). The obtained results indicate that the ratio between H/O escape and space from the Venusian upper atmosphere is about 4 and is in a much better agreement with the stoichiometrically H/O escape ratio of 2:1, which is not the case on Mars. The ongoing detailed analysis of the outflow of ions from the Venus upper atmosphere by the ASPERA-4 and VEX-MAG instruments aboard Venus Express will lead to more accurate atmospheric loss estimations and a better understanding of the planet's water inventory.

For Mars, there are numerous studies on the atmospheric loss of water during the evolution of the planet. Chassefierre and Leblanc (2004) gave a summary of these studies and the resulting total loss of water from Mars. Zhang et al. (1993) and Luhmann et al. (1992) suggested an approach to evaluate the total amount of atmosphere lost to space along the Martian history (which is from 3.7 Gy ago up to present time) based on knowledge of what should have been the early time of the Sun. The solar extreme UV (XUV) flux was roughly three and six times higher than present XUV solar flux, 2.5 and 3.5 Gy ago, respectively (Ayres, 1997; Zahnle and Walker, 1982). This results in a globally hotter Martian thermosphere 3.5 Gy ago. Recent new model of the solar wind history (Wood et al., 2002) suggested a 40 times more massive solar wind in the early solar system (3.5 Gy ago) compared to the widely used model of Newkirk (1981). This has not been included in most models of the atmospheric loss so far. If this later process is neglected, the integrated loss to space associated with the estimates of Luhmann et al. (1992) for dissociative recombination and for pickup O^+ corona, and with the estimates of Leblanc and Johnson (2001) and Leblanc and Johnson (2002) for the sputtering, leads to a total loss to space of a H_2O ocean with a depth of 15 m covering the whole Mars surface. Lammer et al. (2003a) and Lammer et al. (2003b), using the same estimates, found a depth of 12 m. Previous estimates by Kass and Yung (1996) were of 50 m, and by Luhmann et al. (1992) and Luhmann (1997) of 30 m. Krasnopolsky and Feldman (2001) estimated the total loss of water to space based on D/H analysis and chemical model as being more than 30 m in depth. All these values have to be compared to the most recent estimate of a 150 m depth ocean of water covering the Martian surface during the Hesperian (from 3.5 Gy ago) based on geomorphological analysis (see **Section 10.11.3.4**). Carr and Head (2003) concluded that a large majority of this water should have been trapped into the surface since only the equivalent of 20–30 m depth ocean is contained in the present polar caps.

A loss of volatiles from the Martian atmosphere and a corresponding climate change are consistent with the evolution of the surface, which is recorded in the different ages of the various landforms. Fluvial and lacustrine landforms are common in ancient terrains (older than 3.5 Ga), whereas younger areas on Mars show only sparse evidence of a warmer climate that would allow the formation of such features. The morphological evidence for a climate change billions of years ago is complementary to mineralogical evidence for a more water-rich early Mars. In addition to the atmospheric data presented in the paragraph mentioned earlier, the particular clues for this climate change have been presented in the sections on morphology and mineralogy. A detailed discussion of this major climate change, the nature and timing of which is still under debate, is beyond the scope of this chapter, and the reader is referred to excellent studies by, for example, Pollack et al. (1987), Kasting (1991), Pollack (1991), Fanale et al. (1992), Jakosky and Jones (1997), Jakosky and Phillips (2001), and Bogard et al. (2001). In the following paragraph, we briefly summarize the discussion on possible, much more recent climate changes.

For Mars already early studies on Mariner 9 and Viking images showed glacial and permafrost landforms. The higher-resolution data of recent missions like MGS, Mars Odyssey, and Mars Express provided a surprising wealth of data showing details of many cold-climate phenomena. Many of them appear to be young and display a latitude-dependent, nonrandom distribution on a global scale. Such a distribution is typical for climatically controlled surface features. Although young, many of these landforms require the existence of ice and/or water at latitudes where it is not physically stable today. Moreover, morphological structures like the midlatitude cover deposit seem to be in a state of degradation. These observations suggest that recent climate excursions triggered precipitation in midlatitudes and perhaps even in low latitudes, probably as snow. One plausible reason for such climate changes in recent time could be the variable obliquity of Mars' rotational axis (Armstrong et al., 2004; Carr, 1982; Jakosky et al., 1995; Laskar and Robutel, 1993; Laskar et al., 2004; Touma and Wisdom, 1993; Ward, 1973, 1974). In contrast to Earth, whose obliquity is stabilized by the Moon (Laskar et al., 1993), the obliquity of Mars is characterized by chaotic behavior and has a high probability to reach maximum values of 60–80° and minimum values of ~0° (Laskar et al., 2004). At periods of high obliquity, the mean annual insolation at the polar regions is enhanced, and more volatiles tend to sublimate. Therefore, the polar regions experience a net loss of water, which is transported equatorward and precipitated as snow in midlatitudes and low latitudes (Levrard et al., 2004). This snow could have mantled the surface, producing a 'smoothed' appearance of the topography. Where local topographic conditions favored enhanced precipitation, larger amounts of snow could have accumulated and formed glaciers (Forget et al., 2006). In periods of low obliquity, the mean insolation at midlatitudes and low latitudes is enhanced and the ice-related landforms are degraded.

10.11.6 Summary and Outlook

Water is a highly vital, flexible, changeable, and moveable substance that alters and evolves other materials. The H_2O molecule is a major component of planets, moons, asteroids, and comets and acts in atmospheres, on surfaces, and in the subsurface as a weathering agent and transportation and sedimentation medium. It can also influence the rheology of materials and thereby influences the mantle transport processes (see **Chapter 10.09**).

Water is the main ingredient for life. As a polar molecule, it is an ideal solvent and supports several important processes for sustaining life. As water is crucial for habitable environments, its physical conditions constrain habitable zones (see **Chapter 10.14**).

Remote-sensing data show abundant evidence of fluvial and lacustrine processes that have been active on early Mars on a global scale (Noachian) with a declining rate of activity and processes limited to regional and local scales (Hesperian). These landforms also imply a large past reservoir of water on the surface and a past climate on Mars that allowed liquid water to be stable on the surface for longer timescales. Today, Mars is a cold and dry planet, but glacial, periglacial, and fluvial landforms indicate a geologically recent occurrence of water ice in the near-surface regolith, on the surface, and at least episodically in the liquid phase on the surface. The formation of these young landforms on Mars might be due to recent climate changes caused by, e.g., the variable obliquity of Mars' rotational axis.

Strictly even on Mars, all evidence for water is indirect, mainly based on remote-sensing observation of either the O–H bond (Bibring et al., 2005; Christensen et al., 2001a; Formisano et al., 2005) or the hydrogen atom (Feldman et al., 2005). The MER added morphological and indirect geochemical evidence, based on water-related alteration processes. Only in the polar areas we have direct observations of spectral features of water ice (Bibring et al., 2005; Hansen et al., 2005). The NASA Phoenix lander provided the first direct in situ observation of sublimating subsurface water ice exposed in a trench made by the robotic arm (Arvidson et al., 2009; Smith et al., 2009). Radar systems as, currently, MARSIS on Mars Express (Picardi et al., 2005) and SHARAD on MRO allow for the first time to study the subsurface structure and identify potential water or ice deposits below the surface. In combination with the data from the neutron and GRS, this allows a more accurate global inventory of water on Mars today.

Future advances in remote sensing will allow a much lower detection limit and a higher spatial resolution for mapping of water-related features. The HiRISE and CRISM instruments on MRO allow studying the morphological and mineralogical traces of water activity at a very high spatial resolution. Therefore, it will be possible to trace the history of water on Mars with a much higher confidence. The first in situ measurement of water was provided by the mass spectrometer on the Phoenix lander in the polar region of Mars (Smith et al., 2009). To further the understanding of the current-day water cycle on Mars, it is necessary to probe more hypothesized or remotely sensed water reservoirs directly. This includes direct measurements of the soil humidity at different landing sites, lander in the polar areas probing the ice and directly analyzing its composition, and access to the subsurface to probe for subsurface ice deposits. Highly mobile platforms as the NASA rover MSL or the future ESA rover ExoMars, equipped with drilling systems, neutron spectrometer, and GPR, open a new dimension in the analysis of present and past water on Mars.

The NASA MESSENGER mission has proved the existence of ice deposits close to the poles of Mercury and provided an estimate on their extent. The analysis of ice deposits on Mercury will be continued with the ESA mission BepiColombo (Benkhoff et al., 2010), as MESSENGER BepiColombo is equipped with gamma-ray and neutron spectrometers that will allow studying the spatial distribution and abundance of hydrogen in the regolith. Furthermore, the spectrometer on BepiColombo covering the wavelength range from UV to thermal IR will continue the systematic search for ice and other components of the radar-bright material. In combination with significant improvements in the knowledge of topography, the synergetic use of data provided by both spacecraft will allow to better understand the evolution and origin of water ice in the shadowed regions at the poles of Mercury.

For the Moon, the LCROSS mission confirmed the existence of water ice in permanently shadowed craters close to the poles is less certain. For the future (human) exploration of the Moon, these potential deposits are of great importance. Therefore, this will be a prime scientific priority for the new exploration program of the Moon. Further mission plans include landing and sample returns from these areas.

10.12.1 Atmosphere–Surface Interplay on Solar System Bodies

Even without an abundant aqueous phase, planetary surfaces are coupled with planetary atmospheres through complex physical and chemical processes. Volcanic degassing, impacts, and seepage from mantle and crustal rocks supply gases into atmospheres. The condensation of released volatiles affects abundances of atmospheric gases and surface composition. Compositions of atmospheres and surfaces are influenced by chemical interactions of gases with surface rocks and liquids, if they are present. In some cases, atmospheric abundances of volatiles can be controlled (buffered) by condensation/sublimation equilibria or chemical reactions at the surface. The rates of chemical reactions at the atmosphere–surface interface are affected by temperatures that, in turn, are influenced by solar luminosity, cloudiness, and the greenhouse effect. Eolian processes contribute to weathering, mass transfer, and separation of surface solids. Throughout history, atmosphere–surface interactions could have been affected by changing solar luminosity, orbital parameters, internal processes, impact cratering, geologic resurfacing, and gas escape into space.

Three major terrestrial planets – Venus, Earth, and Mars – reveal a broad-scale coupling of atmospheric and solid-body processes. On Earth, the major pathways of endogenic and exogenic processes are mainly determined by mantle convection, plate tectonics and corresponding volcanism, the hydrosphere, life, and impacts. On Mars and Venus, surface composition and climatic evolution are affected by volcanism, impacts, and atmosphere–surface interactions with limited and/or temporal influences from aqueous processes. This chapter is mainly devoted to atmosphere–surface interactions on Venus and Mars.

Despite significant differences in surface temperature, pressure, and atmospheric composition (Table 1), the atmosphere–surface interactions on Venus and Mars have several common characteristics. Aqueous solutions are unstable on both of their surfaces. On both planets, surfaces have not been significantly affected by volcanic, impact, and eolian processes for hundreds of millions of years. Nevertheless, surface materials reveal signs of alteration by coupled physical and chemical processes. Chemical alteration could have included oxidation of primary ferrous (Fe^{2+}-bearing) minerals and sulfides and consumption of sulfur, halogens, and water from the atmosphere. Physical processes include the condensation of species with different volatilities, wind abrasion, generation of fine-grained surface materials, mechanical separation of mineral grains, and formation of eolian features, including layered deposits with low porosity. Atmosphere–surface interactions are altitude- and latitude-dependent, owing to the variations in surface temperature, near-surface pressure, and concentrations of atmospheric gases. On both planets, the composition of atmosphere and surface materials reveals past geologic events, including intensive volcanic/impact degassing and resurfacing, as well as processes that occurred under wetter conditions.

10.12.2 Observational Constraints on Venus and Mars

This section presents data on surface materials and atmospheres in the context of gas–solid-type interactions. More information on planetary surfaces and atmospheres can be found in *Treatise on Geochemistry*, (e.g., Fegley, 2014; McSween and McLennan, 2014).

Table 1 Environmental conditions and the composition of major and chemically active gases in lower atmospheres of Venus and Mars

	Venus[a]	*Mars*[b]
Temperature	740 K	210 K
Pressure	95.6 bar	5.6×10^{-3} bar
CO_2	$96.5 \pm 0.8\%$	95.3%
N_2	3.5 ± 0.8	$2.7 \pm 0.5\%$
^{40}Ar	31^{+20}_{-10} ppm	$1.6 \pm 0.3\%$
$^{36+38}Ar$	35.5^{+20}_{-10} ppm	5.3 ± 1 ppm
O_2	–[c]	$0.13 \pm 0.01\%$
SO_2	150 ± 30 ppm (22–42 km)	<0.1 ppb
H_2O	30 ± 15 ppm (5–45 km)	0.03%[d]
CO	17 ± 1 ppm (17 km)	0.08%
COS	4.4 ± 1 ppm (33 km)	<0.01 ppm
H_2S	3 ± 2 ppm (<20 km)	<0.1 ppm
HCl	0.4 ± 0.03 ppm (0–74 km)	<2 ppb
S_{1-8}	20 ppb (<50 km)	–
HF	5 ± 3 ppb (35–70 km)	–
H_2	–	15 ± 5 ppm
CH_4	–	<1.3 ppb
H_2O_2	–	0–40 ppb 18 ± 0.4 ppb
O_3	–	0.04–0.2 ppm
NO	5.5 ± 1.5 ppb (<60 km)	<1.7 ppb
D/H	0.016 ± 0.002[e] 0.019 ± 0.006 (<50 km)	$(7.8 \pm 0.3) \times 10^{-4}$

ppm, parts per million by volume; ppb, parts per billion by volume.
[a]Venus temperature and pressure correspond to the modal planetary radius (6051.4 km). Gas abundances represent values closer to the surface. Concentrations of CO and COS are latitude- and altitude-dependent. Near-surface concentrations of these and other gases may be different.
[b]Martian surface temperature and pressure are estimates of the global annual averages (Kieffer et al., 1992).
[c]Near the surface, O_2 pressure is evaluated as 10^{-21} bar (Fegley et al., 1997b; Zolotov, 1996).
[d]Variable with season and location.
[e]D/H ratios for Venus represent Pioneer Venus in situ measurements and ground spectroscopy, respectively.

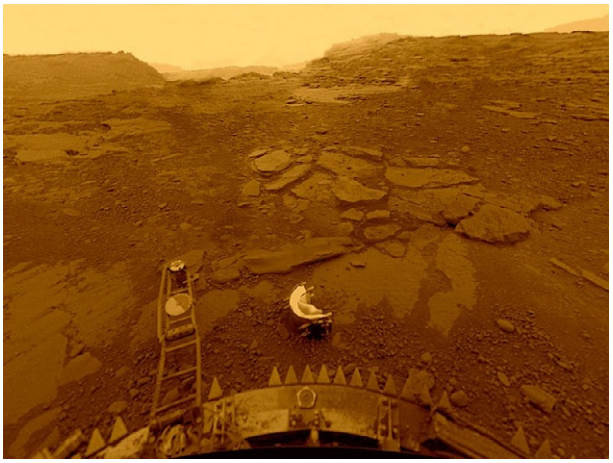

Figure 1 Layered rocks and rock fragments at the surface of Venus at the landing site of Venera 13. The surface is black at Venus' conditions and reddish color represents the surface at room temperature (cf. Pieters et al., 1986). The upper part of the image has been artistically created by Don Mitchell using other Venus' surface images.

10.12.2.1 Physical and Chemical Signs of Surface Rock Alteration

Basalts are the more abundant igneous rocks on Mars and Venus. On Mars, the mafic composition of primary rocks is inferred from studies of Martian meteorites; in situ analyses by the Viking, Mars Exploration Rover (MER), and Mars Science Laboratory (the Curiosity rover) missions; and remote sensing data (Banin et al., 1992; Blake et al., 2013; Clark et al., 1982; McSween and McLennan, 2014; McSween et al., 2006a,b, 2008; Mustard et al., 2005; Rieder et al., 2004). The mainly basaltic composition of Venus' plains is inferred from the morphology of widespread volcanic features observed in Venera 15–16 (Barsukov et al., 1986) and Magellan (Crumpler et al., 1997) radar images and x-ray fluorescence (XRF) analysis at the landing sites of Venera 13–14 and Vega 2 (**Table 2**). Gamma-ray spectrometric analysis of K, U, and Th at Venera 9–10 and Vega 1–2 landing sites is consistent with mafic rocks, while Venera 8 materials resemble alkaline rocks (Surkov et al., 1987).

Despite their chiefly basaltic composition, surface rocks are physically and chemically altered. Planetary surfaces are partially covered by wind-blown material, rock fragments, and fine-grained soil. Porous layered deposits have been observed at the landing sites on Venus (e.g., Basilevsky et al., 1985; Florensky et al., 1977, 1983a,b; Garvin et al., 1984), at Meridiani Planum on Mars (Squyres et al., 2006), and at the Columbia Hills in Gusev crater (**Figures 1** and **2**). It has been suggested that layered rocks at these sites were deposited from the atmosphere by eolian activity, explosive volcanism, and/or impact events (Basilevsky et al., 1985, 2004; Garvin et al., 1984; Grotzinger et al., 2005; Knauth et al., 2005).

Layered rocks observed at Venera 13–14 landing sites are mechanically weak materials with high porosities (50–60%), low densities (1.4–1.5 g cm^{-2}, Florensky et al., 1983a,b), and low bearing capacities (4–5 kg cm^{-2}, Avduevsky et al., 1983; 2.6–10 kg cm^{-2}, Kemurdzhian et al., 1983). These rocks resist drilling similar to weathered porous basalt or ashy tuff (Barmin and Shevchenko, 1983). Layered rocks observed at the

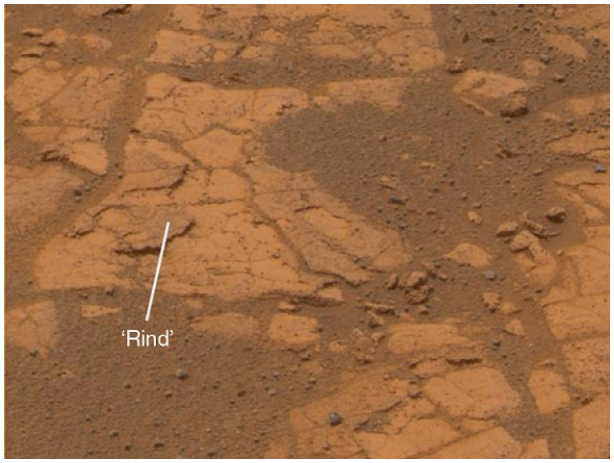

Figure 2 Layered sedimentary rocks at the Meridiani Planum, Mars. The rind-like features appear to cap the rocks and are probably more resistant to wind erosion than surrounding rocks. The image was taken with the Opportunity rover during 552 sol (13 August 2005). Photo credit NASA/JPL/Cornell.

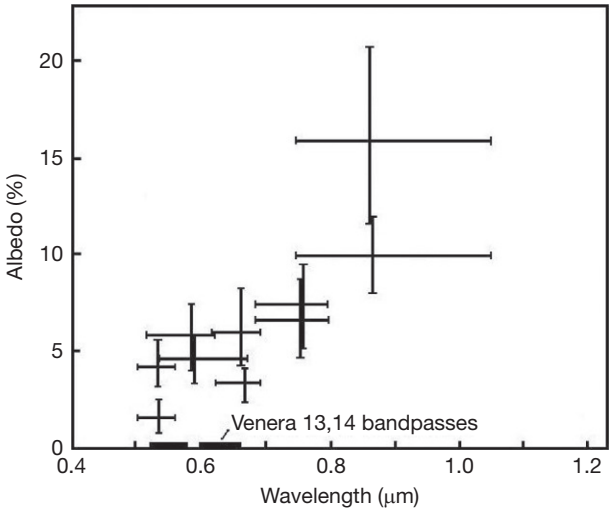

Figure 3 Reflectance properties of the Venus' surface at the Venera 9–10 landing sites (Ekonomov et al., 1980; Pieters et al., 1986). Horizontal bars indicate the width at half height of the Venera filters. Reproduced from Pieters CM, Head JW, Patterson W, et al. (1986) The color of the surface of Venus. *Science* 234: 1379–1383, with permission from AAAs.

Venera 9–10 landing sites have higher bearing capacities (30–300 kg cm^{-2}), although they possess properties analogous to volcanic tuffs and/or weathered basalts (Basilevsky et al., 2004; Kemurdzhian et al., 1983). Predominantly horizontal layering and some signs of cross-bedding (Venera 10) are consistent with deposition from the atmosphere followed by mild lithification and erosion. Fine-grained material observed in Venera 9–10 and 13 panoramas is the likely product of the degradation of local rocks (Basilevsky et al., 2004; Florensky et al., 1977; Garvin et al., 1984).

Radar observations of Venus' volcanic plains by the Pioneer Venus, Venera 15–16, and Magellan orbiters revealed a dielectric constant (δ) of ~5, typical for basalts (Ford and Pettengill, 1983; Pettengill et al., 1997). These data are consistent with the electrical resistance of rocks at the landing site of Vega 2 (10^6 Ωm), which is common for heated basalts (Kemurdzhian et al., 1983). Rocks at the landing sites of Venera 13–14 had significantly lower electrical resistances (89 and 73 Ωm, respectively; Kemurdzhian et al., 1983). These measurements suggest lateral heterogeneity of surface material. On the highlands, ~4.5 km above the mean planetary radius (6051.5 km), surface materials are characterized by elevated radar reflectivity that corresponds to a dielectric constant as high as 20–30 (Ford and Pettengill, 1983; Pettengill et al., 1997). These high δ values are inconsistent with unaltered igneous rocks.

Martian layered rocks at Meridiani Planum (**Figure 2**) and Gusev crater (e.g., Home Plate in the Columbia Hills) are characterized by high porosity, low density, and sometimes cross-bedded structures (e.g., Fergason et al., 2006; Grotzinger et al., 2005). The thermal inertia of soils and bedforms at both MER landing sites is consistent with particle diameters between 45 and 160 μm (silt to fine sand; Fergason et al., 2006), which agrees with the grain size of the most easily suspended particles (100–150 μm; Greeley et al., 1980). The finest grains could represent a globally homogenized material that has been observed at the Viking and Mars Pathfinder landing sites (Bell et al., 2000; Christensen and Moore, 1992). In addition, rocks, soils, and individual sand grains are at least partially coated by particles with a diameter of 0.2–10 μm, which represents atmospheric dust.

On Mars and Venus, surface materials exhibit specific absorptions in the visible and near-infrared spectral ranges, indicating the presence of Fe^{3+}-bearing (ferric) species, which are uncommon in unaltered basalts. Reflectance spectra of Venus' surface measured at the Venera 9–10 landing sites (Ekonomov et al., 1980) roughly match with the spectrum of the ferric oxide hematite (α-Fe_2O_3) heated to Venus' surface temperatures (Pieters et al., 1986), as can be seen in **Figures 3** and **4**. On Mars, the absorption of light by ferric oxides is responsible for the reddish hue of dust, soils, and rock coatings (Bell et al., 2000; Soderblom, 1992). This inference is consistent with the detection of goethite (α-FeOOH), hematite, nanophase ferric oxide/oxyhydroxide, ferric sulfates, and clays by thermal emission (Christensen et al., 2001; Glotch et al., 2006) and Mössbauer (Klingelhöfer et al., 2004; Morris et al., 2006, 2008) spectroscopies. Only minor alteration observed in Martian meteorites (Bridges et al., 2001; Gooding, 1992), which were excavated by impacts, implies that oxidation occurs mainly at the Martian surface.

Chemical analyses of surface materials on both planets reveal incorporation of volatile elements into alteration products. Venus' surface rocks (**Table 2**) are significantly enriched in S compared with basalts, which typically contain <0.2 wt% S. Martian soils (**Table 3**) are enriched in S, Cl, Br, and bound H_2O compared with normal basalts. Rock fragments possess enrichments in S and halogens, indicating dust coatings and/or weathering rinds (Gellert et al., 2006; Rieder et al., 1997, 2004). The variable abundances of volatiles imply their exogenic source. Elevated abundances of sulfur observed in Venus' and Mars' surface rocks may indicate global processes of basalt enrichment in near-surface environments.

10.12.2.2 Atmospheric Compositions in the Context of Atmosphere–Surface Interactions

Carbon dioxide and N_2 are the major atmospheric components on Mars and Venus (Table 1). CO_2 is a major component of terrestrial volcanic gases (Oppenheimer, 2003; Symonds et al., 1994) and could be an abundant product of mantle outgassing on other terrestrial planets. On Venus, the mass of atmospheric CO_2 is similar to the mass of CO_2 stored in terrestrial crustal carbonates (Table 4). Compared to Earth, this suggests that the majority of CO_2 degassed on Venus resides in its atmosphere. On Mars, the low mass of CO_2 in the atmosphere, even when normalized to planetary mass, may indicate early incorporation of CO_2 in carbonates and/or escape of CO_2 into space.

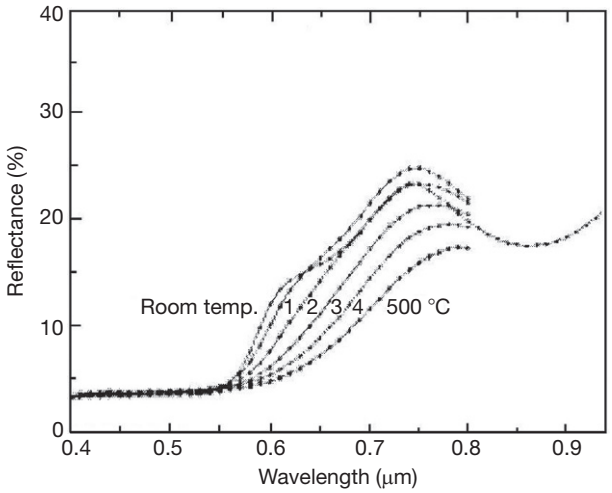

Figure 4 Laboratory reflectance spectra of the ferric oxide hematite at temperatures ranging from room temperature to 500 °C. Reproduced from Pieters CM, Head JW, Patterson W, et al. (1986) The color of the surface of Venus. *Science* 234: 1379–1383, with permission from AAAs.

On both planets, active trace species play a major role in atmospheric chemical processes and rock alteration. On Mars, photochemically generated species (e.g., CO, O_2, H_2, H_2O_2, O_3, HO_2, O, OH, H, NO, and NO_2) are distributed throughout the lower atmosphere and can affect the surface composition (Krasnopolsky, 2011; McElroy et al., 1977; Yung and DeMore, 1999). On Venus, highly oxidized photochemically derived species are subjected to thermochemical reactions below clouds (48–60 km) and may not reach the surface. Near the surface, atmospheric chemistry is controlled by thermochemical reactions, with an exception of photochemical interaction between S_3 and S_4 gases. In contrast, in the Martian atmosphere, thermochemical processes are insignificant because of low densities and temperatures.

On Mars, densities of atmospheric gases vary with season and latitude. Nonsymmetrical seasonal condensation of atmospheric CO_2 in polar regions causes variations in total atmospheric pressure (James et al., 1992). Similarly, the abundance and partial pressure (P) of water vapor are strongly dependent on season and latitude, reaching the highest values in spring in the Northern Hemisphere (Jakosky and Haberle, 1992; Smith, 2002).

On Venus, altitudinal variations in concentrations of trace gases are caused by temperature–pressure-dependent

[a]Terrestrial data are from Ronov and Yaroshevsky (1976) and Volkov (1992).

thermochemical reactions and Hadley circulation beneath the cloud deck. Thermochemical processes below the clouds create concentration gradients for several species. For example, thermochemical interaction of CO with S-bearing gases to form COS could be implied by the observed decreasing CO and increasing COS abundances toward the surface (Krasnopolsky, 2007; Krasnopolsky and Pollack, 1994). The upward motion of gases in the equatorial region and downwellings in pole regions in the Hadley cell could produce higher concentrations of CO in high latitudes and elevated abundances of COS in equatorial regions.

At Venus' surface, catalysis by solid phases and sluggish air circulation in the boundary layer may allow thermochemical equilibration at least among some gases. For example, a model of chemical equilibration among CO_2, CO, COS, and SO_2 at the surface is consistent with observations (Fegley et al., 1997b; Krasnopolsky and Pollack, 1994; Zolotov, 1996). Concentrations of several other near-surface trace gases may be controlled by thermochemical equilibria as well (**Table 5**). The possibility of equilibration among gases increases below the surface, where migration of gases is controlled by diffusion through pore spaces. High porosity facilitates gas–surface interactions in the near-surface layer. Without new data from Venus, assuming thermochemical equilibrium provides a way to evaluate concentrations of undetected gases. Above Venus' surface, especially at elevations of several kilometers, equilibrium predictions are not consistent with observations (e.g., Krasnopolsky, 2007; Krasnopolsky and Pollack, 1994; Zolotov, 1996). Disequilibria among major chemically active gases (CO_2, SO_2, CO, and COS) in Venus' highlands constrain the evaluation of atmospheric composition and pathways of gas–mineral interactions.

10.12.3 Chemistry of Atmosphere–Surface Reactions on Mars and Venus

Atmospheric–surface reactions have been considered since the early 1960s in attempts to interpret spacecraft and telescopic observations, as reviewed by Von Zahn et al. (1983), Lewis and Prinn (1984), Volkov et al. (1986), Banin et al. (1992), Fegley and Treiman (1992), Gooding et al. (1992), Zolotov and Volkov (1992), Fegley et al. (1997a), Wood (1997), and Fegley (2014). Despite many theoretical and some experimental efforts, there is no consensus among planetologists on the stability of minerals, as well as rates and timing of processes.

Table 5 Composition of the near-surface atmosphere of Venus according to a thermochemical equilibrium model for conditions at the modal planetary radius (6051.4 km, 740 K, and 95.6 bar), in volume fraction

Gas	*Mole ratio*	*Gas*	*Mole ratio*
CO_2	0.965	H_2S	1.1×10^{-7}

10.12.3.1 Redox Processes

Chemical reactions involving electron transfers (redox processes) are the major class of reactions at the atmosphere–surface interface on Venus and Mars. Photochemical production of oxidized atmospheric gases (e.g., SO_3, O_2, and O_3) and volcanic supply of CO_2, SO_2, and H_2O create the possibility for oxidation of freshly exposed igneous rocks. The observed oxidizing nature of surface materials on Mars and Venus (see **Section 10.12.2.1**) implies that atmospheric oxidants were present and involved. On Mars and Venus, surface rocks are only partially oxidized. On both planets, a major phase of mineral oxidation could have occurred during earlier epochs that were warmer and more humid (see **Section 10.12.5**).

10.12.3.1.1 Oxidation on Venus

The atmospheric redox state near the mean planetary radius on Venus corresponds to conditions at which the iron oxides magnetite ($Fe^{2+}Fe^{3+}{}_2O_4$ and Fe_3O_4) and hematite coexist with each other (Fegley et al., 1997b; Zolotov, 1996), consistent with the interpretation of near-infrared reflectance patterns of rocks observed at the Venera 9–10 landing sites (Pieters et al., 1986). An oxidized, hematite-bearing surface

environment agrees with the results from the color experiments on the Venera 13–14 landers that provided a lower limit for atmospheric CO of 2.3–6.8 ppm (Fegley et al., 1997b; Zolotov, 1996).

The strong absorption of light in the visible spectral range observed for Venera 9–10 and Venera 13–14 rocks (Figure 3) is consistent with the low albedo of magnetite and hematite at the surface temperature. The lack of Fe enrichment in analyzed rocks (Table 2) compared with typical basalts implies only a low-albedo coating of ferric oxides. An analysis of Venera 13 color data reveals an enrichment of surface fines in 'red' Fe^{3+}-bearing material (Shkuratov et al., 1987). This interpretation agrees with diffusion-limited oxidation by atmospheric gases by which smaller grains alter faster. In addition, glassy impact- or volcanic-generated components in Venus' fines should experience higher rates of alteration compared to crystalline minerals.

Magnetite can form as an intermediate phase during oxidation of ferrous silicates to hematite. Theoretical studies of mineral stability show that primary ferrous minerals in basalts (olivines and pyroxenes) could be oxidized by O-bearing atmospheric gases, leading to the production of reduced gases. The pathways of oxidation to magnetite can be exemplified by the following reactions:

$$3FeO + CO_2 \rightarrow Fe_3O_4 + CO \quad [1]$$

$$3FeO + 0.5SO_2 \rightarrow Fe_3O_4 + 0.25S_2 \quad [2]$$

$$3FeO + H_2O \rightarrow Fe_3O_4 + H_2 \quad [3]$$

Here, ferrous iron oxide is a component of rock-forming silicates such as olivine and pyroxene and silicate glasses. In addition to ferrous silicates, the primary iron sulfides troilite (FeS) and pyrrhotite ($Fe_{1-x}S$) can be oxidized to ferric oxides and/or pyrite (FeS_2), as can be seen in Figure 5.

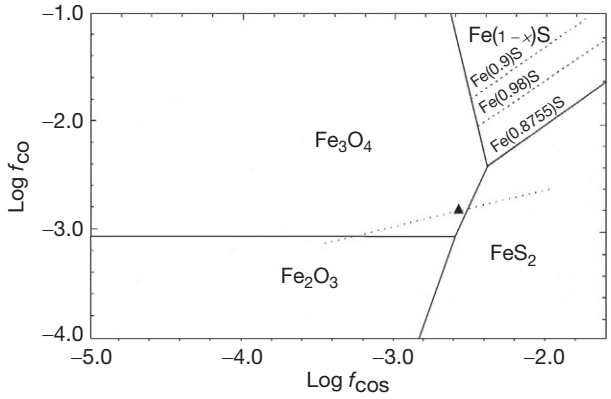

Figure 5 Stability of minerals in the Fe–S–O system at the conditions of Venus' surface (740 K and 95.6 bar total pressure). Activities of minerals are unity. The dotted line represents equilibrium conditions among CO_2, CO, COS, and SO_2 at CO_2 volume fraction of 0.965 and mole fraction of SO_2 of 130 ppm. The filled triangle represents equilibrium conditions at which mole fraction of CO is 17 ppm and volume fraction of COS is 28 ppm. The plot demonstrates that abundances of gases in the near-surface atmosphere (Table 5) are close to the conditions of magnetite–pyrite, hematite–magnetite, and hematite–magnetite–pyrite equilibria.

Pyrrhotite-to-pyrite conversions can occur through the uptake of H_2S and/or S_2 via reactions

$$Fe_{1-x}S + H_2S \rightarrow (1-x)FeS_2 + xS_2 + H_2 \quad [4]$$

$$Fe_{1-x}S + 0.5(1-2x)S_2 \rightarrow (1-x)FeS_2 \quad [5]$$

The correspondence of atmospheric redox conditions to the conditions of the magnetite–hematite equilibrium is not likely to be accidental and could reflect ongoing magnetite-to-hematite transition via some of the following reactions:

$$2Fe_3O_4 + CO_2 \rightarrow 3Fe_2O_3 + CO \quad [6]$$

$$2Fe_3O_4 + 0.5SO_2 \rightarrow 3Fe_2O_3 + 0.25S_2 \quad [7]$$

$$2Fe_3O_4 + H_2O \rightarrow 3Fe_2O_3 + H_2 \quad [8]$$

It is not clear which atmospheric gas plays the major role in rock oxidation. If equilibrium models for atmospheric chemistry are valid, all considered oxidation reactions have the same thermodynamic potential. One cannot tell which reaction is the major one without the consideration of reaction kinetics. The efficiency of basalt oxidation by CO_2 at Venus' surface conditions has been demonstrated experimentally (Fegley et al., 1995). Oxidation by SO_2 can occur through disproportionation of sulfur and release of S_2 (Terradellas and Bonnetain, 1973). Water is an oxidant of ferrous silicates under hot O_2-free conditions. More experiments are needed to evaluate the relative role of the considered oxidation reactions [1]–[8] in the preceding text. At different altitudes, temperature and compositional changes should affect the thermodynamics and kinetics of redox reactions. New observations and experiments are needed to understand redox processes at high altitudes.

The coexistence of magnetite and hematite at the surface may buffer atmospheric CO_2/CO, SO_2/COS, SO_2/S_2, and H_2O/H_2 ratios, which designate the oxidation state of the lower Venus' atmosphere. Buffering by reactions [6]–[8] means that the gas fugacity ratios remain unchanged until magnetite is consumed. Here, the magnetite-to-hematite conversion can occur only through oxidation by one or two gases, likely CO_2 and/or H_2O, followed by thermochemical re-equilibration among other gases. The dominance of ferrous minerals in mafic crustal rocks compared to the amount of oxidized gases and a slow rate of H_2 escape (Donahue et al., 1997) could have prevented profound oxidation of rocks to magnetite and hematite. In other words, slowly reacting Fe oxides may maintain the redox conditions (fO_2) in the near-surface atmosphere, where the majority of air mass is located.

10.12.3.1.2 Oxidation on Mars

The reddish color of the Martian surface and the detection of hematite, goethite, and nanophase Fe^{3+} oxide/oxyhydroxide; Ca-, Mg-, and Fe^{3+}-sulfates; and perchlorates at the surface of Mars (Hecht et al., 2009; Klingelhöfer et al., 2004; Morris et al., 2006, 2008; Leshin et al., 2013) and Martian orbital spectrometers (e.g., Christensen et al., 2001; Gendrin et al., 2005; Murchie et al., 2009) are consistent with near-surface oxidation.

As on Venus, Martian surface conditions thermodynamically favor oxidation of Fe^{2+} silicates and sulfides to Fe^{3+}-species and sulfates (Gooding, 1978; Gooding et al., 1992; O'Connor, 1968). On Mars, oxidation of minerals may be

driven by photochemically produced O_2, O_3, and H_2O_2 (e.g., Encrenaz et al., 2012; McElroy et al., 1977; Parkinson and Hunten, 1972). In addition, H_2O_2 can form by electrochemical processes in Martian dust devils and storms (Atreya et al., 2006; Delory et al., 2006). In all cases, peroxides are produced via dissociation of atmospheric O-bearing gases. The formation of perchlorates (Hecht et al., 2009; Leshin et al., 2013) could involve photochemistry-driven oxidation of Cl species in the atmosphere and/or at the surface (Catling et al., 2010). The presence of H_2O_2, perchlorates, and possibly other photochemically derived oxidants in the soil is consistent with the results of Viking biological experiments (Klein, 1978; Oyama and Berdahl, 1977, 1979; Zent and McKay, 1994) and initial results obtained by the Curiosity rover.

The mechanisms and environments of Martian surface oxidation could have varied in time and space and remain poorly known. Huguenin (1973a,b) reported experimental results showing rapid photooxidation of magnetite to hematite in an O_2-bearing atmosphere. Subsequent experiments by Clark et al. (1979) and Morris and Lauer (1980) failed to observe alteration of magnetite, as well as photostimulated alteration of other minerals. This inconsistency questioned results from theoretical works in which the effects of solar irradiation on the formation of goethite, clays, and other hydrated minerals were investigated (Huguenin, 1974, 1976). Similarly, the formation of peroxides in Martian soil through frost weathering of ferrous silicates (Huguenin, 1982; Huguenin et al., 1979) remains to be verified. Some insights could be obtained from the studies of rocks exposed in polar regions on Earth. In contrast to inorganic species, photochemical oxidation of organic compounds occurs readily under Martian conditions (e.g., Moores and Schuerger, 2012; Poch et al., 2013).

The occurrence of hematite-rich spherules at Meridiani Planum (**Figure 2**; Klingelhöfer et al., 2004), layered sulfate deposits at Valles Marineris and other locations (Gendrin et al., 2005; Langevin et al., 2005; Murchie et al., 2009; Roach et al., 2010), and localized goethite and sulfate enrichments in Gusev crater (Ming et al., 2006; Morris et al., 2008) reveals aqueous precipitation. It is possible that atmospheric and soil oxidants dissolved in surface aqueous solutions caused oxidation of reduced solutes (e.g., Fe^{2+}) and sulfide minerals via overall reactions

$$Fe^{2+} + 0.25O_2 + 1.5H_2O \rightarrow FeOOH + 2H^+ \quad [9]$$

$$FeS + 2.25O_2 + 1.5H_2O \rightarrow FeOOH + 2H^+ + SO_4^{2-} \quad [10]$$

where FeS represents iron sulfides and FeOOH stands for ferric oxides and oxyhydroxides. The presence of dissolved perchlorates and H_2O_2 increases the rate of oxidation. The contribution of ClO_4^- and/or H_2O_2 to aqueous oxidation might have been essential at low water/rock ratios that may represent episodic formation of water films or precipitation of atmospheric aerosols.

Reactions [9] and [10] produce protons that decrease the solution pH and the oxidation rate. In terrestrial environments, aqueous oxidation of sulfides leads to pH values as low as −2 (Nordstrom et al., 2000). On Mars, mineral precipitation in acidic near-surface aqueous environments is consistent with MER observations at Meridiani Planum and Gusev crater (Clark et al., 2005; Haskin et al., 2005; Ming et al., 2006; Morris et al., 2008). In particular, the detection of jarosite (a complex Fe^{3+} sulfate), in layered rocks at Meridiani, indicates low-pH, oxidizing conditions at the time of mineral formation (Klingelhöfer et al., 2004). The presence of jarosite shows that limited amounts of solution did not neutralize before evaporating and/or freezing. In other locations, surface aqueous processes could have occurred at higher water/rock ratios and led to complete neutralization, consistent with the detection of Fe–Mg phyllosilicates in Noachian deposits (Ehlmann et al., 2011; Murchie et al., 2009; Poulet et al., 2005). The composition of these phyllosilicates indicates their formation in reduced enthronements. The lack of atmospheric oxidants could have caused subsurface solutions to be reduced and alkaline in composition.

The scale of aqueous oxidation on Mars could have been limited by the mass and production rate of atmospheric oxidants. Periods of intensive volcanism may have been characterized by low concentrations of oxidants owing to their interaction with reduced volcanic gases. Although strong impacts could have generated an array of strong oxidants (see **Section 10.12.3.8**), the limited oxidation of surface materials is consistent with the widespread occurrence of olivine and Fe^{2+}-bearing pyroxenes in soils and exposed igneous rocks (e.g., Hoefen et al., 2003; Klingelhöfer et al., 2004; McSween et al., 2008, 2010; Mustard et al., 2005; Vaniman et al., 2014). Spectral and chemical observations of rock fragments and red-colored magnetite-rich dust collected on MER magnets (Goetz et al., 2005) imply that the formation of ferric oxides affected only the surfaces of mineral grains and rock fragments.

During periods characterized by a reducing but warm atmosphere, surface oxidation could have occurred by water via reactions [3] and [8]. The escape of H_2 produced through dissociation of H_2O would have contributed to net oxidation. Deep below the Martian surface, oxidation by liquid water may have occurred over Mars' history. Slow interaction of H_2 with dissolved carbonate species (HCO_3^- and CO_3^{2-}) can account for the formation of simple organic species.

10.12.3.2 Reactions with Sulfur Gases

Sulfur-bearing species are abundant in the Martian soil, rock coatings, and sedimentary deposits, as well as in Venus' rocks in which S was analyzed (**Tables 2** and **3**). In all cases, the S content does not correlate with rock composition, consistent with a secondary origin of sulfur. Despite the elevated S content, only a fraction of metals (Ca, Mg, and Fe) are bonded to sulfur, indicating incomplete alteration of surface rocks with respect to sulfur.

Although the mineralogy of S-bearing phases remains to be determined for many of Mars' and all of Venus' rocks, sulfates are the most likely secondary minerals. On Mars, the presence of sulfates is inferred from correlations with Mg (e.g., Bell et al., 2000; Clark et al., 1982, 2005), from infrared and Mössbauer observations by MER (e.g., Glotch et al., 2006; Klingelhöfer et al., 2004; Morris et al., 2006, 2008; Squyres et al., 2012), and from near-infrared spectra from the Martian orbiters (e.g., Gendrin et al., 2005; Langevin et al., 2005; Murchie et al., 2009; Roach et al., 2010). These data are consistent with the presence of Mg sulfates with various degrees of hydration (e.g., kieserite, $MgSO_4 \cdot H_2O$, and epsomite, $MgSO_4 \cdot 7H_2O$), gypsum

($CaSO_4 \cdot 2H_2O$), and ferric sulfates. Gypsum is present in some Martian meteorites (Bridges et al., 2001). Several other sulfates may be present as well.

On Venus, thermodynamic instability of rock-forming calcium silicates (plagioclases and pyroxenes) with respect to atmospheric SO_2 (**Table 1**) should drive the formation of anhydrite ($CaSO_4$) (Barsukov et al., 1982; Fegley and Treiman, 1992; Volkov et al., 1986). The formation of sulfates in O_2-free conditions can occur through disproportionation of SO_2 via gas–solid-type reactions

$$Ca_2Si_2O_6(\text{in pyroxene}) + 3SO_2 \rightarrow 2CaSO_4 + 2SiO_2 + 0.5S_2 \quad [11]$$

$$CaAl_2Si_2O_8(\text{in plagioclase}) + 1.5SO_2 \rightarrow CaSO_4 + 2SiO_2 + Al_2O_3 + 0.25S_2 \quad [12]$$

Alternatively or additionally, oxidation of S^{4+} (in SO_2) to S^{6+} (in sulfate) by atmospheric CO_2 (e.g., Fegley and Treiman, 1992) or H_2O may form $CaSO_4$, releasing CO or H_2, respectively. Although the presence of anhydrite in Venus' rocks has not been confirmed, conversion of diopside ($CaMgSi_2O_6$) to $CaSO_4$ has been observed in experiments at a temperature of 1106 K (Fegley and Prinn, 1989).

Despite a strong thermodynamic drive for anhydrite formation, the composition of Venus' rocks (**Table 2**) indicates incomplete sulfurization of Ca silicates (**Figure 6**). It can be seen that Venera 14 rocks are less altered with respect to S consumption. This is consistent with reduced physical weathering relative to Venera 13 rocks (Basilevsky et al., 1985; Garvin et al., 1984), which suggests younger rocks at the Venera 14 landing site. However, the timescale of SO_2 removal from the atmosphere is not known. It is not clear if current or recent volcanism is needed to replenish atmospheric SO_2.

In addition to sulfates, surface materials on both planets may contain secondary sulfides formed at the surface. On Mars, cooling of H_2S-rich hydrothermal fluids may cause precipitation of pyrite, as happens on Earth in oceanic 'black smokers.' Rare occurrences of liquid water at the surface and limited oxidants could have restricted subsequent oxidation of pyrite to ferric oxides and sulfates. In other words, both primary and secondary sulfides may be present in Martian surface materials, consistent with recent Curiosity data (McAdam et al., 2014; Vaniman et al., 2014). Likewise, thermodynamically unstable olivine, Fe–Mg pyroxenes, and magnetite are present in Martian soils and dust (Goetz et al., 2005; Hoefen et al., 2003; Klingelhöfer et al., 2004; McSween et al., 2010; Morris et al., 2006, 2008; Mustard et al., 2005).

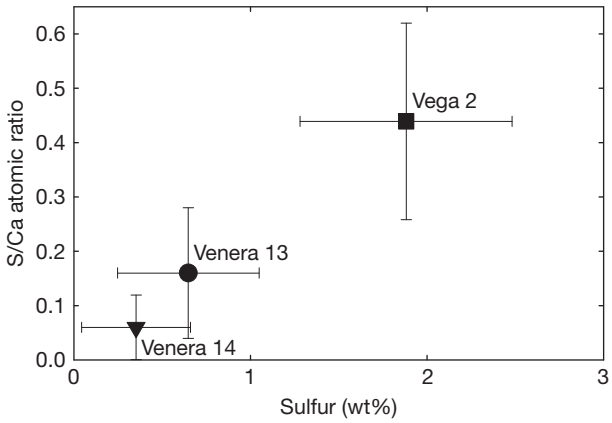

Figure 6 Sulfur content in Venus' rocks plotted against the S/Ca ratio. The S/Ca ratio in rocks is less than that in anhydrite (unity), indicating incomplete sulfurization of Ca-bearing minerals. Data are from Surkov et al. (1984, 1986).

On Venus, the instability of pyrrhotite and troilite with respect to oxidation (see **Section 10.12.3.1**) does not exclude the occurrence of pyrite, which can stably coexist with magnetite and hematite at the conditions of plains (**Figure 5**). The evaluations of mineral stability are limited by the uncertainties of thermodynamic data for gas and solid phases, impure solid phases, and uncertainties in the composition of the near-surface atmosphere. These factors led to controversial conclusions about pyrite stability on Venus (e.g., Barsukov et al., 1982; Fegley and Treiman, 1992; Fegley et al., 1997a; Klose et al., 1992; Wood, 1997).

Excess sulfur in surface materials on Venus and Mars likely has a volcanic source. On Mars, sulfur outgassing is consistent with the isotopic composition of S in Martian meteorites, which reveals photochemistry-driven mass-independent fractionation of sulfur in the atmosphere (Farquhar et al., 2000). On Venus, a volcanic origin of sulfur agrees with widespread volcanic features and elevated abundances of sulfur gases in the atmosphere. On both planets, volcanic and impact processes could have recycled sulfur through atmosphere and crustal reservoirs.

On Venus and Mars, the photochemical oxidation of sulfur gases produces sulfuric acid aerosols. In the sulfur-rich Venusian atmosphere, constantly produced aerosols form clouds at an altitude of 48–60 km that do not affect the surface (Esposito et al., 1997; Von Zahn et al., 1983). On Mars, sulfuric acid aerosols form after volcanic eruptions (Settle, 1979; Tian et al., 2010) and impact cratering (see **Section 10.12.3.8**). The negligible amounts of S-bearing gases in the present atmosphere (**Table 1**) suggest that they were consumed by weathering processes that followed the last volcanic or impact event. The deposition of sulfate aerosols leads to their neutralization through mineral alteration. As a result, sulfates form on the surfaces of mineral grains and rock fragments. In addition to sulfates, acid weathering by volcanic/impact aerosols on Mars would cause the deposition of silica and ferric oxides. Indeed, Fe^{3+}-rich coatings, likely nanophase oxides/oxyhydroxides, are ubiquitous on Martian surface materials (e.g., Goetz et al., 2005; Morris et al., 2006, 2008). Silica coatings/deposits have been suggested from orbital thermal infrared and near-infrared spectra (e.g., Michalski et al., 2005; Milliken et al., 2008; Roach et al., 2010) and detected by in situ investigations in Gusev crater (Ruff et al., 2011). The trapping of precipitated sulfuric acid aerosols in surface ices would have prevented the evaporation of aerosols and led to the acid-sulfate weathering of underlying rocks (Zolotov and Mironenko, 2007). The acid weathering of mineral dust in ices could have led to the formation of layered sulfate-rich rocks observed at the Meridiani Planum and other places (Niles and Michalski, 2009).

Although thermodynamics favor mineral weathering by sulfur gases under cold and dry Martian conditions (Gooding, 1978; Gooding et al., 1992), most proposed reactions remain poorly explored. Modeling experiments (Clark et al., 1979) indicate that conversions of carbonates and nitrates (if they are present) to corresponding sulfates are the

most likely pathways of interaction of gaseous sulfur oxides with surface minerals. However, low-temperature conversion of silicates to sulfates could be inhibited without aqueous phase.

10.12.3.3 Reactions with H_2O

Water vapor exists in the atmospheres of Mars and Venus (**Table 1**) and can interact with surface materials. On Mars, water condenses as ice, adsorbs on surface materials, and chemically bonds to minerals. On Venus, water vapor cannot condense anywhere near the surface and could be consumed via surface oxidation (e.g., reactions [3] and [8]) rather than through the formation of OH-bearing minerals. On both planets, early atmospheres could have contained a higher abundance of water (Donahue et al., 1997; Lammer et al., 2008; Owen, 1992), causing competitive hydration and oxidation of surface materials. Low-temperature conditions at elevation would have favored hydration and restricted dehydration. Many minerals may have lost water during subsequent evolution.

On Mars, the occurrence of water ice and hydrated minerals is controlled by their thermodynamic stability and kinetics of hydration and dehydration. Stabilities of ice and hydrated minerals on the surface vary with latitude and season. Ice and highly hydrated minerals (e.g., meridianite, $MgSO_4 \cdot 11H_2O$; antarcticite, $CaCl_2 \cdot 6H_2O$; and gypsum) are stable at high latitudes and during winter in midlatitudes. Elevated abundances of ground hydrogen at latitudes greater than ~40° inferred with neutron spectrometry from orbit (Boynton et al., 2002; Feldman et al., 2004; Mitrofanov et al., 2004) agree with thermodynamic models of ice stability (e.g., Mellon and Jakosky, 1995) and surface morphology features. Hydrated minerals may contribute to the high abundance of subsurface hydrogen (in ice + hydrates) at high latitudes. High H concentrations in some large equatorial regions (e.g., Arabia) are inconsistent with thermodynamic models of the latitudinal distribution of ice and hydrates. It is possible that highly hydrated minerals formed at low latitudes during periods of high obliquity (Kieffer and Zent, 1992) and have not dehydrated to minerals stable under current climatic conditions (Feldman et al., 2004). Slow dehydration of epsomite, $MgSO_4 \cdot 7H_2O$, and/or starkeyite, $MgSO_4 \cdot 4H_2O$ (e.g., Steiger et al., 2011; Wang et al., 2011), provides an explanation.

At Venus' surface, all hydrated minerals and the majority of OH-bearing minerals are unstable (Zolotov et al., 1997). Only some micas (e.g., phlogopite, $KMg_3Al_3Si_2O_{10}(OH,F)_2$) may be stable, especially at elevation. Partial substitution of the OH group by F favors phlogopite stability. Despite its stability, OH–F phlogopite formation requires transport of metals from different minerals, which is unlikely at present surface conditions. If micas and amphiboles were supplied from interior, they could survive at the current surface owing to slow dehydration (Johnson and Fegley, 2003, 2005). However, dehydration may have occurred at elevated atmospheric greenhouse temperatures caused by global volcanism 0.4 ± 0.1 Ga.

On both planets, the loss of water from the atmosphere in oxidation processes and H_2 escape could be compensated by internal processes. On Mars, polar caps, ground ice, and hydrated minerals are the major near-surface water reservoirs. Magmatic H_2O degassing could have played a role in earlier epochs. On Venus, atmospheric water could be resupplied via diffusion of H_2O and H_2 gases from nominally anhydrous minerals, which may account for the majority H_2O inventory (Zolotov et al., 1997). Volcanic degassing on Venus may not be an important source of atmospheric water because of suppressed explosive activity (Head and Wilson, 1986), a low abundance of H_2O in magmas, and its high solubility.

10.12.3.4 Reactions with CO_2

Carbon dioxide is the most abundant gas in the atmospheres of Mars and Venus that significantly affects mineral–gas interactions. On Venus, the massive CO_2 atmosphere accounts for the high surface pressure and temperature (see **Table 1**) and could be the major gas oxidizing surface materials (reactions [1] and [6]). On Mars, seasonal condensation and sublimation of CO_2 in polar regions are responsible for the annual cycle of atmospheric pressure (James et al., 1992). The presence of carbonates in Martian igneous rocks (meteorites), soils, and sedimentary deposits reveals the fixation of atmospheric CO_2 in the crust (e.g., Boynton et al., 2009; Ehlmann et al., 2008; Leshin et al., 2013; Morris et al., 2010).

At present conditions, a significant chemical fixation of CO_2 in carbonates is unlikely on both planets. Experimental data demonstrate that carbonatization of silicates is favored under aqueous conditions (Tanner et al., 1985), which are absent at current surfaces. Although the formation of Martian carbonates on irradiated surfaces has been predicted in theoretical models (Huguenin, 1974, 1976), an experimental work (Mukhin et al., 1996) reveals the possibility of photostimulated decomposition of carbonates. Booth and Kieffer (1978) experimentally demonstrated the formation of only traces of carbonates during the interaction of Ca silicates with CO_2 under Martian temperatures with or without mild irradiation. It follows that carbonates observed in Martian materials could have formed in aqueous environments.

Although low totals in Venus' surface analysis (**Table 2**) may reveal the presence of carbonates (Fegley et al., 1997a), the formation of calcite ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$) is forbidden because of their thermodynamic instability with respect to high fugacity of atmospheric SO_2 (e.g., Fegley and Treiman, 1992; Volkov et al., 1986), which would destroy them rapidly (Fegley and Prinn, 1989). If indigenously formed calcite is present on Venus' surface, the conversion of calcite to anhydrite may occur via net reaction

$$CaCO_3 + 1.5SO_2 \rightarrow CaSO_4 + CO_2 + 0.25S_2 \qquad [13]$$

which was studied by Terradellas and Bonnetain (1973), and would result in rapid destruction of calcite at Venus' surface temperature. Siderite ($FeCO_3$) is unstable with respect to oxidation to ferric oxides. On the Martian surface, Ca carbonates could be attacked by SO_2, SO_3 (Clark et al., 1979; Gooding et al., 1992), acidic aerosols and rains of volcanic/impact origin, and other low-pH fluids, as illustrated by the reactions

$$CaCO_3 + SO_2 + 0.5O_2 \rightarrow CaSO_4 + CO_2 \qquad [14]$$

$$CaCO_3 + 2H^+ + SO_4^{2-} + H_2O \rightarrow CaSO_4 \cdot 2H_2O + CO_2 \quad [15]$$

$$CaCO_3 + 2H^+ + 2Cl^- + 5H_2O \rightarrow CaCl_2 \cdot 6H_2O + CO_2 \quad [16]$$

Magnesite ($MgCO_3$) is the only rock-forming carbonate stable with respect to SO_2 on the surfaces of Venus and Mars. Its occurrence at Venus' surface is unlikely because of thermodynamic and kinetic problems for its formation at present conditions. On Mars, a detection of Mg-rich carbonates in some surface materials (Ehlmann et al., 2008; Morris et al., 2010) and possibly in atmospheric dust (Bandfield et al., 2003) and soils (Leshin et al., 2013) may in part reflect their relative stability with respect to S oxides and sulfuric acid solutions.

The rapid destruction of calcite and dolomite compared to slow, if any, carbonatization of surface materials implies a likely absence of carbonates at the surface of Venus. An exposure of ancient sedimentary carbonates is not consistent with basaltic lava morphology of Venus' plains, and long sinuous channels (Baker et al., 1997) could have been formed by molten chlorides (see **Section 10.12.3.5**) rather than low-viscosity carbonate magmas. The paucity of carbonates on Venus agrees with the fact that there are similar masses of CO_2 in Venus' atmosphere and Earth's carbonates (**Table 4**). It follows that a popular idea of buffering atmospheric CO_2 by the Urey (1952) carbonate–silicate equilibrium,

$$CaCO_3 + SiO_2 \rightarrow CaSiO_3 + CO_2 \quad [17]$$

(e.g., Adamchik and Draper, 1963; Fegley and Treiman, 1992; Lewis, 1970; Mueller, 1964), may be invalid despite the fact that the equilibrium PCO_2 in reaction [17] at 740 K is similar to the PCO_2 at Venus' surface. In addition, equilibrium [17] could be unstable with respect to variations in atmospheric temperature and/or pressure [Hashimoto et al., 1997; Treiman and Bullock, 2011]. However, a possibility for equilibrium [17] may exist below the surface (see **Section 10.12.5**).

On Mars, secondary carbonates in crustal igneous rocks and sedimentary deposits may account for the major reservoir of CO_2 formed in aqueous conditions. It is possible that carbonates were deposited in a primordial ocean on Venus, if it ever existed. Subsequent volcanic and impact degassing of chemically active gases would have led to chemical weathering of surface carbonates on both planets. Sulfates and chlorides are the likely minerals formed after carbonates (reactions [13]–[16]). On Mars, subsurface carbonates may not be much affected, except for local dissolution by acidic fluids of near-surface origin. On Venus, early formed carbonates (if they formed) could be partially/completely decomposed, contributing to greenhouse heating from a thickening atmosphere (see **Section 10.12.5**).

10.12.3.5 Reactions with Halogen-Bearing Species

Halogens are delivered into planetary atmospheres through magmatic and impact degassing. On Earth (Oppenheimer, 2003; Symonds et al., 1994) and Mars, they degas as hydrogen halides (HCl and HF) and SiF_4. On Venus, hydrogen-depleted magmas can emit diatomic halides, S- and S–O-halides, and SiF_4. The low abundances of Cl- and F-bearing gases in the atmospheres of Mars and Venus (**Table 1**) imply that degassed halogens have been consumed by surface materials. It is likely that planetary crusts are enriched in previously degassed halogens that are mainly stored in metal halides (e.g., NaCl, KCl, $CaCl_2$, and $MgCl_2$) and halogen-bearing salts (e.g., apatite). Chlorides could be the most abundant halogen compounds owing to the higher solar abundance of Cl compared with other halogens. In addition, significant quantities of fluorine could be preserved in igneous rocks, especially those with elevated alkali content (Venera 8 and Venera 13 landing sites and Columbia Hills basalts). On both planets, heating of surfaces and crusts could have caused the mobilization, redistribution, and recycling of halogens. These processes may include magmatic/impact degassing, assimilation in magma chambers, melting and release of halogen-bearing salts as well as aqueous activity, and brine formation and evaporation.

Martian surface materials are characterized by elevated and variable Cl and Br contents compared to basaltic rocks. The incorporation of degassed halogens in the soil could have occurred through precipitation of volcanic/impact aerosols, dissolution in aqueous solutions, and gas–mineral-type reactions. The hydrolysis of hydrogen halides produces acidic solutions that dissolve surface minerals followed by precipitation of halides of Ca, Mg, Na, K, and Fe upon freezing or evaporation. Weathering of rocks by acid gases, aerosols, acid rains, and surface solutions would convert primary and secondary minerals to corresponding halides. These transformations can be illustrated by reactions [16] and [18]:

$$Ca_2Si_2O_6(\text{in pyroxene}) + 4HCl(\text{gas, aerosol, solute}) \rightarrow 2CaCl_2 \cdot 2H_2O + 2SiO_2 \quad [18]$$

Throughout Martian history, these highly water-soluble salts were probably mobilized and redeposited by sporadic aqueous solutions, consistent with the occurrence of chloride-rich deposits in Martian highlands (Osterloo et al., 2010). At present, deep crustal brines are most likely enriched in Cl and Br, which lower the freezing temperature (Burt and Knauth, 2002). Variable S/Cl/Br ratios in layered deposits at Meridiani Planum are consistent with element separation in aqueous processes (Clark et al., 2005; Marion et al., 2009). Surface materials also contain perchlorates likely formed through photochemical oxidation of chlorides in the atmosphere and/or at the surface (Catling et al., 2010; Leshin et al., 2013).

Hydrogen halides (HCl and HF) are present in trace amounts in Venus' atmosphere (**Table 1**). These gases could have originated from hydrolysis of H-free volcanic gases (e.g., Cl_2, SCl_2, and SiF_4) and halogen-bearing surface materials (apatite and glasses). In turn, their interactions with primary and secondary minerals would lead to the formation of halogen salts. Although halogens have not been analyzed in Venus' rocks, the high upper limits of Cl (**Table 2**) do not exclude elevated abundances of halogens.

It is possible that atmospheric abundances of HCl and HF reflect chemical equilibria among these gases and secondary minerals at the surface (Fegley and Treiman, 1992; Lewis, 1970; Mueller, 1968). The low masses of atmospheric halogens (**Table 4**) compared with possible masses of halogens in a permeable surface layer imply that the atmospheric abundances of halogens are controlled by surface mineralogy.

Atmospheric masses of Cl and F can be consumed in global layers 22 and 0.15 cm thick, respectively (at 0.1 wt% of Cl and F). A comparison of the mass of Cl in Venus' atmosphere with that in terrestrial oceans and sediments (**Table 4**) suggests a comparable reservoir of halogens in Venus' crust (Fegley and Treiman, 1992; Zolotov and Volkov, 1992).

Venus' halides could have been mobilized in the crust because of their low melting points compared to silicates. Channels (Baker et al., 1997) and crater outflows observed in Magellan radar images may have been formed by molten halides. Some halides could have accumulated in the crust through evaporation of putative early ocean. It is possible that eutectic melts of halogen salts currently exist in Venus' crust. Likewise, Cl–Br–Ca–Mg–Na–(SO_4) eutectic aqueous brines may be present deep below the Martian surface.

10.12.3.6 Condensation of Metal and Nonmetal Species: The Role of Altitude

Volcanism, impacts, gas–solid-type weathering, and thermal rock outgassing delivered many elements into planetary atmospheres before they condensed. Terrestrial silicate volcanism degasses many metals (e.g., Na, K, Bi, Hg, Pb, Cu, Zn, Cd, and Sb) and nonmetals (B, Se, and As) (Oppenheimer, 2003). On Venus and Mars, volcanic sources of S in surface materials may imply elevated abundances of Se, Te, As, and volatile metals.

A sizeable temperature gradient between Venus' plains (730–750 K) and mountaintops (650–700 K) should cause preferential condensation of heavy elements in elevated regions. Thermodynamic calculations demonstrate that sulfides, sulfosalts, halides, and chalcogenides of Pb, Bi, As, Cu, and Sb may condense on mountaintops and account for the high dielectric constant (Brackett et al., 1995; Schaefer and Fegley, 2004). Lower temperatures at elevation lead to lower rates of chemical weathering and would favor longer preservation of locally unstable phases. It follows that some metal/sulfide condensates may be unstable with respect to gas–solid weathering reactions.

10.12.3.7 Kinetic Aspects of Surface–Gas-Type Reactions

Gas–solid-type reactions affect individual mineral grains that are subjected to isochemical weathering. As a result, alteration products should consist of mechanical mixtures of minerals formed through weathering of primary phases. Because weathering products form at the surface of mineral grains, smaller particles are subjected to more alteration and secondary particles are smaller than initial grains. In many cases, weathering is controlled by diffusion of reacting gases through a layer of alteration products. Physical removal of alteration products from mineral surfaces would increase the rate of chemical weathering. It follows that small particles could be most chemically altered, consistent with observations on Mars (e.g., Yen et al., 2005) and Venus (Shkuratov et al., 1987). Despite wind abrasion and thermodynamic potential for weathering reactions at planetary surfaces, many gas–mineral-type interactions are inefficient because of slow reaction rates, especially at the diffusion-controlled stage. As a result, significant portions of surface rocks and fine-grained materials on Mars and Venus remain chemically unaltered.

On Venus, kinetic parameters of key oxidation reactions [1]–[3], [6]–[8] and sulfurization reactions [11] and [12] remain unknown. Although rapid formation of anhydrite through SO_2–calcite interaction is evident from many experiments (e.g., Fegley and Prinn, 1989; Terradellas and Bonnetain, 1973), this reaction may not be relevant to the present-day Venus' surface (see **Section 10.12.3.4**).

On Mars, rates and mechanisms of gas–solid weathering processes remain poorly explored, partially because of low reaction rates at subzero temperatures and low densities of atmospheric gases. The formation and reactivity of carbonates through gas–solid reactions (Booth and Kieffer, 1978; Mukhin et al., 1996) remain to be confirmed, including the effects of irradiation and gas diffusion through reaction products. The study of photostimulated oxidation, hydration (e.g., Huguenin, 1973a,b, 1974, 1976, 1982; Morris and Lauer, 1980), and dehydration (Morris and Lauer, 1981; Yen et al., 1999) could be revisited. Despite modeling experiments by Clark et al. (1979), kinetic parameters of low-temperature weathering by sulfur and hydrogen halide gases remain unknown. Recent experimental investigations of hydration and dehydration of sulfates could be used to evaluate timing of H_2O exchange between the atmosphere and hydrated salts (e.g., Steiger et al., 2011; Wang et al., 2011).

10.12.3.8 Local Reactions Caused by Impacts and Volcanic Eruptions

Impacts and volcanic eruptions create highly variable local environments in which chemical transformations are governed by mass transfer and reaction rates. In impact events, thermal dissociation of species leads to chemically contrasting gas mixtures (e.g., H_2, O_2, CO, CO_2, SO_3, and nitrogen oxides) that affect local and global atmospheric environments (e.g., Kawaragi et al., 2009; Pope et al., 1997; Prinn and Fegley, 1987; Toon et al., 1997). Reactions in volcanic/impact sites can include the oxidation of ferrous iron and sulfides, reduction of iron to Fe^0 metal at $T > 1500$ K, dehydration and hydration of minerals, thermal decomposition of carbonates, and conversion of carbonates to sulfates. On Earth, oxidation by volcanic gases mixed with air often leads to hematite-bearing pumice with a reddish color. On Mars and Venus, high-temperature oxidation by H_2O and/or CO_2 in impact/volcanic gases could have contributed to the formation of sulfates and ferric oxides in soil and dust. Although hot CO_2 could be the major oxidizing agent on Venus (Fegley et al., 1995), impacts of comets and carbonaceous chondrites may cause some oxidation by H_2O. On both planets, hematite could have formed via oxidation in impact/volcanic events.

On Mars, slow cooling of lavas and impact melts from inefficient convection and low atmospheric density allowed a great degree of chemical alteration of melts and hot rocks. However, the low PO_2 in the atmosphere, especially during periods of volcanic activity, would not have favored rapid oxidation of hot surface materials. On Venus, rapid cooling of silicate melts at the contact with the dense atmosphere (Frenkel and Zabalueva, 1983) could have been compensated by the high densities of chemically active gases (CO_2 and SO_2).

On Mars, volcanic/impact melting of ice-rich deposits could have led to local hydration, especially in fluidized

outflow deposits. Materials in Martian surge deposits could have been modified (oxidized, hydrated, and weathered) shortly after deposition (Knauth et al., 2005). On Venus, an impact-generated layered material suggested at Venera landing sites (e.g., Basilevsky et al., 2004) may be composed of materials that were altered by impact events. The presence of chemically distinct fine-grained material in parabolic crater ejecta deposits is consistent with their elevated dielectric constant (up to eight) (Campbell et al., 1992; Pettengill et al., 1997).

On Earth, Mars, and Venus, impact/volcanic degassing of sulfur-rich rocks would lead to an array of sulfur species and could affect global atmospheric composition. The impact decomposition of crustal sulfates during the Chicxulub event at the Cretaceous–Tertiary boundary released sulfur oxides into the atmosphere followed by downpours of acid rain (Gupta et al., 2001; Pope et al., 1997). On sulfate-rich Mars, raining from impact-generated clouds (Segura et al., 2002, 2012) could be responsible for observed signs of acid-sulfate weathering (Zolotov and Mironenko, 2007). The thermal decomposition of carbonates during impacts and/or their interaction with released sulfur oxides and acid aerosols/rainfalls would have altered and/or obliterated surface carbonates on Mars. On Venus, impact/volcanic release of sulfur gases would temporarily affect the mass of sulfuric acid clouds.

10.12.4 Wind-Related Processes

Eolian processes provide the major mechanism for mass transfer on contemporary surfaces of Mars and Venus (Greeley and Iversen, 1985). Both erosional (yardangs) and depositional (dunes) features are observed (Greeley et al., 1992, 1997). On Mars, dust devils and global dust storms are widely observed from orbit and the surface (Balme and Greeley, 2006). On both planets, the orientation of eolian features is consistent with general circulation models.

The effectiveness of eolian transport depends on air density, temperature, and gravity, which are significantly different on Mars and Venus (Greeley et al., 1992, 1997). Nevertheless, models and experiments demonstrate that particles that are a few hundred microns in diameter can be transported on both planets. Particles with a diameter of 100 μm represent the most mobile fractions (Greeley et al., 1980, 1992, 1997). Larger and smaller particles require stronger winds to be transported.

On Mars, low gravity and high wind velocity overcome the effects of low air density and cause significant eolian transport. Dust with grain sizes of a few microns is homogenized in the atmosphere on a planetary scale. Globally, deflation characterizes some low-albedo regions and accumulation is typical in high-albedo regions. Larger particles (up to perhaps a centimeter in diameter) are transported by saltation and creep, forming areas dominated by deflation and accumulation. Martian polar deposits (Thomas et al., 1992) and layered rocks with cross-beddings investigated by MER (e.g., Grotzinger et al., 2005) indicate a substantial eolian transport and accumulation throughout history.

On Venus, measurements of wind speed near the surface (<2 m s^{-1}, Ksanfomality et al., 1993), extrapolation of wind velocities to the surface (0.5–1 m s^{-1}, Counselman et al., 1979), and wind tunnel experiments (Greeley et al., 1987) suggest the possibility of present-day eolian activity of Venus. This is consistent with the observation of wind-related features (mostly wind streaks) in Magellan radar images (Greeley et al., 1997). Fine-grained material is mainly supplied from impact cratering and chemical weathering. The apparent paucity of dunes on Venus could be related to a lack of sand-size particles.

The orientation of Venusian wind features indicates the upper altitude superrotation of the atmosphere and the extension of Hadley circulation to the surface (Greeley et al., 1997). Wind transport is consistent with the presence of parabola-shaped zones of low radar backscatter around the relatively fresh impact craters. Models show that wind activity would disperse the inferred fine-grained materials in the parabolas over a few tens of millions years.

Without aqueous solutions, physical weathering of surface rocks is mostly restricted to wind abrasion and rock disintegration caused by chemical weathering of individual grains. Despite vivid signs of eolian activity, the estimated rates of eolian erosion are small on both planets. On Mars, an erosion rate of ~0.03 nm year^{-1} indicates slight surface changes since the Hesperian epoch (~3 Ga) (Golombek et al., 2006). Modeling experiments demonstrate the possibility of rock abrasion even for moderate wind velocities (0.5–0.7 m s^{-1}) at the surface of Venus (Greeley et al., 1987). Despite these results, volcanic features remain well preserved (Crumpler et al., 1997). In particular, during the Magellan mission, no surface changes were observed that could be attributed to eolian processes.

10.12.5 Atmosphere–Surface Interactions Throughout History

Although gas–solid-type interactions prevailed over the majority of planetary histories, the effectiveness of these interactions varied over time along with changes in surface temperatures and atmospheric compositions. On Mars and Venus, significant atmosphere–surface interaction could have occurred earlier in history under wetter conditions and different temperatures, as well as through multiple episodes of volcanic eruptions and impacts.

Elevated D/H ratios in the current atmospheres of Mars ($7.8 \pm 0.3 \times 10^{-4}$) and Venus ($2.4 \pm 0.5 \times 10^{-2}$) compared to the Earth's oceanic value (1.56×10^{-4}) indicate more humid conditions in their earlier atmospheres, which deteriorated by the escape of H (Donahue et al., 1997; Krasnopolsky and Feldman, 2001; Owen, 1992). On Mars, a low $^{14}N/^{15}N$ ratio in the atmosphere (170×15; Owen, 1992) compared to the Earth's value (272) implies gas escape from a denser early atmosphere. Despite a low solar luminosity, the greenhouse effect in denser and/or more humid atmospheres could have produced elevated surface temperatures on Mars and Venus. However, that cloud condensation should have affected gas abundances (e.g., CO_2 condensation on Mars, Kasting (1991)) and surface temperatures through albedo changes (Hashimoto and Abe, 2001).

The oxidation of ferrous minerals and sulfides by water (reactions [3] and [8]) and H_2 production is a likely process on early planets (Lewis and Prinn, 1984; Wänke and Dreibus, 1987). H_2 escape contributes to net oxidation of surfaces and

atmospheres. The high oxidation state of most Martian meteorites is consistent with early oxidation of the lithosphere by H_2O.

Hydration of surface material is another likely process on early planets. On Mars, somewhat warmer and wetter conditions during the Noachian epoch are supported by the presence of phyllosilicates (Carter et al., 2013; Ehlmann et al., 2011; Murchie et al., 2009; Poulet et al., 2005), valley networks (Carr, 1996), and heavily eroded terrains (Craddock and Howard, 2002). On Venus, the evolution of the greenhouse effect is poorly constrained and early hydration remains conjectured. The majority of hydrated phases would have been dehydrated during subsequent evolution, especially during increases in surface temperatures.

Humid conditions in the early atmospheres would have favored the fixation of atmospheric CO_2 in carbonates. On Mars, the formation of carbonates in aqueous environments provides a major pathway to diminish an early CO_2 atmosphere. On Venus, carbonates could have been deposited in a primordial ocean, if one ever existed. Subsequent metamorphic reactions in the lithosphere could have led to the establishment of carbonate–silicate equilibria below the surface. Such a mechanism might be consistent with a buffering atmospheric CO_2 by equilibrium [17]. Calcium-bearing minerals below the surface should be protected from atmospheric SO_2, HCl, and HF. These gases could be consumed through weathering in upper subsurface layers and may not reach putative carbonate-bearing rocks at depth.

Throughout the geologic histories of Mars and Venus, volcanic activity and impact events would have affected atmospheric composition and surface temperature (Fanale et al., 1992). In particular, injection of water and CO_2 into the atmosphere would have increased the surface temperature through greenhouse heating. On Mars, elevated temperatures would have led to further supplies of H_2O and CO_2 from polar caps and crustal reservoirs, which may have stabilized liquid water on the surface.

On Venus, intensive volcanism 0.4 ± 0.1 Ga ago (Basilevsky et al., 1997) would have been accompanied by IR-absorbing volcanic gases and a corresponding increase in surface temperature. Even a small fraction of water vapor in the products of volcanic degassing would have led to significant rising of atmospheric and lithospheric temperature. The temperature rise would have facilitated partial melting of igneous rocks and softening of the lithosphere and triggered further volcanism (Solomon et al., 1999). High-temperature reactions of atmospheric gases with hot surface materials could have led to significant alteration of surface rocks. In particular, degassed SO_2 and halogens could have been partially consumed by surface materials. Volcanically released H_2O would have been consumed by high-temperature oxidation of rocks (reactions [3] and [8]). It is possible that most chemical alterations currently observed on the surface occurred during the short but intense period of volcanic activity. Since the resurfacing event, abundances of minor atmospheric gases and the redox state may have been controlled by gas–mineral reactions. Changes in surface temperature altered the partial pressures of gases in gas–mineral-type reactions. For example, the oxidation state of the atmosphere and abundances of S-bearing gases could have been controlled by surface reactions that involve magnetite, hematite, and pyrite.

10.12.6 Summary and Unsolved Questions

Despite significant differences in environmental conditions on Mars and Venus, atmosphere–surface interactions reveal several common features. On both planets, atmospheric gases have oxidized surface materials. The dissociation of H_2O and hydrogen escape from early atmospheres could have caused partial oxidation of crustal materials. Although early atmospheric conditions could have favored the formation of carbonates and hydrated minerals, current environments may not be feasible for carbonate formation. Throughout history, volcanic/impact degassing was followed by consumption of sulfur and halogens into surface materials through weathering reactions. On both planets, volcanic/impact degassing, surface temperature, and gas–mineral reactions are interrelated through the greenhouse heating and cloud feedbacks.

Specifics of atmosphere–surface interaction on Mars include (1) seasonal cycles of condensation and sublimation of H_2O and CO_2, (2) possible seasonal hydration and dehydration of some salts, (3) atmosphere–surface redistribution of H_2O and CO_2 and hydration and dehydration of minerals during obliquity cycles, (4) low-temperature inhibition of a majority of thermochemical chemical reactions at the present surface, (5) suppressed crystallization of amorphous materials, (6) a possible contribution of photostimulated reactions involving minerals and organic compounds, (7) a possible liquid water–rock reactions below the surface, and (8) potential formation of the majority of secondary minerals by participation of aqueous solutions earlier in its history.

Venus' specifics include (1) oxidation and sulfurization of surface rocks through gas–solid-type reactions, (2) isochemical weathering of individual solid phases with respect to nonvolatile elements at Venus' surface temperature (e.g., Al, Si, Mg, Fe, Ca, and Na), (3) unlikely current hydration and a possibility of dehydration of early formed phases, (4) the possibility of gas–gas and gas–mineral equilibria at the atmosphere–surface interface that determine the oxidation state and sulfur and halogen contents in the atmosphere, (5) a strong altitudinal effect for chemistry and physics of gas–surface interactions, (6) chemical weathering of minerals by unequilibrated atmospheric gases at elevations, (7) possible condensation of heavy metal compounds on mountaintops, and (8) the possibility for efficient gas–mineral-type reactions during intensive global volcanism.

A few of unsolved questions are the following: Under what environmental conditions were planetary surface materials oxidized and enriched in volatiles? What is the contribution of gas–mineral-type reactions to the composition of planetary surfaces? How have gas–mineral interactions changed over planetary history? What is the effect of irradiation on mineralogical transformations on the Martian surface? What are the abundances of C, halogens, and H in surface rocks on Venus? Do Venus' atmospheric gases equilibrate with each other and surface minerals? Which atmospheric gases are controlled by atmosphere–surface reactions on Venus? What are the alteration pathways and secondary mineralogies on Venus' lowlands and highlands?

Further progress could be made by integration of space missions, telescopic observations, experimental work, and theoretical models. A mission to Venus should aim to determine the composition of the near-surface atmosphere and the mineralogy of the surface. Experimental efforts focused on the kinetics of gas–mineral reactions on Venus and Mars should be complimented with coupled kinetic–thermodynamic models.

10.13.1 Introduction and Scope

The enormous topic of planetary atmospheres ranges from the origin of atmospheres to the fluid dynamics of small weather systems, so here, I restrict the scope to broad essentials at a level suitable for a PhD research student. I assume knowledge of calculus, plus basic physics and chemistry, but little else. The audience could also include researchers in allied fields – for example, planetary geologists, geochemists, or astronomers. I focus on atmospheres in the solar system. Exoplanets represent a new frontier that should reveal a larger diversity of atmospheres (Seager, 2010; Seager and Deming, 2010; Seager et al., 2010). But at the moment, only a little can be said about exoplanet atmospheres with any certainty. Currently, observational data from such atmospheres are arguably much sparser than data were for atmospheres in our solar system before the Space Age. Rather than speculate, I concentrate on key principles associated with the planetary atmospheres that we know best. In fact, these are what will be needed to interpret exoplanet atmospheres correctly (see **Chapter 10.21**).

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00185-8

Until the last 5 years or so, introductory syntheses about atmospheres were mostly confined to the Earth (e.g., Houghton, 2002; Wallace and Hobbs, 2006), with a few exceptions (Chamberlain and Hunten, 1987; Yung and DeMore, 1999), but now, the coverage of planetary atmospheres is more available. A primer by Ingersoll (2013) is a good read for all levels, while Taylor (2010) provides a useful introduction aimed at mid-level undergraduates. At the research level, general texts are Pierrehumbert (2010), Sanchez-Lavega (2010), and Catling and Kasting (in press). In a more specialized area, Yung and Demore (1999) provided a detailed monograph on photochemistry. Recent papers have also reviewed the probable atmospheric circulation regimes of exoplanets (Showman et al., 2010, 2013).

The structure of this review is as follows. In order to discuss atmospheres, I start with an overview of composition and basic physical properties, including the layers of atmospheres. Thus, **Section 10.13.2** describes structure and thermodynamics. Atmospheric composition determines physical properties, which in turn affects climate through the greenhouse effect. A planet's climate requires a grasp of the radiative transfer of energy, which is discussed in **Section 10.13.3**. A brief overview of the photochemistry of atmospheres is then given in **Section 10.13.4** to provide an appreciation of the globally averaged bulk composition and vertical distribution of constituents. However, atmospheric motions transport heat and constituents, including condensable species, and are indispensable for several aspects of climate and chemistry. Principles of atmospheric motion are described in **Section 10.13.5**. Together, these various topics – thermodynamics, radiation, chemistry, and dynamics – provide the essentials of planetary atmospheres. Finally, in **Section 10.13.6**, I very briefly note some key outstanding questions.

One topic is missing: atmospheric origin and evolution. This subject is of profound interest but involves considerable geochemistry and familiarity with all the topics of this review, so the reader is referred to Catling and Kasting (in press) that comprehensively reviews this area (see **Chapter 10.14**).

10.13.2 Composition and Vertical Structure

10.13.2.1 The Observed Compositional Diversity of Atmospheres

A physically meaningful classification of the composition of planetary atmospheres falls into two chemical categories: reducing and oxidizing. A redox (reduction–oxidation) state indicates the chemical character of atmospheres, for example, whether elements such as carbon are likely to be found in their reduced form (methane, CH_4) or oxidized variety (carbon dioxide, CO_2).

The solar system contains several examples of oxidizing and reducing atmospheres. Reducing atmospheres are those that are relatively rich in reducing gases, typically hydrogen-bearing gases, such as hydrogen itself (H_2), methane (CH_4), and possibly ammonia (NH_3). Examples include all the giant planets and Saturn's largest moon, Titan (**Table 1**). In principle, an atmosphere dominated by carbon monoxide (CO) would also be reducing (perhaps applicable to some hot giant exoplanet atmospheres (Moses et al., 2011) or early Mars (Zahnle et al., 2008)), although we do not have an example in the modern solar system, and such an atmosphere would likely contain considerable H_2 as well. The atmosphere of the early Earth was also reducing, albeit weakly, before its oxygenation at 2.4 Ga (Ga = giga anna = billions of years ago) (Catling, 2014; Lyons et al., 2014). In contrast, oxidizing atmospheres are relatively poor in reducing hydrogen-bearing gases and include modern Earth and Mars (**Table 2**). Molecular O_2 has a volume abundance of 21 and 0.15% on Earth and Mars, respectively, which greatly exceeds the amount of hydrogen-bearing reducing gases of 1.8 ppmv (parts per million by volume) CH_4 on Earth (Hartmann et al., 2013) and 15 ± 5 ppmv H_2 on Mars (Krasnopolsky and Feldman, 2001). Venus is unusual. The upper atmosphere of Venus is oxidizing, with a tenuous ozone (O_3) layer at 90–105 km altitude on the nightside (Montmessin et al., 2011), while the atmosphere below ~20 km altitude is arguably weakly reducing because sulfur is converted into various reduced forms (Krasnopolsky and Pollack, 1994). Noting sulfur oxidation numbers in square brackets, these sulfur species include sulfur dioxide (SO_2) [+4], carbonyl sulfide (OCS)[−2], hydrogen sulfide (H_2S) [−2], and elemental sulfur allotropes of 1–8 atoms ($S–S_8$)[0]. The OCS is sourced from weathering of sulfides on the surface, or volcanic outgassing, or the reduction of sulfur by carbon monoxide (e.g., $S_2 + CO$), which is present at ~20 ppmv below 20 km (Fegley, 2014). Unlike Earth and Mars, O_2 is absent in Venus' atmosphere with an upper limit of <0.3 ppmv.

Broadly speaking, planetary formation theories from a Sun-like nebula (reviewed by Chambers, 2014) favor more hydrogen-rich atmospheres far from a star and more oxidizing atmospheres nearby, but this can be confounded in an extrasolar system if a planet's orbital distance changes in planetary migration. Also, the very early rocky planets in our own solar system may have had hydrogen-rich atmospheres (Abe, 2011).

Redox also indicates the possible chemistry of aerosols, which are fine particles found in atmospheres. In general, oxidizing atmospheres with sulfurous gases tend to produce sulfate aerosols at altitude (McGouldrick et al., 2011), such as in the Earth's stratosphere (Crutzen, 1976; Robock, 2000), on Venus (Thompson et al., 2011), or on Mars when it was volcanically active (Settle, 1979; Smith et al., 2014; Tian et al., 2010). In contrast, reducing atmospheres generate hydrocarbon aerosols, including the giant planets (Irwin, 2009; Moses et al., 2004; West et al., 1991, 2004, 2009), Titan (Krasnopolsky, 2010; Lavvas et al., 2008a,b; Wilson and Atreya, 2004), and probably the early Earth (Pavlov et al., 2001; Wolf and Toon, 2010; Zerkle et al., 2012).

In addition to the atmospheres discussed in the preceding text, some smaller bodies possess very thin atmospheres. Exospheres exist directly above the surfaces of several moons, which are defined as atmospheric layers of such low density that they are virtually collisionless. We find the following thin atmospheres, where the surface pressure is given in bar (1 bar = 10^5 Pa) in parentheses:

(i) N_2-rich atmospheres above surfaces covered in N_2 ice: Triton ($\sim(14–20) \times 10^{-6}$), the largest moon of Neptune, and Pluto ($\sim 15 \times 10^{-6}$)

Table 1 The composition of reducing atmospheres

Species	*Jupiter*	*Saturn*	*Uranus*	*Neptune*	*Titan*
H_2	$86.4 \pm 2.6\%$	$88 \pm 2\%$	$82.5 \pm 3.3\%$	$80 \pm 3.2\%$	0.099%
He	$13.6 \pm 0.3\%$	$12 \pm 2\%$	$15.2 \pm 3.3\%$	$19.0 \pm 3.2\%$	
CH_4[a]	$0.204 \pm 0.049\%$	$0.47 \pm 0.2\%$	~2.3% (below CH_4 clouds)	~1–2% (below CH_4 clouds)	5.65% (1.48% in stratosphere)
$^{13}CH_4$	$1.9 \pm 0.1 \times 10^{-5}$	$5.1 \pm 0.2 \times 10^{-5}$			0.062%
N_2	–	–	–	–	94.2%
NH_3[a]	$5.74 \pm 0.22 \times 10^{-4}$ (8.9–11.7 bar, below NH_3 clouds)	$\sim 1.1 \times 10^{-4}$ ($p > 1$ bar, below NH_3 clouds)	$< 1 \times 10^{-7}$	6×10^{-7} (at 6 bar)	
H_2O[a]	$4.23 \pm 1.38 \times 10^{-4}$ (at 17.6–20.9 bar)	2.3×10^{-7} (upper troposphere)	$6–14 \times 10^{-9}$ (at $p < 0.03$ mbar)	$1.7–4.1 \times 10^{-9}$ (at $p < 0.6$ mbar)	$< 10^{-8}$
H_2S[a]	$6.7 \pm 0.4 \times 10^{-5}$ (at $p > 16$ bar)	$< 0.4 \times 10^{-6}$	$< 8 \times 10^{-7}$	$< 3 \times 10^{-6}$	–
Ne	1.99×10^{-5}				$< 2 \times 10^{-5}$ ^{20}Ne
Ar	$1.57 \pm 0.35 \times 10^{-5}$				3.4×10^{-5} ^{40}Ar 2.1×10^{-7} ^{36}Ar
C_2H_6	$5.8 \pm 1.5 \times 10^{-6}$ (stratosphere)	$7.0 \pm 1.5 \times 10^{-6}$ (stratosphere)	1.5×10^{-5} (at 0.5–1 mbar)	1.5×10^{-6} (stratosphere)	$\leq 1 \times 10^{-5}$
PH_3	$1.04 \pm 0.1 \times 10^{-6}$	$5.9 \pm 0.2 \times 10^{-6}$ ($p > 0.5$ bar)	$< 8.3 \times 10^{-7}$		-
C_2H_2	$\sim 4 \times 10^{-8}$ (at 5 mbar)	$3.0 \pm 0.2 \times 10^{-7}$ (at 1 mbar)	$\sim 1.0 \times 10^{-8}$ (stratosphere)	$6.0^{+14.0}_{-4.0} \times 10^{-9}$ (stratosphere)	$\leq 2 \times 10^{-6}$
C_2H_2	3.5×10^{-10} (at $p < 10$ mbar)	3.4×10^{-10} (at $p < 10$ mbar)	$4.0 \pm 0.5 \times 10^{-11}$ (at 0.1 mbar)	6×10^{-8} (at $p < 5$ mbar)	10^{-8} (above stratospheric condensation)
CO	$1.6 \pm 0.3 \times 10^{-9}$ (at 5–8 bar)	$< 10^{-7}$ (stratosphere)	$< 4 \times 10^{-8}$ (stratosphere)	$6.5 \pm 3.5 \times 10^{-6}$ (stratosphere)	4.7×10^{-5}
D/H	$2.3–2.6 \times 10^{-5}$	$1.7^{+0.75}_{-0.45} \times 10^{-5}$			$1.35 \pm 0.3 \times 10^{-4}$ in H_2 $1.32^{+0.15}_{-0.11} \times 10^{-4}$ in CH_4
$^{13}C/^{12}C$	0.0108 ± 0.0005	0.011			0.01099 ± 0.00017 in CH_4

[a]Condensable species, so levels are indicated.

Gases are given as volume mixing ratios. CH_4 is condensable on Titan, Uranus, and Neptune. H_2O and NH_3 are condensable on the giant planets, while H_2S reacts with NH_3 to form ammonium hydrosulfide (NH_4SH) clouds.

(ii) O_2-rich exospheres above moons covered in water ice: Jupiter's moons, Europa ($\sim 10^{12}$–10^{13} O_2), (Smyth and Marconi, 2006), Ganymede ($\sim 10^{-12}$ O_2) (Hall et al., 1998), and Callisto ($\sim 10^{-12}$ O_2 possibly + CO_2) (Carlson, 1999; Kliore et al., 2002; Liang et al., 2005), and Saturn's moons, Rhea ($\sim 10^{-12}$ O_2 and CO_2) (Teolis et al., 2010) and Dione ($\sim 10^{-12}$ O_2) (Tokar et al., 2012)

(iii) Volcanogenic atmospheres: SO_2 on Io ($\sim 10^{-7}$–10^{-9}), a moon of Jupiter, and a water vapor–CO_2 exosphere on Enceladus, a moon of Saturn

The tenuous N_2-rich atmospheres (with minor CH_4) on Triton and Pluto arise from vapor equilibrium with N_2 (and CH_4) ice at prevailing surface temperatures. The O_2-rich exospheres on the moons of Jupiter and Saturn come from the breakdown of water ice on the surfaces of these moons by radiolysis and sputtering (Johnson et al., 2009). Radiolysis is the chemical alteration of ices by charged particles, and sputtering is when charged particles collide and eject atoms or molecules. The faster escape of the hydrogen compared with that of the oxygen leaves oxygen lingering behind in an exosphere. The charged particles come from magnetospheres, which are envelopes of ions around planets controlled by the planetary magnetic fields.

Volcanic small bodies have a different class of atmosphere. The very thin SO_2 atmosphere on Io, a rocky body, is sourced from high-temperature volcanism at a rate of 10^5 kg s^{-1} SO_2 (Lellouch et al., 2003). The SO_2 freezes to form frost away from the hot vents (Schmitt et al., 1994). Elemental sulfur is also volcanically outgassed, with $SO_2/S_2 \sim 3$–12 in the plume of the volcano Pele (Spencer et al., 2000). In contrast to Io, Enceladus is covered in water ice and affected by cryovolcanism, that is, a form of volcanism where ice turns to vapor or gets ejected as a result subsurface heating, unlike volcanism that involves molten rock. Plumes at the south pole of Enceladus release icy particles at a rate of 200 ± 30 kg s^{-1} (Hansen et al., 2011) from parallel lineaments called 'tiger stripes' (~500 m deep, ~130 km long, 2 km wide) (Porco et al., 2006), causing a very asymmetrical exosphere (Tenishev et al., 2010).

The very thin atmospheres described in the preceding text are mentioned for completeness. Henceforth, I restrict most of the discussion to thicker atmospheres, the thinnest being that of Mars.

Table 2 The composition and properties of oxidizing atmospheres (noting that the lower atmosphere of Venus could be considered somewhat reducing)

Parameter	*Venus*	*Earth*	*Mars*
Mean surface pressure (bar)	95.6	1.0	0.006
Mean surface temperature (K)	735	288	218
Mass relative to the Earth (5.97×10^{24} kg)	0.815	1.0	$0.107 \approx 1/9$
Mean radius relative to the Earth (6371 km)	0.950	1.0	$0.532 \approx 1/2$
Key gases in atmosphere (by volume)	CO_2 96.5% N_2 3.5% SO_2^c ● 150 ± 30 ppm (22–42 km) ● 25 ± 150 ppm (12–22 km) ^{40}Ar 70 ± 25 ppm $^{36+38}Ar$ 75 ± 35 ppm H_2O^c 30 ± 15 ppm (5–45 km) CO^c ● 45 ± 10 ppm (cloud top) ● 17 ± 1 ppm (12 km) He 12 (+24/−8) ppm Ne 7 ± 3 ppm H_2^c 2.5 ± 1 ppm (50–60 km) HCl 0.4 ppm (70 km) ^{84}Kr 50 ± 25 ppb	N_2[a] 78.084% O_2[a] 20.946% H_2O 0.1 ppm – 4% (varies) Ar 9340 ppm CO_2[a,b] ● ~280 ppm (pre-industrial) ● 396.5 ppm (year 2013) Ne 18.18 ppm ^4He 5.24 ppm CH_4[a] 1.7 ppm Kr 1.14 ppm H_2[a] 0.55 ppm N_2O[a] ~320 ppb CO[a] 125 ppb	CO_2 96.0 ± 0.7% N_2 1.89 ± 0.01% Ar 1.93 ± 0.01% O_2 0.145 ± 0.09% CO 0.06% H_2O ~0.03% (varies) He 10 ppm H_2 15 ± 5 ppm Ne 2.5 ppm Kr 0.3 ppm O_3 0–80 ppb H_2O_2 0–40 ppb SO_2[d] <0.3 ppb

[a]Biologically cycled and influenced.
[b]Currently increasing about 2 ppm per year because of anthropogenic emissions.
[c]Altitude-dependent.
[d]Indicates lack of volcanic outgassing.

10.13.2.2 Nomenclature for the Vertical Structure of Atmospheres

Along with composition, a basic description of any atmospheres involves atmospheric structure. The term conventionally refers to the vertical temperature profile, which provides information about how chemical and physical processes change with altitude. The average thermal profile is also the basis for naming atmospheric layers using a system developed for Earth in the early 1900s (Lindemann and Dobson, 1923; Martyn and Pulley, 1936); thus, the nomenclature works with only some degree of success for other bodies. New atmospheric layers begin where there is a temperature inflection (**Figure 1**). On Earth, the five layers are the following: (i) the troposphere (tropos – Greek for the 'turning' of convection), where temperature declines from the surface to the tropopause (pause – Greek for 'stop'), which lies at an average pressure of 0.16 bar (Sausen and Santer, 2003). The tropopause altitude is 0.2 bar (11 km) in the US Standard Atmosphere but varies in detail with latitude from 0.1 to 0.3 bar (tropics to pole) (Hoinka, 1998). (ii) The stratosphere (stratus–Greek for 'layered'), where temperature increases from the tropopause to the stratopause at ~50 km altitude where the air pressure is ~100 Pa (1 mbar). (iii) The mesosphere from the stratopause to the mesopause, at ~85 km altitude, where the air pressure is about 1–0.1 Pa (0.01–0.001 mbar). (iv) The thermosphere from the mesopause to the thermopause (or exobase) at that varies over altitudes of ~250–500 km as solar ultraviolet (UV) flux changes over cycles ranging from daily to the 11-year solar cycle. (v) The exosphere, which blends into interplanetary space.

Convection dominates lower tropospheres. Solar radiation heats the surface of rocky planets or is absorbed in the deeper portions of tropospheres on giant planets. Consequently, warm buoyant air rises to altitudes of lower pressure where it expands and cools. Cool air parcels sink and warm. The net effect of such convection is a decline of temperature with altitude. On Earth, the rate that temperature decreases, the lapse rate, averages ~6 K km^{-1} globally. In the upper troposphere where the air is thinner, radiation transfers energy instead of convection above a radiative–convective boundary. Higher still, emission of thermal infrared (IR) radiation from the air to space becomes so efficient that a temperature minimum or tropopause is achieved. The tropopause occurs near an average pressure of roughly 0.1 bar on Earth, Titan, and the giant planets. The similarity is because of a common scaling of broadband IR opacity and pressure. In upper tropospheres, the IR opacity is pressure-dependent in the same way – varying approximately with the square of the pressure – while all these atmospheres are roughly similar in their strong opaqueness to IR at deeper pressures, such as 1 bar,

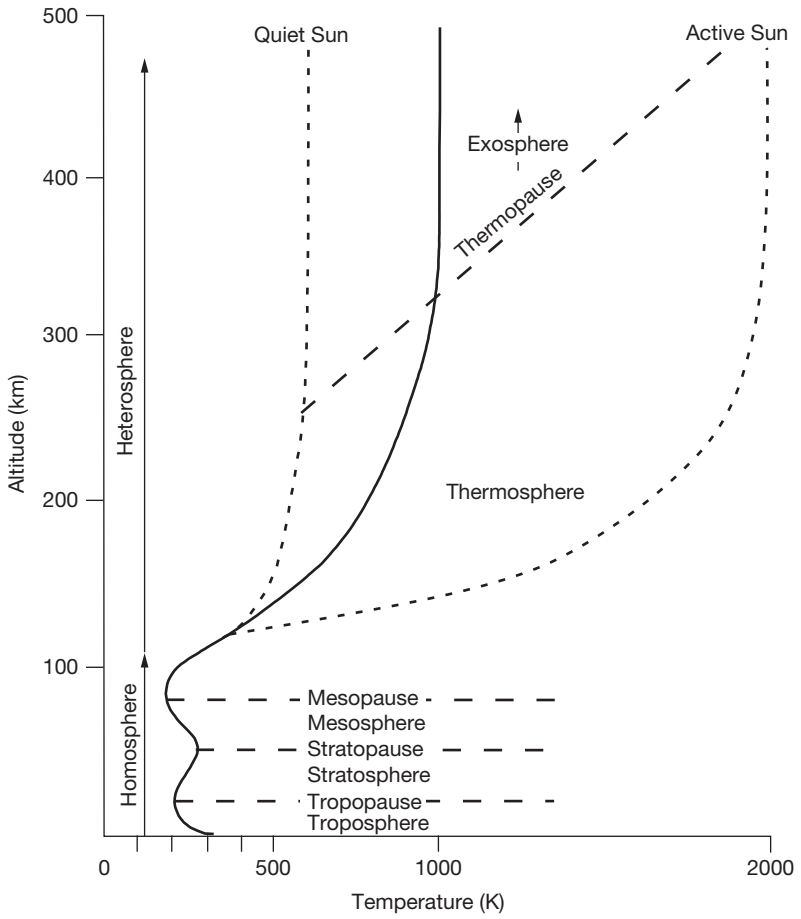

Figure 1 The terminology for vertical layers of the Earth's atmosphere, shown schematically. (Drawn by the author.)

despite the big differences in atmospheric composition and gravity (Robinson and Catling, 2014) (see **Section 10.13.3.4**).

In stratospheres, the absorption of shortwave solar radiation causes a temperature inversion, defined as a temperature increase with altitude. On Earth, the ozone absorbs UV radiation, whereas on the giant planets and Titan, aerosol particles and methane absorb at wavelengths in the UV, visible, and near-IR. Mars and Venus, which have predominantly CO_2 atmospheres, do not have strong shortwave absorbers above their tropospheres, so in the global average, they lack stratospheric inversions and tropopause minima (see **Section 10.13.3.4**).

Above the Earth's stratosphere, CO_2 emission to space causes the mesosphere to have the lowest atmospheric temperatures. A cold mesopause forms the lower boundary of the thermosphere where temperature increases with altitude. Mesopauses occur around ~1–0.1 Pa in planetary atmospheres in the solar system. They are cold because the air is so thin in upper mesospheres that energy-exchanging collisions between molecules become less frequent than photon emission at a level of radiative relaxation (Curtis and Goody, 1956; López-Puertas and Taylor, 2001). Consequently, excited molecules lose energy by radiation rather than by collisions.

In thermospheres, absorption of extreme ultraviolet radiation (EUV) (with wavelength shorter than ~120 nm) causes temperature to increase. Molecules are broken apart by EUV and photochemical reactions, and EUV and x-rays ionize both molecules and atoms. In the tenuous gas, infrequent collisions between electrons and ions create an ionosphere, a shell of electrons and ions that extends on Earth from the mesosphere into the exosphere. The Earth's hot thermosphere (~1000 K at 250 km altitude) reflects the slow rate of removing heat. Atoms and atomic ions do not have vibrational or rotational transitions and so are poor radiators, unlike molecules. Instead, heat is transferred inefficiently by conduction downward to the cold mesopause where radiative cooling is effective. Unlike the Earth, the upper thermospheres on Mars and Venus are relatively cold at ~270 K for Mars and ~250 K for Venus, because their ~96% CO_2 causes efficient radiative cooling to space (**Section 10.13.4.5**). Finally, exospheres lie above thermospheres and are where atmospheres become collisionless.

Chemically, we can divide atmospheres into two big layers: a homosphere where bulk gases are well mixed up to a homopause and a heterosphere above the homopause where molecular diffusion becomes more important than turbulent mixing. The homopause occurs where the diffusion separation time and turbulent mixing time of gases are equal. This tends to occur within a few orders of magnitude of 0.01 Pa (or 0.1 μbar). On Earth, the homopause is at ~100 km height. Above, at 250–1000 km altitude, diffusive separation causes atomic oxygen (O) to become the dominant species, while higher up, helium dominates, and then, hydrogen above 2500 km height.

Species escape from the base of exospheres (the exobase) if their upward velocity exceeds the escape velocity v_{esc}, which is given by a balance between gravitational energy and kinetic energy (KE):

$$\frac{1}{2}mv_{esc}^2 = \frac{GMm}{r} \Rightarrow v_{esc} = \sqrt{\frac{2GM}{r}} \Rightarrow \underbrace{v_{esc} \propto \sqrt{\frac{a^3}{a}} \propto a}_{\text{if same density body of radius } a} \quad [1]$$

Here, r is the radial distance, G is the universal gravitational constant (6.672×10^{-11} N m^2 kg^{-2}), M is the mass of the planet, a is the planet's radius, and m is the molecular mass. Today, hydrogen escapes efficiently from Earth at a small rate ~3 kg s^{-1}. Hydrogen atoms at the exobase in the tail of the Maxwell–Boltzmann velocity distribution have enough thermal velocity to evaporate and escape even though the root-mean-square speed (given by $1/2mv^2 = (3/2)kT$, where $k = 1.381 \times 10^{-23}$ J K^{-1} is Boltzmann's constant and T is exobase temperature) is less than the Earth's escape velocity. Alternatively, the hydrogen is lost when chemical or charged particle reactions impart speed to hydrogen atoms. The rate-limiting step is not a loss from the exobase itself but diffusion from the homopause to the exobase. Consequently, hydrogen is said to be lost at an upper limit by diffusion-limited escape (Hunten, 1973; Walker, 1977). Diffusion-limited escape of hydrogen is an excellent theory given that data suggest that it happens on Venus, Earth, Mars, and Titan.

For completeness, there are three ways that gases escape from planets: (i) thermal escape, with end-member approximations of thermal evaporation (as mentioned in the preceding text) called Jean's escape at one end and pressure-driven hydrodynamic escape at the other (e.g., Catling and Zahnle, 2009; Johnson et al., 2013; Walker, 1982), (ii) nonthermal escape where an atom or molecule is boosted to escape velocity because of a chemical reaction or ionic interaction, and (iii) impact erosion where atmospheric gases are expelled as a result of the large body impacts. Helium escapes from the Earth today through nonthermal escape. However, bodies can lose their atmospheres in bulk. Theory demonstrates that the two mechanisms that most efficiently strip away substantial atmospheres are hydrodynamic escape driven by stellar irradiation (Lammer et al., 2008; Sekiya et al., 1980, 1981; Watson et al., 1981; Zahnle and Kasting, 1986; Zahnle et al., 1990) and impact erosion (Griffith and Zahnle, 1995; Melosh and Vickery, 1989; Walker, 1986; Zahnle et al., 1992). Currently, in the solar system, only Pluto's atmosphere is believed to be undergoing hydrodynamic escape (Trafton et al., 1997). The reader is referred to Catling and Kasting (in press) and Lammer (2013) for more discussion of escape processes.

10.13.2.3 The Equation of State, Atmospheric Composition, and the Hydrostatic Equation

The most basic physics of atmospheres involves connecting the distributions of pressure, temperature, and density with (i) an equation of state and (ii) a hydrostatic equation.

Except for deep within giant-planet atmospheres, the ideal gas law works well as for (i)

$$p = nkT = \underbrace{(n\overline{m})}_{\rho}\left(\frac{k}{\overline{m}}\right)T \Rightarrow p = \rho\overline{R}T \quad [2]$$

Here, k is Boltzmann's constant, $\overline{m}$ is the mean molecular mass, n is the number density or number of molecules per unit volume, and $\rho = n\overline{m}$ is the mass density. The universal gas constant R (8.314 J K^{-1} mol^{-1}) is related to a specific gas constant (different for each atmosphere) by $\overline{R} = R/\overline{M} = K/\overline{m}$, where $\overline{M}$ (kg mol^{-1}) is the mean molar mass. Dalton's law states that the total pressure is the sum of partial pressures p_i, for each species i, $p = \sum p_i$. Applied to eqn [2], the mean molecular mass is

$$\overline{m} = \frac{\sum_i n_i m_i}{n} = \frac{\overline{M}}{N_A} \quad [3]$$

where m_i is the mass of the ith molecule and N_A is Avogadro's number. On Mars, for example, using the data of Table 2, the mean molar mass $\overline{M} = 0.0435\,\text{kg mol}^{-1}$ and $\overline{R} = R/\overline{M} = 191\,\text{J kg}^{-1}\,\text{K}^{-1}$. For dry air on Earth, $\overline{M} = 0.029\,\text{kg mol}^{-1}$ and $\overline{R} = R/\overline{M} = 287\,\text{J K}^{-1}\,\text{kg}^{-1}$.

We usually describe atmospheric composition with the volume mixing ratio f_i, for species i, which is also the mole fraction. Less commonly, we use a mass mixing ratio μ_i, which is the mass of a particular gas divided by the total mass of a gas mixture sample. For an ideal gas,

$$f_i = \frac{p_i}{p} = \frac{V_i}{V} = \frac{n_i}{n}, \quad \mu_i = \frac{\rho_i}{\rho}\frac{m_i}{\overline{m}}\frac{p_i}{p} = \frac{m_i}{\overline{m}}f_i \quad [4]$$

In all atmospheres, high total pressure at low altitudes pushes upward against the weight of overlying air, so that pressure declines with altitude. Air settles into hydrostatic equilibrium. This equilibrium assumes no vertical motion – a good approximation over large horizontal scales (e.g., a few kilometers on the Earth) that average out updrafts and downdrafts. A column of air with unit area cross section and small height Δz has a mass $\rho\Delta z$, so that the pressure change going up in height Δz is $\Delta p = -(\rho\Delta z)g =$ force/(unit area), where g is the gravitational acceleration. Written in calculus form, we get the hydrostatic equation relating pressure, density, and altitude:

$$\frac{\partial p}{\partial z} = -\rho(z)g(z), \quad p(z) = \int_z^\infty \rho(z)g(z)\mathrm{d}z \quad [5]$$

For an ideal gas, the air density is $\rho = p/\overline{R}T$ (eqn [2]), so that we can rewrite eqn [5] as

$$\frac{\partial p}{\partial z} = \left(\frac{-g(z)}{\overline{R}(z)T(z)}\right)p \Rightarrow \frac{\partial p}{p} = -\left(\frac{\partial z}{H}\right) \Rightarrow p = p_s\exp\left(-\int_0^z\left(\frac{\mathrm{d}z}{H}\right)\right) \Rightarrow p \approx p_s\exp\left(-\frac{z}{H}\right)_{\text{isothermal}} \quad [6]$$

Here, p_s is the surface pressure and we introduce a vertical length scale called the scale height,

$$H = \overline{R}T/g = kT/\overline{m}g \quad [7]$$

If we make the approximation that the temperature, gravity, and specific gas constant are constant with height, the integral of eqn [6] can be evaluated to give the exponential shown in the last expression. Thus, we see the meaning of the scale height: the vertical distance over which pressure drops by a factor of $1/e = 1/(2.7183) \approx 1/3$. In an isothermal atmosphere, density also drops by $1/e$ over the same height, but the density scale height will be slightly different if there is any temperature change with altitude. In the solar system, $H \approx 5$–20 km because the ratio $\overline{T}/\overline{m}g$ in $H = kT/\overline{m}g$ is similar given that smaller T (and larger g for Jupiter) compensates for small $\overline{m}$ in H_2-rich giant planets.

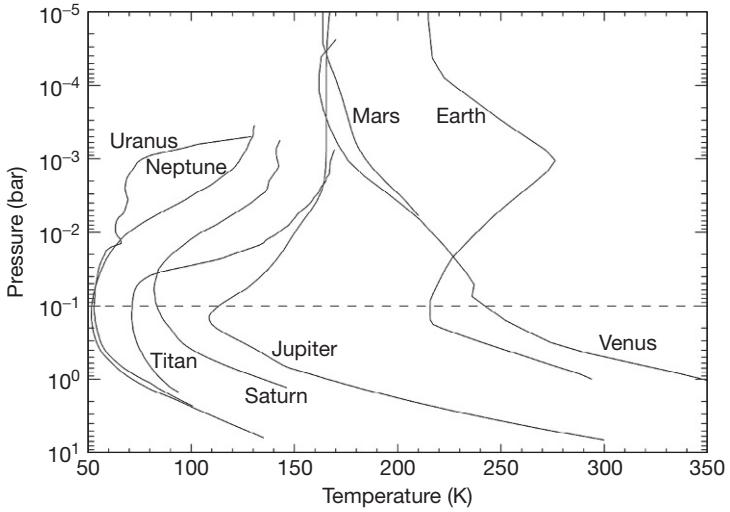

Figure 2 Temperature–pressure profiles for planetary atmospheres in the solar system. The dashed line at 0.1 bar indicates that planets with stratospheric temperature inversions have tropopause minima near this pressure level. (Drawn by the author.)

The surface pressure measures an atmosphere's mass because pressure is the weight of a column of air per unit area. Ignoring lateral forces in the real 3-D spherical geometry (which are a minor correction), we have

$$p_s = M_{col} g \Rightarrow M_{col} = \frac{p_s}{g} \qquad [8]$$

where M_{col} is the column mass. For example, $M_{col} = (610\ \text{Pa})/(3.72\ \text{m s}^{-2}) = 164\ \text{kg m}^{-2}$ on Mars, $10^4\ \text{kg m}^{-2}$ on Earth, and $2 \times 10^5\ \text{kg m}^{-2}$ on Titan. Equation [8] can also be applied to the column mass above some reference pressure level for giant planets.

The hydrostatic equation combined with number density gives us another way to describe atmosphere composition, namely, column abundance N_c, which is the number of molecules above a unit area. For example, the typical abundance of terrestrial ozone is $N_{O3} \approx 8 \times 10^{18}$ molecules cm^{-2}. At altitude z, the column abundance $N_c(z)$ is defined by

$$N_c(z) = \int_z^\infty n(z)\mathrm{d}z \qquad [9]$$

The column mass is $N_c(z)\overline{m}$, so the pressure at altitude z, by eqn [8], is $p(z) = N_c(z)\overline{m}g$. Using this, we obtain an expression for the column abundance in terms of scale height H:

$$N_c(z) = \frac{p(z)}{\overline{m}g} = \frac{n(z)kT(z)}{\overline{m}g} \Rightarrow N_c(z) = n(z)H(z) \qquad [10]$$

In some planetary literature, column abundance is expressed as 'cm-atm' or 'cm-amagat,' which are equivalent. These units are the depth in centimeters that would be produced if a gas in a column of air were all extracted and compressed to 1 atm (101325 Pa) pressure and 0 °C; they are given by the normalization $N_c(z)/n_0$, where $N_c(z)$ is in units of molecules cm^{-2} and $n_0 = 2.687 \times 10^{19}$ molecules cm^{-3} is the Loschmidt number, the number density of an ideal gas at 1 atm and 273.15 K. Ozone column abundance is also expressed with the Dobson unit (DU), which is the depth in thousandths of centimeters of a column of ozone taken to 1 atm and 0 °C, that is, DUs are $1000 N_{O3}/n_0$. The Earth's ozone column is typically 300 DU (0.3 cm-atm) compared with a maximum of 6 DU on Mars.

10.13.2.4 Convection and Stability

Atmospheric temperatures vary with altitude (Figures 1 and 2) primarily because of radiation and convection, although large-scale atmospheric motion also plays a role (Section 10.13.5).

In lower tropospheres, warm air rises and cold air sinks so that heat is transferred upward by convection. Air expands and becomes buoyant, that is, less dense than surroundings, through (i) radiative heating, (ii) contact with a planetary surface warmed by sunlight, (iii) exothermic condensation of substances such as water vapor in the Earth's atmosphere (see Chapter 10.11), and (iv) heating from the interior of a planet, which is significant on giant planets but not usually on rocky ones.

Convection commences when the lapse rate exceeds a certain threshold. The lapse rate is denoted $\Gamma = -(\mathrm{d}T/\mathrm{d}z)$ and usually given in K km^{-1}. The minus sign is a convention to make Γ positive for typical tropospheric conditions. Convection is very efficient in transporting heat upward to the upper troposphere. There, the overlying atmosphere is relatively transparent to thermal IR and energy is radiated to space. Also, in the upper troposphere, the lapse rate is no longer steep and convection ceases. In this way, a state of radiative–convective equilibrium is achieved, in which outgoing IR radiation from the warm planet balances the energy of incoming sunlight and sets a characteristic radiative–convective temperature profile (see Section 10.13.3.4).

The adiabatic lapse rate is the threshold lapse rate for convection. If the actual lapse rate is bigger or smaller, the atmosphere convects or it does not. Adiabatic means no exchange of energy with surroundings. So if a vertically displaced air parcel expands or contracts adiabatically to adjust to its surrounding pressure, the temperature change as a function of height is readily calculable. Applying conservation of energy to the parcel, we have

$$\underbrace{\mathrm{d}q}_{\text{heat added/kg (zero for adiabatic)}} = \underbrace{c_v \mathrm{d}T}_{\text{change in internal heat/kg}} + \underbrace{p\mathrm{d}\alpha}_{\text{work done/kg}} \qquad [11]$$

Here, dq is heat input per unit mass (zero if adiabatic) and c_v is the specific heat at constant volume. Work is 'force × incremental distance' or 'pressure (p) × incremental volume change.' Because we are dealing with energy per unit mass, we define volume per unit mass as $\alpha = 1/\text{density} = 1/\rho$, so that work is $p d\alpha$. Since $\alpha = \overline{R}T/p$ from eqn [2], the product rule of differentiation gives us $d\alpha = (\overline{R}/p)\,dT - (\overline{R}T/p^2)\,dp$. Substituting in eqn [11], we have

$$dq = c_v\,dT + \not{p}\left[\frac{\overline{R}}{\not{p}}\,dT - \frac{\overline{R}T}{p^{\not{2}}}\,dp\right] = (c_v + \overline{R})\,dT - \left(\frac{\overline{R}T}{p}\right)dp$$

$$\Rightarrow dq = c_p\,dT + g\,dz \qquad [12]$$

In the middle expression, we have inserted $c_p = c_v + \overline{R}$ from kinetic theory, which relates specific heat at constant pressure (c_p) to specific heat at constant volume. We also substituted $-g\,dz$ for $(\overline{R}T/p)\,dp$ using the first expression in eqn [5], the hydrostatic equation. For adiabatic changes, $dq = 0$. Thus, from the last expression in eqn [12], we obtain the adiabatic lapse rate for dry air:

$$\Gamma_a = -\left(\frac{dT}{dz}\right) = \frac{g}{c_p} \qquad [13]$$

This simple but fundamental equation gives the temperature change with altitude of a dry parcel of air moving up and down through an atmosphere in hydrostatic equilibrium. Table 3 gives the specific heat capacities, gravitational accelerations, and lapse rates Γ_a of various planetary atmospheres.

Comparison of the ambient lapse rate Γ with Γ_a indicates susceptibility to convection. When $\Gamma < \Gamma_a$, a parcel that rises adiabatically cools more than the gentler ambient decrease of temperature with height. This cold, dense parcel sinks back downward, so the atmospheric profile is convectively stable. Conversely, when $\Gamma > \Gamma_a$, a parcel that rises adiabatically is warmer than surroundings, and the parcel continues to rise. The resulting rapid mixing by convection of such unstable atmospheres tends to adjust the temperature profile toward the adiabatic one. Thus, we find planetary atmospheres typically with $\Gamma \leq \Gamma_a$ (ignoring local circumstances such as thunderstorms) (Table 3).

Our analysis is incomplete because condensable species and aerosols strongly affect temperature profiles. For example, in the Earth's troposphere, the condensation of water vapor releases heat making Γ smaller than the adiabatic value. Condensation of sulfuric acid on Venus has a similar thermodynamic effect. We discuss a saturated adiabatic lapse rate (SALR) in Section 10.13.2.5. For deep atmospheres, such as on Venus, one should also take account of the temperature dependence of specific heat capacity c_p so that $\Gamma_a = \Gamma_a(T)$.

A shorthand description of the stability of temperature gradients uses potential temperature θ, which is the temperature that a parcel of air would have if it were taken to a reference pressure p_{ref} (e.g., 10^5 Pa for Earth) dry adiabatically. Potential temperature is an alternative thermodynamic variable to temperature and, from its definition, is constant with altitude z if the lapse rate is adiabatic. Otherwise, an increase of θ with z indicates convective stability, while negative $\partial\theta/\partial z$ indicates instability. Using the adiabatic version of eqn [12] with $dq = 0$, we define θ as follows:

$$\frac{dT}{T} = \left(\frac{\overline{R}}{c_p}\right)\frac{dp}{p} = \kappa\frac{dp}{p};\quad \text{integrate } (\theta, T),\ (p_{ref}, p)$$

$$\Rightarrow \ln\left(\frac{T}{\theta}\right) = \kappa \ln\left(\frac{p}{p_{ref}}\right) \Rightarrow \theta = T\left(\frac{p_{ref}}{p}\right)^{\kappa} \qquad [14]$$

where $\kappa = \overline{R}/c_p$. The final expression in eqn [14] is Poisson's (adiabatic state) equation. We use eqn [14] later in Section 10.13.3.4, and potential temperature comes up again in Section 10.13.5.

In convectively stable atmospheres, a buoyancy force causes vertically displaced parcels to return to their original altitude, but overshooting creates oscillations at an angular frequency called the Brunt–Väisälä frequency, N_B. Large-scale oscillations of air create buoyancy waves (also called gravity waves) that are important in the turbulence of upper atmospheres (Section 10.13.5.7). The Brunt–Väisälä frequency can be derived by considering an adiabatic air parcel of volume V displaced upward δz from an altitude where the temperature is T to a place where the environmental temperature is T_{env}. The parcel cools adiabatically to a new temperature $T_p = T - \Gamma_a \delta z$, while the environment cools less at the ambient lapse rate as $T_{env} = T - \Gamma \delta z$. The difference in density between the parcel

Table 3 Thermodynamic and physical properties of various planetary atmospheres

Γ_a is the tropospheric adiabatic lapse rate, while Γ is the observed tropospheric lapse rate.

[a]On giant planets, g varies from equator to pole.

[b]Menou and Rauscher (2009).

(ρ_p) and air (ρ_e) drives a buoyancy force, which we can write as Newton's second law:

$$\underbrace{(\mathcal{V}\rho_p)}_{\text{mass}}\underbrace{\frac{d^2(\delta z)}{dt^2}}_{\text{acceleration}}=\underbrace{-g(\rho_p-\rho_e)\mathcal{V}}_{\text{buoyancy force}}\quad\Rightarrow\frac{d^2(\delta z)}{dt^2}=g\left(\frac{\rho_e}{\rho_p}-1\right)=g\left(\frac{T_{env}}{T_p}-1\right)\qquad[15]$$

Substituting for temperatures T_p and T_{env}, we get

$$\frac{d^2(\delta z)}{dt^2}=g\left(\frac{T-\Gamma_a\delta z}{T-\Gamma\delta z}-1\right)=g\left(\frac{\Gamma\delta z-\Gamma_a\delta z}{T-\Gamma\delta z}\right)\approx g\left(\frac{\Gamma-\Gamma_a}{T-\cancel{\Gamma\delta z}}\right)\delta z$$

$$\Rightarrow\ddot{\delta z}+\frac{g}{T}(\Gamma_a-\Gamma)\delta z=0\qquad[16]$$

In the last expression of eqn [16], we recognize simple harmonic motion, that is, the '$\ddot{x}+\omega^2x=0$' of elementary physics. Thus, the square of the angular (Brunt–Väisälä) frequency of oscillation is

$$N_B{}^2\equiv\frac{g}{T}(\Gamma_a-\Gamma)\equiv\frac{g}{T}\left(\frac{dT}{dz}+\frac{g}{c_p}\right)\equiv\frac{g}{T}S\qquad[17]$$

Here, $S(\mathrm{K\,km^{-1}})$ is static stability, which measures the difference between the adiabatic lapse rate (eqn [13]) and actual lapse rate ($-dT/dz$) and is usually positive. Equation [17] makes intuitive sense: the more stable the atmosphere, the higher the oscillation frequency, like stiffening an oscillating spring.

The effect of buoyancy oscillations can be observed. Vertical deflection of horizontal air flow over an obstacle such as a mountain on Earth or a large crater rim on Mars sometimes causes oscillations where the air swings up and down beyond the obstacle at a frequency $\sim N_B/2\pi$, forming a standing buoyancy wave. At the cold crests of the waves, moisture can condense into a series of parallel clouds called lee wave clouds, given that they form in the lee of the obstacle. Roughly speaking, the distance between parallel clouds has wavelength, $\lambda=$(horizontal wind velocity/frequency)$=u/(N_B/2\pi)$, which obviously can change with altitude-dependent u and N_B. Approximate terrestrial values of $N_B=0.01\ \mathrm{s^{-1}}$ and $u=10\ \mathrm{m\,s^{-1}}$ give $\lambda\sim6$ km, consistent with satellite imagery of lee wave cloud spacing of 3–20 km.

10.13.2.5 Condensables and the Clausius–Clapeyron Equation

Gases that condense – condensables – affect atmospheres through release or uptake of heat when they change into a liquid or solid from the vapor phase, and vice versa. Condensables include H_2SO_4 (SO_3+H_2O) on Venus, H_2O on Earth, H_2O and CO_2 on Mars, H_2O and NH_3 on Jupiter and Saturn, and CH_4 on Titan, Uranus and Neptune, and HCN on Titan. Some condensables also form rain (e.g., CH_4 on Titan), snow (e.g., CO_2 in Mars' polar atmosphere), and clouds (e.g., CH_4 on Titan, Uranus, and Neptune).

The key concept governing condensable behavior is saturation vapor pressure (SVP), which is the vapor pressure exerted in equilibrium with a liquid or solid condensed phase. The curve of SVP versus temperature for a particular substance defines the transition between vapor and condensed phases

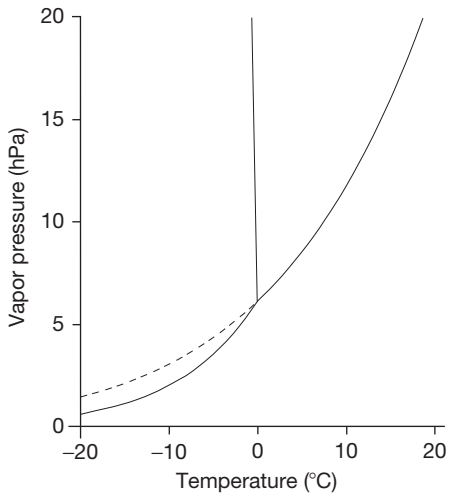

Figure 3 The saturation vapor pressure (SVP) curve between the vapor phase and condensed phase (liquid or ice) for water. The dashed line is the SVP with supercooled water. (Drawn by the author.)

(Figure 3). The Clausius–Clapeyron equation defines this SVP curve as a unique function of temperature. On Earth, we use a Clausius–Clapeyron equation for water, but analogous equations apply for other condensables. When noncondensable gases are part of a gas mixture, the vapor pressure of the condensable gas is a partial pressure, and if that partial pressure reaches SVP, then the solid or liquid phase forms.

The Clausius–Clapeyron equation comes from thermodynamics. Two phases are in equilibrium along the SVP versus T line, so the Gibbs free energy change of the phase transition is zero everywhere along the line. If e_s is the SVP, it can be shown by considering Gibbs free energy that the slope of e_s versus temperature T is given by (e.g., Atkins and De Paula, 2010)

$$\frac{de_s}{dT}=\frac{\delta s}{\delta\alpha}=\frac{\text{entropy gained per kg from condensed to vapor}}{\text{volume increase per kg from condensed to vapor}}=\frac{l_c}{T\delta\alpha}=\frac{l_c}{T(\alpha_{vapor}-\alpha_{condensed})}\approx\frac{l_c}{T\alpha_{vapor}}\qquad[18]$$

where α is specific volume ($\alpha=1/\rho$), which, in the last step, we reasonably assumed, is far larger than for the vapor than for condensed phase, that is, $\alpha_{vapor}\gg\alpha_{condensed}$. We also substituted $l_c=T\delta s$, where l_c is the latent heat or enthalpy, which is heat absorbed (or released) when a unit mass changes from one phase to another at constant temperature and pressure. For different phase transitions, this quantity can be 'latent heat of vaporization' for liquid–vapor, or latent heat of fusion for ice–liquid, or latent heat of sublimation for ice–vapor. We can define a specific gas constant for the condensable species vapor as $R_c=R/M_c=k/m_c$, where M_c and m_c are its molar mass and molecular mass, respectively. By substituting for $\alpha_{vapor}=R_cT/e_s$ from the ideal gas law, we obtain the Clausius–Clapeyron equation:

$$\frac{de_s}{dT}=\frac{l_ce_s}{R_cT^2}\Rightarrow\frac{d(\ln e_s)}{dT}=\frac{l_c}{R_cT^2}\Rightarrow e_s(T)=e_s(T_0)\exp\left(\int_{T_0}^{T}\frac{l_c}{R_c}\frac{dT}{T^2}\right)\approx e_s(T_0)\exp\left[\frac{l_c}{R_c}\left(\frac{1}{T_0}-\frac{1}{T}\right)\right]\qquad[19]$$

Here, the last step makes the approximation that l_c does not change with temperature. Because exponents are additive,

eqn [19] shows $e_s \propto \exp(-m_c l_c/kT)$. Thus, SVP is a Boltzmann equation, which makes sense: the numerator $m_c l_c$ is the energy to free a molecule from its neighbors, while the denominator kT is the average molecular energy. For water vapor above liquid water, we use $T_0 = 273.15\,\mathrm{K}$, $e_s(T_0) = 611\,\mathrm{Pa}$, $R_c = 461\,\mathrm{J\,K^{-1}\,kg^{-1}}$, and latent heat of vaporization $l_c = 2.5 \times 10^6\,\mathrm{J\,kg^{-1}}$, finding that SVP roughly doubles for every 10 K temperature rise.

On some bodies, SVP is essential for understanding the bulk atmospheric gas. On Mars, for example, CO_2 condenses at the cold poles. A temperature of 148 K corresponds to an SVP of 6 mbar (~600 Pa) for CO_2, which is a typical air pressure on the surface of Mars (Leighton and Murray, 1966). Consequently, Mars's CO_2 ice caps are buffered at a temperature near 148 K. On Triton and Pluto, the atmospheric pressure is essentially the SVP of N_2 over N_2 ice at temperatures of 38 and ~40 K, respectively (Brown and Ziegler, 1979; Lellouch et al., 2011; Zalucha et al., 2011).

The presence of even a minor condensable can change the lapse rate considerably, as water vapor does on Earth. Once condensation starts in a cooled, vertically displaced parcel of air, further condensation (into liquid or ice) reduces the rate of cooling by release of latent heat. An SALR, or moist adiabat, denoted Γ_{sa}, occurs when chilled moist air is held at saturation by the warming associated with continual condensation of vapor. This lapse rate is called the pseudoadiabatic lapse rate if condensates are assumed to fall out of the parcel because then the process is not reversible and adiabatic. However, saturated and pseudoadiabats tend to be similar because condensation products carry relatively little heat out of a parcel of air. The SALR can be derived as a function of temperature and saturation mass mixing ratio $\mu_{cms} = (m_c/\overline{m}) f_c = \epsilon(e_s/p)$, where f_c is the volume mixing ratio of the condensable, p is the total pressure, and ϵ is the ratio of molecular masses. In this way, the SALR can be expressed as a modification of the adiabatic lapse rate, that is, $\Gamma_{sa} = \Gamma_a \times f(T, \mu_{cms})$ (e.g., see Andrews (2010), pp. 37–39). Formulations of the SALR for major constituent condensation are also possible (Ingersoll, 1969; Kasting, 1988, 1991).

Under saturated conditions, static stability is controlled by comparing the actual lapse rate to the saturated lapse rate, Γ_{sa}. Air is stable if $\Gamma < \Gamma_{sa}$. For example, on Earth, $\Gamma_{sa} \approx 4\,\mathrm{K\,km^{-1}}$ in warm humid air near the ground, $\Gamma_{sa} \approx 6$–$7\,\mathrm{K\,km^{-1}}$ in the middle troposphere, and Γ_{sa} is close to dry adiabatic in the cold, dry upper troposphere. In the Earth's tropics, observations show that moist convection controls static stability up to ~0.4 bar (Zelinka and Hartmann, 2011).

A further nuance applies to giant planets, where the weight of saturated air parcels is greater than the dry atmosphere unlike the case for water-saturated parcels on Earth or methane-saturated parcels on Titan that tend to be buoyant. Ammonia and water on Jupiter and Saturn have greater molecular mass (17 and $18\,\mathrm{g\,mol^{-1}}$, respectively) than the hydrogen–helium dry atmospheres (2.22 and $2.14\,\mathrm{g\,mol^{-1}}$, respectively), and the same situation applies to methane on Uranus and Neptune. If the abundance of a condensable species drops faster in the environment with altitude than in a rising air parcel, the parcel will tend to be heavy relative to the environment and sink back downward. Consequently, convection on giant planets is favored when the relative humidity in the environment is high and disfavored by a steep compositional gradient in the environment due to condensation. Temperature profiles on Uranus and Neptune are superadiabatic where methane condenses, which suggests that convection may be inhibited there (Guillot, 1995).

SVP also gives us a first-order understanding of clouds. Clouds will form on average where the mean pressure–temperature conditions reach the SVP for various condensables (Sanchez-Lavega et al., 2004) (**Figure 4**).

10.13.3 Radiation

10.13.3.1 Planetary Energy Balance, Blackbody Radiation, and the Greenhouse Effect

Physical and chemical processes in planetary atmospheres are driven by sources of free energy, meaning energy that can do useful work. For most planets, light from the parent star dominates free energy sources, although some giant planets have an internal energy flux that leaks to the exterior and is significant compared to the energy flux received from the parent star.

Consequently, for planetary atmospheres, the solar flux at the top of the atmosphere is a key parameter. Satellites measure the Earth's solar constant as $S_0 = 1360.8 \pm 0.5\,\mathrm{W\,m^{-2}}$ (Kopp and Lean, 2011), consistent with ground-based inferences (Chapman et al., 2012). As a result, the solar flux at the top of the atmosphere averaged over the area of the whole Earth and over time is $S_0/4 \approx 340\,\mathrm{W\,m^{-2}}$. We divide S_0 by 2 to account for glancing angles on a spherical planet, and we divide it by 2 again because only one side of the Earth is in daylight. Alternatively, another way to understand the factor of ¼ is that the solar flux intercepted by a planet of radius R is equivalent to that on a projected disk of area πR^2. So, the ¼ factor represents the ratio of received flux on a disk to the whole planetary area ($\pi R^2/4\pi R^2$) to get a global average in $\mathrm{W\,m^{-2}}$.

A fraction of sunlight's incident power is reflected and scattered back to space, which, over all wavelengths, is called the Bond albedo A (or planetary albedo). For the solar system planets with atmospheres, A ranges from 0.25 for Mars to 0.76 for Venus (Moroz et al., 1985), the giant planets have $A \approx 0.3$, while for Earth, A is 0.3 (Trenberth et al., 2009). Thus, the solar flux absorbed by the Earth's surface and atmosphere is $(1-A) \times (S_0/4) = (1\text{–}0.3) \times (1361\,\mathrm{W\,m^{-2}}/4) \approx 238\,\mathrm{W\,m^{-2}}$.

An essential concept for understanding what happens to the energy on planets is blackbody radiation. All objects emit a spectrum of electromagnetic radiation based on their temperature (e.g., a molten lava emits visible light plus radiation extending into the IR), and for practical purposes, blackbody radiation can be simply considered as an idealized spectrum that depends only on the temperature of the emitting object. Temperature determines the flux of emitted radiation as a function of wavelength, and when the flux is summed over all wavelengths, the total flux depends only on temperature also. Historically, the blackbody concept originated in considering radiation within a closed cavity that had walls that perfectly absorbed and emitted radiation at all wavelengths. At equilibrium, the spectrum was found to be uniquely related to the cavity wall temperature T by the Planck function, $B(T)$:

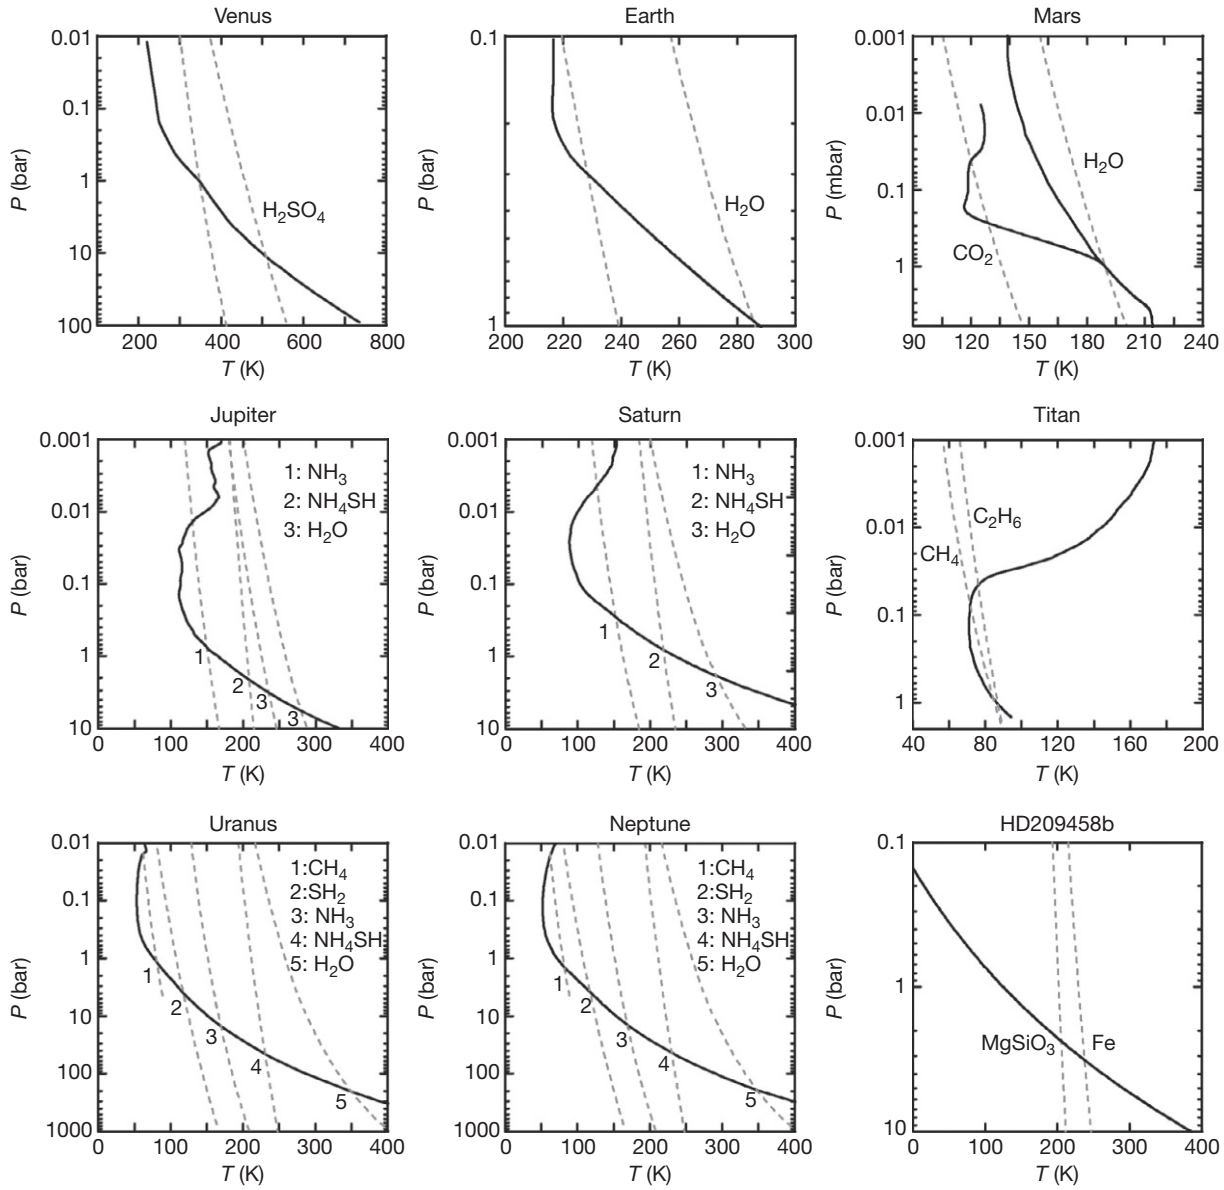

Figure 4 Use of the vapor pressure and saturation vapor pressure (SVP) for various condensables to predict cloud formation in solar system atmospheres and hot Jupiter HD209458b. The solid line is the vertical profile of pressure (p) versus temperature (T). For Mars, an annual average p-T profile is shown as well as a colder profile. The dashed lines are the saturation vapor pressure (SVP) curves for various condensable species, as indicated, assuming a fixed volume mixing ratio of condensable. It is assumed that particles condense when the partial pressure (e) reaches the saturation vapor pressure (e_s), that is, where $e = f_c p(T) e_s(T)$, where f_c is the volume mixing ratio of the condensable. Thus, the base of clouds is marked where a dashed line crosses the solid pressure–temperature profile. Below this level, the phase is vapor because the ambient air is too hot. Various mixing ratios are assumed to calculate the dashed curves as follows: Venus 2 ppm and 2000 ppm H_2SO_4 (where liquid clouds form); the Earth 250 ppm and 1.5% H_2O, giving rise to ice and liquid clouds, respectively; Mars 0.95 CO_2 and 300 ppm H_2O giving ice clouds; Jupiter 200 ppm NH_3, 36 pppm NH_4SH, 50 ppm H_2O, 0.17% H_2O giving solid phase clouds except for the higher water level; Saturn 200 ppm NH_3, 36 pppm NH_4SH, 0.17% H_2O, giving solid particles; Titan 5% CH_4, 10 ppm C_2H_6, giving solid particles; Uranus and Neptune 2% CH_4, 37 ppm SH_2, 200 ppm NH_3, 36 pppm NH_4SH, 0.17% H_2O, giving solid particles; and HD209458b 75 ppm $MgSiO_3$ and 68 ppm Fe, giving solid particles. Reprinted from Sanchez-Lavega A, Perez-Hoyos S, and Hueso R (2004) Clouds in planetary atmospheres: A useful application of the Clausius–Clapeyron equation. *American Journal of Physics* 72: 767–774.

$$\underbrace{B_\upsilon \,\mathrm{d}\upsilon = \frac{2h\upsilon^3}{c^2}\frac{\mathrm{d}\upsilon}{(\mathrm{e}^{h\upsilon/kT}-1)}}_{B_\upsilon \text{ in } \mathrm{Wm^{-2}\,Hz^{-1}\,sr^{-1}}},\quad \underbrace{B_\lambda \,\mathrm{d}\lambda = \frac{2hc^2}{\lambda^5}\frac{\mathrm{d}\lambda}{(\mathrm{e}^{hc/\lambda kT}-1)}}_{B_\lambda \text{ in } \mathrm{Wm^{-2}\,m^{-1}\,sr^{-1}}},$$

$$\underbrace{B_{\tilde{\upsilon}}\,\mathrm{d}\tilde{\upsilon} = 2hc^2\frac{\tilde{\upsilon}^3\,\mathrm{d}\tilde{\upsilon}}{(\mathrm{e}^{hc\tilde{\upsilon}/kT}-1)}}_{B_{\tilde{\upsilon}} \text{ in } \mathrm{Wm^{-2}\,(cm^{-1})^{-1}\,sr^{-1}}} \qquad [20]$$

Here, $h = 6.626 \times 10^{-34}$ J s is Planck's constant and c is the speed of light, which is related to the frequency (υ) and wavelength (λ) of radiation by $c = \upsilon\lambda$. The third expression in eqn [20] is in terms of wavenumber $\tilde{\upsilon} = 1/\lambda$, as used by some spectroscopists. Thus, each form of the Planck function in the preceding text applies when the spectrum is specified in units of frequency (Hz), wavelength (m), or wavenumber (usually $\mathrm{cm^{-1}}$), respectively. In eqn [20], blackbody radiation $B_\upsilon(T)$ is a

radiance (or intensity), which is the power (W) per unit frequency (or wavelength or wave number) interval crossing unit area (m^{-2}) in unit solid angle (steradian^{-1} or sr^{-1}) in a given direction.

A flux density or irradiance (often shortened to just 'flux') has units of $Wm^{-2}\,Hz^{-1}$ (or $Wm^{-2}\,m^{-1}$ or $Wm^{-2}\,cm^{-1}$) and is the intensity integrated over all directions. In spherical polar coordinates, an elemental solid angle is $\sin\theta d\theta d\phi$ where θ is the angle from the polar axis and ϕ is the azimuthal angle. If the intensity B_υ is isotropic (i.e., independent of θ), the flux over an entire hemisphere is π times B_υ, as follows:

$$F_\upsilon = \int_0^{\phi=2\pi}\int_0^{\theta=2\pi} B_\upsilon \cos\theta \underbrace{\sin\theta}_{x}\, d\theta d\phi = 2\pi\int_0^{x=1} B_\upsilon x\, dx$$
$$= 2\pi B_\upsilon \left[\frac{x^2}{2}\right]_0^1 = \pi B_\upsilon \qquad [21]$$

The flux over all frequencies ($W\,m^{-2}$) is found by substituting for B_υ (eqn [20]) in eqn [21] and integrating

$$F = \int_0^\infty \pi B_\upsilon\, d\upsilon = \frac{2\pi h}{c^2}\int_0^\infty \frac{\upsilon^2 d\upsilon}{\left(e^{h\upsilon/kT}-1\right)}$$
$$= \frac{2\pi k^4 T^4}{c^2 h^3} \underbrace{\int_0^\infty \frac{x^3 dx}{(e^x-1)}}_{\text{standard integral}=\pi^4/15} = \left(\frac{2\pi^5 k^4}{15c^2h^3}\right)T^4 \Rightarrow F = \sigma T^4 \qquad [22]$$

Here, we substituted $x = h\upsilon/kT$ to obtain a standard integral. The final expression in eqn [22] is the Stefan–Boltzmann law with the Stefan–Boltzmann constant $\sigma = 5.67\times10^{-8}\,W\,m^{-2}\,K^{-4}$.

Blackbodies are ideal absorbers and emitters, and because planets are made of materials that absorb IR radiation strongly and reach thermal equilibrium, the spectrum that planets emit can be represented by a blackbody. Essentially, a planet absorbs visible sunlight, warms up, and radiates like a blackbody in the IR. When outgoing radiation balances incoming radiation along with an additional internal heat flux F_i (as occurs on the giant planets), the planet achieves an effective temperature T_e, that is, the equivalent blackbody temperature that characterizes the total flux output:

$$\underbrace{(1-A)\frac{S_p}{4}}_{\text{absorbed solar radiation}} + \underbrace{F_i}_{\text{internal heat flux}} = \underbrace{\sigma T_e^4}_{\text{outgoing IR radiation}},$$

$$\text{or } (1-A)\frac{S_p}{4} = \underbrace{\sigma T_{eq}^4}_{\text{outgoing IR radiation}} \quad \text{if } F_i \ll (1-A)\frac{S_p}{4} \qquad [23]$$

Here, S_p is the solar flux at the orbital distance of the planet from the Sun. When the internal heat flux is negligible, the effective temperature is called the equilibrium temperature, T_{eq}, because there is equilibrium between incoming sunlight and outgoing IR. On Jupiter, F_i is $\sim5.4\,W\,m^{-2}$ compared with $8.1\,W\,m^{-2}$ of absorbed sunlight (Hanel et al., 1981). For giant planets, sources of internal energy include gravitational energy released from formation and contraction as well as subsequent internal differentiation. However, unlike the other gas giants, Uranus has little internal heat flow ($42\pm47\,mW\,m^{-2}$ (Pearl et al., 1990)), which is puzzling. For the Earth, $F_i \sim 0.09\,W\,m^2$ can be neglected, $S_p = 1361\,W\,m^{-2}$, and Bond albedo $A = 0.3$. Solving eqn [23] gives equilibrium temperature $T_{eq} = 255$ K, which is also the Earth's effective temperature. Clearly, this temperature is not achieved at the surface, which has a mean temperature of 288 K. For planets with atmospheres, the difference between the surface temperature and effective temperature arises because of the greenhouse effect described in the succeeding text.

An idealized atmospheric level where Earth achieves its effective temperature can be estimated. The Earth's average tropospheric lapse rate is $\sim6\,K\,km^{-1}$, so given the surface temperature of 288 K, the air temperature will be at 255 K at ~5 km altitude. This altitude is called the emission level, although it is somewhat fictitious because in reality, the atmosphere radiates to space from different levels as a function of wavelength, depending upon the IR transparency of the overlying air at that wavelength. Nonetheless, the Earth cannot buck conservation of energy, and in equilibrium, it must radiate a total flux back to space equivalent to a 255 K blackbody of the Stefan–Boltzmann law.

The greenhouse effect is when an atmosphere warms up and provides a flux of thermal IR radiation to the surface (or lower layers of giant planets) that adds to the shortwave solar flux. The surface of a rocky planet with an atmosphere is warmer than it would be without an atmosphere because the surface receives energy from both the Sun and the heated atmosphere. For specificity, the fraction of the total flux reaching the surface due to IR from the atmosphere is about 99.9%, 2/3, 1/3, and 9/10 for Venus, Earth, Mars, and Titan, respectively (Courtin et al., 1992). For rocky planets, the difference between T_{eq} and surface temperature T_s is another way to express the size of the greenhouse effect:

$$\Delta T_g \equiv T_s - T_{eq} \qquad [24]$$

For the Earth, $\Delta T_g = 288 - 255 = 33$ K. Of course, this definition assumes that the albedo would be the same where the air removed – which it certainly would not – so ΔT_g should be viewed judiciously as a useful metric, a way to express the flux difference of about $150\,W\,m^{-2}$ between blackbodies at 255 and 288 K. Of course, slowly rotating airless bodies can have large day–night temperature differences, and so, the mean temperature will be different from the equilibrium temperature, as is well known (Pierrehumbert, 2010).

There are various greenhouse gases. In the Earth's modern clear sky atmosphere, water vapor contributes $\sim$60% of ΔT_g, CO $\sim$25%, and ozone $\sim$8%, with the rest from CH_4, N_2O, anthropogenic chlorofluorocarbons (CFCs), and other trace gases (Karl and Trenberth, 2003; Stephens and Tjemkes, 1993). Importantly, water vapor condenses and exits the atmosphere as rain or snow, whereas the Earth's other main greenhouse gas, CO_2, does not condense. H_2O is effectively 'a slave' to the forcing by the concentration of CO_2. By forcing, we mean a persistent disturbance to the climate system that changes the energy balance. If CO_2 levels goes up, more water vapor enters a warmer atmosphere and increases the greenhouse effect. Thus, the climatic role of water vapor is a feedback rather than a forcing (Lacis et al., 2010, 2013). The bulk background gases that absorb very little IR, such as N_2 and O_2, are themselves

critical for the greenhouse effect because collisions of greenhouse gases (CO_2, H_2O, etc.) with N_2 or O_2 take away or add energy to the greenhouse gas molecules, which allows them to absorb over a much wider range of photon wavelengths. This process of pressure broadening (see **Section 10.13.3.5**) is fundamental to the greenhouse effect in thick atmospheres. On other bodies, rather than just trace gases, the bulk atmospheric gases are greenhouse gases. On all the giant planets, H_2 is the main source of IR opacity (see **Section 10.13.3.5**), on Titan, N_2, H_2, and CH_4 are important (McKay et al., 1991; Samuelson et al., 1981), while CO_2 is the key greenhouse gas on Venus (Bullock and Grinspoon, 2001; Titov et al., 2007) and Mars.

Clouds can cool a planet because of their contribution to the albedo, but they can also warm through adding to the greenhouse effect. For example, on Earth, icy cirrus clouds contribute to greenhouse warming since they are largely transparent to solar radiation but opaque to thermal IR, while low-lying marine stratus predominantly contributes to shortwave albedo. If we take clouds into account in our apportioning of the greenhouse effect on Earth, water vapor is responsible for ~50%, clouds ~25%, CO_2 ~20%, and other gases the remainder (Schmidt et al., 2010). Regarding their cooling effect, clouds contribute about half of the Earth's albedo of 0.3. According to satellite measurements, clouds reduce the Earth's absorbed radiation by $-48\,W\,m^{-2}$, but enhance the greenhouse effect by $+30\,W\,m^{-2}$. So, overall, clouds cool the Earth by $-18\,W\,m^2$ (Ramanathan and Inamdar, 2006). A hypothetical Earth without clouds would be far warmer (Goldblatt et al., 2013).

Like water vapor, clouds are a feedback and change in response to levels of CO_2 and other greenhouse gases. Feedbacks can alter the mean temperature of a planet in positive feedback (like the aforementioned water vapor feedback) or stabilize it in negative feedback. Another important positive feedback is the ice-albedo feedback. An increase in surface temperature causes a decrease in albedo from diminished snow and ice cover, which causes further warming, or the other way, cooling increases albedo with more snow and ice, causing further cooling. The ice-albedo feedback is crucial for understanding the Earth's ice ages during the last few million years (Lorius et al., 1990). Negative feedbacks include an increase in outgoing thermal IR as a planet warms up, operating on short timescales of weeks. Over geologic timescales, geochemical cycles act as negative feedbacks on the Earth's climate. The important one for Earth is the carbonate–silicate negative feedback, which acts over a timescale of ~0.5 My (Berner, 2004; Walker et al., 1981). If the climate warms, greater rainfall and temperatures consume atmospheric CO_2 in weathering reactions on the continents, which cools the Earth. If the climate cools, the consumption of CO_2 from dry air is slowed, and CO_2 accumulates due to volcanic emissions, which increases the greenhouse effect. On long times, negative feedbacks have evidently 'won' overall because the Earth has remained habitable since at least 3.5 Ga (Buick, 2007).

One further importance of blackbody theory is that it tells us the wavelength where most of the radiative energy is emitted from planets and stars. The Planck function is maximal where $\partial B_\lambda/\partial\lambda = 0$, which gives Wien's law:

$$\lambda_{max} T = 2.897 \times 10^{-3}\ \text{meters} \bullet K \qquad [25]$$

The Sun behaves like a blackbody because the ions and electrons inside the Sun are in thermal equilibrium. So, solar radiation has an effective temperature of 5780 K. Wien's law indicates peak emission at $\lambda_{max} = (0.0029\,m\,K)/(5780\,K) = 0.5\,\mu m$, in the visible. The Earth is roughly 20 times cooler than the Sun's surface, and so, its Wien peak is 20 times larger at ~10 μm. Given typical temperatures, planets generally have their Wien peak at thermal IR wavelengths, which is where many atmospheric gases and aerosol particles absorb strongly.

Several atmospheres have windows, which are spectral intervals that are relatively transparent to thermal IR compared to high opacity at other wavelengths. A window can be a key means for a planet to radiate IR energy to space and cool. On Titan, a window at 16.5–25 μm is close to Titan's Wien peak of 31 μm. H_2, which is a minor constituent (~0.1%), absorbs weakly in this window (McKay et al., 1989). On Earth, the key atmospheric window of 8–12 μm encompasses the Wien peak at ~10 μm. Again, absorption by a minor constituent, water vapor, modulates the outgoing IR flux through the window. On Venus, dense CO_2 and clouds leaves only a few narrow windows in the near-IR. The significant ones are 1–1.2 μm in which only H_2O absorbs, 1.7 μm where CO and HCl absorb, and 2.2–2.5 μm where CO and SO_2 are seen (Crisp and Titov, 1997; Titov et al., 2007). These are wavelengths to peer relatively deep into Venus' atmosphere, which is otherwise opaque.

10.13.3.2 Radiative Transfer: Shortwave and Infrared

Atmospheres like the Earth's are transparent to incoming solar radiation but not entirely. The ozone in the Earth's stratosphere absorbs solar UV (0.2–0.4 μm) in the Hartley and Huggins bands, and ozone in both the stratosphere and troposphere absorbs visible light in the 0.4–0.85 μm Chappuis band. The Earth's tropospheric water vapor absorbs solar near-IR (1–4 μm region). A more extreme case is Titan's stratospheric methane and haze of aerosols, which absorb in the UV, visible, and near-IR (for methane) to such an extent that the reduction of solar flux reaching Titan's surface is called an antigreenhouse effect (McKay et al., 1989, 1991). Temporary antigreenhouse effects are also possible from debris raised in asteroid impacts (Pollack et al., 1983) or, on Earth, smoke created in nuclear war (Robock et al., 2007; Turco et al., 1983).

Radiative transfer restricted to the visible and UV is simpler than in the IR because the Planck function (eqn [20]) indicates that we can neglect visible or UV emission at temperatures typical of planetary surfaces and atmospheres. This is not true for IR calculations. The starting point in radiative transfer is the extinction law (or Beer–Lambert–Bouguer law). Experiments show that the loss of intensity of a beam of light of frequency ν passing through a substance depends linearly on the incident intensity I_ν and the elemental mass of absorbing or scattering material expressed as $\rho_a\,ds$, where ρ_a is the density of the absorber or scatterer ($kg\,m^{-3}$) and ds is the elemental path length:

$$dI_\nu = -k_\nu I_\nu \rho_a ds \Rightarrow I_\nu = I_{\nu 0}\exp\left(-\int_0^s k_\upsilon \rho_a\, ds'\right) = I_{\nu 0} e^{-\tau_\nu} \qquad [26]$$

Here, the proportionality constant k_υ is the mass extinction coefficient ($m^2\,kg^{-1}$) or opacity. In eqn [26], $I_{\nu 0}$ is the intensity at distance $s = 0$ and τ_ν is a dimensionless optical path or

optical thickness along the beam direction. We usually define our optical path as increasing from the top of the atmosphere downward. In this geometry, we call τ_v the optical depth. In the case of a pencil beam inclined at zenith angle θ (from the vertical), the elemental path along the beam ds is related to that along the vertical path dz by geometry as $\cos\theta = dz/ds$. Replacing ds in eqn [26] by $dz/\cos\theta$ gives

$$I_v = I_{v0} e^{-\tau_v/\cos\theta} \Rightarrow \text{transmissivity } T_v = e^{-\tau_v/\cos\theta} \quad [27]$$

Here, the transmissivity (or transmittance) T_v is the ratio of light getting through (I_v) to the incident intensity (I_{v0}).

The visible optical depth can be large in planetary atmospheres. On Mars, the broadband visible optical depth in global dust storms reaches ~5 (Colburn et al., 1989; Kahn et al., 1992), which means that direct-beam sunlight is attenuated by a factor of $e^{-5} \approx 1/148$. On Titan's surface at 0.5 μm visible wavelength, the extinction optical depth is ~10 due to atmospheric haze (Tomasko and West, 2009). However, these surfaces are not dark because the total flux at the ground is the sum of a direct flux from the Sun's direction and a diffuse flux from the whole sky. The diffuse flux includes all scattered solar radiation from the sky, including scattered light from clouds or particles that is not in the direct beam. On Mars, for example, much light scattered by dust out of the direct solar beam reaches the ground diffusely (Haberle et al., 1993a). On Earth, when the sky is covered by dense cloud and the Sun cannot be seen, the ground is similarly well illuminated by a diffuse flux.

The extinction coefficient k_v considered in the preceding text is the sum of absorption and scattering due to gases or aerosols. We define the ratio of scattering to extinction as single scattering albedo ω_0,

$$k_v = \underbrace{a_v}_{\text{absorption coefficient}} + \underbrace{s_v}_{\text{scattering coefficient}}, \quad \omega_0 = \frac{s_v}{a_v + s_v} \quad [28]$$

The single scattering albedo is 1 for purely scattering media and <0.5 for strongly absorbing media. It is one of the three key parameters used to characterize optical properties of aerosols or cloud particles. The second is a volume absorption (or scattering) coefficient defined as $Q_{as}A_{xs}n$, where Q_{as} is a dimensionless absorption or scattering efficiency (when absorption and scattering are combined, Q_{as} can be redefined as an extinction efficiency), A_{xs} is the geometric cross section, and n is number density. Thus, we would write $dI_v = -I_v Q_{as} n A_{xs} ds$ in eqn [26]. For terrestrial cloud droplets, $Q_{as} \sim 2$ in the visible. The third parameter is the asymmetry factor g_s, a function that indicates whether scattering is isotropic ($g_s = 0$) or scatters in the forward ($0 < g_s \leq 1$) or backward ($-1 \leq g_s < 0$) direction. These parameters are used in models of scattering; for example, see Petty (2006).

Absorption of photons warms aerosols, causing them to heat atmospheres during daytime (e.g., dust on Mars (Pollack et al., 1979) or black carbon on Earth (Ramanathan and Carmichael, 2008)), while for gases, absorption can excite a molecule or atom into vibration or rotation or both. At high pressures, collisions generally occur before an excited atom or molecule undergoes radiative decay and emits a photon in a random direction, with the result that vibrational or rotational energy is converted into KE and heat, called thermalization or quenching. Absorption of EUV photons in the upper atmosphere can instead create ions in photoionization or break molecules in photodissociation.

In contrast to absorption, scattering is when radiation is redirected out of the original direction of propagation as a result of interaction with aerosols or when radiative decay of a molecule emits a photon in a random direction, attenuating the direct beam. The type of scattering can be diagnosed from the size of a scatterer using a dimensionless size parameter, where r_p is the scatterer radius and λ is the wavelength of radiation,

$$x = \frac{2\pi r_p}{\lambda} \quad [29]$$

For gas molecules or particles with $r_p \ll 1$, the scattering of solar radiation is Rayleigh scattering, which is isotropic with a scattering efficiency $Q_s \propto \lambda^{-4}$, a strong wavelength dependence that causes the Earth's blue sky when convolved with the solar spectrum. Aerosols (dust, smoke, and cloud droplets) with $0.1 < x < 50$ scatter according to Mie scattering (for spherical particles), typically with forward scattering. Mie theory gives the electromagnetic field around a dielectric particle. Photons can be scattered into the beam and scattered out of the beam in multiple scattering by aerosols. Finally, for particles with $x > 50$, there is just geometric scattering, where $Q_s \approx 2$ and the scattering cross section grows in proportion to the cross-sectional area πr_p^2.

To deduce information about the atmospheric structure and composition, we frequently view an IR spectrum from a planet remotely. On Earth, satellite measurements show that our planet does not have the smooth idealized curve of the Planck function but has big 'dips' in the spectrum compared to a blackbody curve at ~320 K surface temperature (in the case of **Figure 5(a)**) because of absorption by key greenhouse gases. The bottom of the dips indicates the effective temperature of the emission where photons are emitted not from the surface but a cooler atmospheric level, for example, the bottom of the CO_2 band at 15 μm emits at about the tropopause temperature, while water vapor at 20 μm emits from around the mid-troposphere (**Figure 5(b)**). The area under the Planck curves gives the total power emitted, which is reduced by the area of the dips. Thus, in order to maintain equilibrium between solar flux received and planetary flux emitted, the surface temperature (which is seen in the atmospheric window at 8–12 μm) increases above a 255 K blackbody curve. Effectively, **Figure 5(a)** visualizes the Earth's greenhouse effect.

To make a quantitative sense of remote measurements such as those in **Figure 5(a)**, we use the physics of IR radiative transfer. If we consider a monochromatic beam of radiance I_v [W m^{-2} Hz^{-1} sr^{-1}] passing through an elemental path ds, then the intensity change will be that emitted into the beam minus that extinguished by absorption or scattering:

$$dI_v(s) = \underbrace{(k_v \rho_a ds) J_v}_{\text{light scattered in or emitted}} - \underbrace{(k_v \rho_a ds) I_v}_{\text{extinction}} \Rightarrow \frac{dI_v}{k_v \rho_a ds} = J_v - I_v \quad [30]$$

Here, ρ_a is the density of the absorbing or scattering gas and J_v [W m^{-2} Hz^{-1} sr^{-1}] is a source function, which accounts for thermal emission or scattering into the beam. The term labeled 'extinction' uses the extinction law, eqn [26]. The final expression in eqn [30] is the general radiative transfer equation with

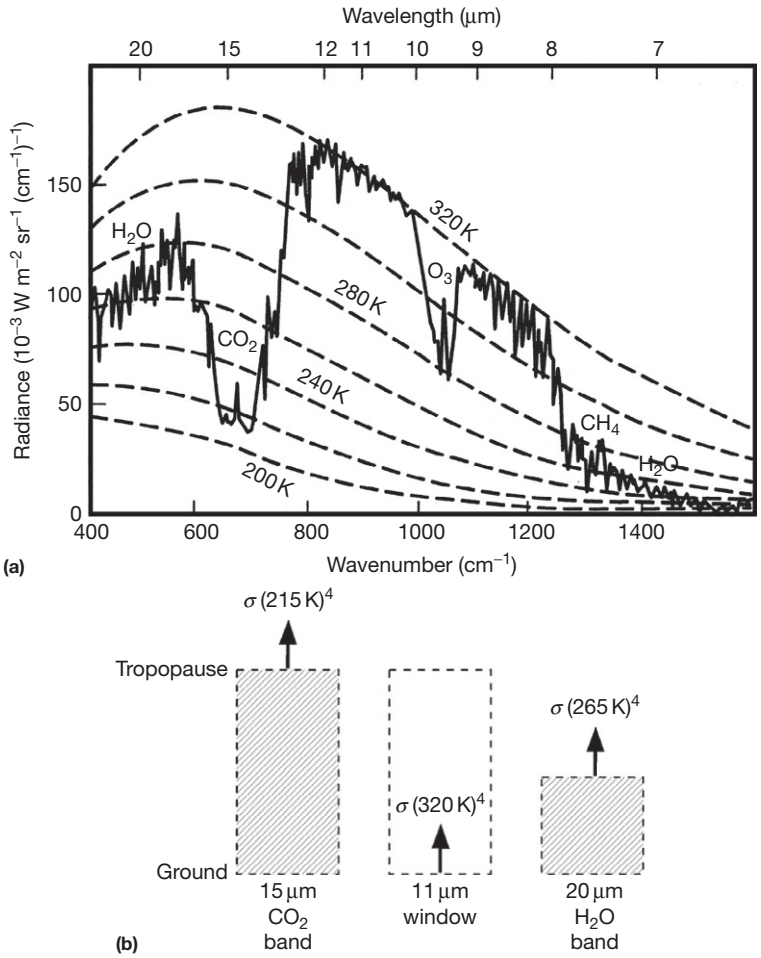

Figure 5 (a) The Planck function for noon over a vegetated region of the Niger Valley in N. Africa where the surface temperature is 320 K. Dashed lines show blackbody curves for particular temperatures (Adapted from Hanel RA, Conrath BJ, Kunde VG, et al. (1972) The Nimbus 4 infrared spectroscopy. Experiment, I: calibrated thermal emission spectra. *Journal of Geophysical Research* 77: 2629–2641). (b) A schematic diagram showing the meaning of parts of the curve in (a). The arrows indicate the layers in the atmosphere where blackbody fluxes originate, according to the Stefan–Boltzmann law. (Drawn by the author.)

no particular coordinate system or assumption about whether the source function behaves like a blackbody or not.

Next, we impose a coordinate system and assume that the medium is a blackbody, that is, a purely absorbing, non-scattering medium in thermal equilibrium with source function $J_\nu = B_\nu =$ the Planck function and k_ν the mass absorption coefficient. Minus signs are confusing in radiative transfer due to different geometric conventions, so let us be clear that we now define our IR optical depth as measured downward along a path s, that is, τ is zero at an observer at $s = \infty$ and increases backward along the beam to some value τ inside the atmosphere. Thus,

$$\tau = \int_s^\infty k_\nu \rho_a \, ds = \int_{\tau=\tau}^{\tau=0} -d\tau, \quad \text{or} \quad \text{if } s \text{ is altitude:}$$

$$\tau = \int_z^\infty k_\nu \rho_a \, dz = \int_{\tau=\tau}^{\tau=0} -d\tau \qquad [31]$$

With these assumptions, the equation of radiative transfer becomes

$$\frac{dI_\nu(s)}{d\tau_\nu(s_1, s)} = I_\nu(s) - B_\nu(s) \qquad [32]$$

where the elemental optical path $d\tau$ is between distance s and some distance s_1. This is sometimes called Schwarzschild's equation after Karl Schwarzschild who first considered such a radiative transfer equation for the Sun's atmosphere in 1914. With a little work, a solution to eqn [32] can be found by multiplying by an integrating factor, $e^{-\tau_\nu(s_1, s)}$, integrating between 0 and s_1, and rewriting as

$$I_\nu(s_1) = I_{\nu 0} e^{-\tau_\nu(s_1, 0)} + \int_0^{s_1} B_\nu(s) e^{-\tau_\nu(s_1, 0)} k_\upsilon \rho_a \, ds \qquad [33]$$

The first term is just the exponential attenuation of the emission from $s = 0$ to $s = s_1$. The second is the sum of the contributions from each point s along the path 0 to s_1, each exponentially attenuated by the path length to the observer.

Another useful form of the radiative transfer equation makes the plane-parallel approximation, that is, where pressure, temperature, and composition are assumed to be functions of height only. Then, if a beam of radiance I_ν passes upward

through a layer of depth dz at an angle θ to the vertical, geometry gives $dz = ds\cos\theta = (ds)\mu$, defining the cosine of zenith angle as $\mu = \cos\theta$. Given our definition of optical depth (eqn [31]), the equation for radiative transfer in a plane-parallel atmosphere is a slight modification of eqn [32], as follows, where we return to generality by using J_ν:

$$\mu\frac{dI_\nu}{d\tau_\nu} = I_\nu - J_\nu \qquad [34]$$

If we imagine looking down on a planet from some level in the atmosphere, we integrate eqn [34] from that level where the optical depth is τ to the surface where $\tau = \tau_*$. Given τ as a limit of integration, we use a dummy variable $\tau' - \tau$ in the integral for path lengths. To obtain the upward intensity at any level where the optical depth is τ, we multiply by an integrating factor $e^{-(\tau'-\tau)/\mu}$ and solve. Assuming that a υ (frequency) subscript on τ is implicit, the solution for upward intensity is

$$I_\nu(\tau)^\uparrow = I_\nu(\tau_*)e^{-(\tau_*-\tau)/\mu} + \int_\tau^{\tau_*} J_\nu(\tau')e^{-(\tau'-\tau)/\mu}\frac{d\tau'}{\mu} \quad \left(1 \geq \mu > 0\right) \qquad [35]$$

where the arrow superscript indicates upward. If we are looking down from space, we simply put $\tau = 0$ in the limit of integration, and the intensity observed at the satellite instrument is

$$I_\nu(\tau=0)^\uparrow = \underbrace{I_\nu(\tau_*)e^{-\tau_*/\mu}}_{\text{surface contribution}} + \underbrace{\int_0^{\tau_*} J_\nu(\tau')e^{-\tau'/\mu}\frac{d\tau'}{\mu}}_{\text{contributions along the path}} \qquad [36]$$

Here, the first term is the extinction along the path from the ground to the spacecraft where $I_\nu(\tau_*)$ is the upward intensity at the ground. The second term is the upward emission contribution from points along the path to the spacecraft. Here, $J_\nu(\tau')$ corresponds to emission in the upward direction. The same expression can also be written in altitude coordinates but is more complicated:

$$I_\nu(z)^\uparrow = I_\nu(z=0)e^{-\frac{1}{\mu}\int_0^z k_\nu(z')\rho_a(z')dz'} + \int_0^z k_\nu(z')\rho_a(z')J_\nu(z')e^{-\frac{1}{\mu}\int_0^z k_\nu\rho_a dz''}\frac{dz'}{\mu} \qquad [37]$$

We derive a hemispheric monochromatic flux F_ν from the measured intensity I_ν at a particular frequency ν by integrating over a hemisphere. Then, we derive a total flux (W m^{-2}) by integrating over all frequencies. We will use eqn [37] in the succeeding text.

10.13.3.3 Optical Thickness and Thinness

Vertical sections of atmospheres are described as optically thick ($\tau_\nu \gg 1$) or optically thin ($\tau_\nu \ll 1$) to radiation of a particular frequency. 'Optically thick' just means opaque to a particular frequency or frequency band of radiation, and 'optically thin' means nearly transparent. This is a useful concept in looking at spectra such as **Figure 5(a)**. The IR photons can be thought of as 'escaping' from the level where the IR optical depth drops below ~1 and then passing up through overlying 'optically thin' or IR-transparent air to space. We can also apply the idea to incoming solar flux. Solar photons are mainly absorbed in the atmosphere near the level of unity optical depth for a particular UV or visible wavelength. As a result, UV heating or ionization can occur at this level.

It is possible to justify the concept of absorption near $\tau_\nu \sim 1$ quantitatively for both solar and IR radiation. For solar radiation, we work with fluxes directly because of the typical lack of emission in atmospheres at solar frequencies. Within a planetary atmosphere at height z, the vertical component of direct flux crossing a surface parallel to the ground for a solar beam at zenith angle θ and frequency ν can be deduced from the extinction law (eqn [27]) as

$$F_\upsilon = \mu F_{\upsilon\odot}e^{-\tau_\upsilon/\mu} \qquad [38]$$

The volume heating rate Q [W m^{-3} Hz^{-1}] is related to how this flux changes with altitude due to absorption by the expression, $Q = -(dF_{\text{net},\nu}/dz)$, where $F_{\text{net},\nu}$ is the net flux, that is, the upward minus the downward flux. With no upward solar flux, the heating rate is

$$Q = \frac{dF_\upsilon}{dz} = \underbrace{\frac{dF_\upsilon}{d\tau}}_{-k_\upsilon\rho_\upsilon}\frac{d\tau_\upsilon}{dz} = \left(-\frac{1}{\mu}\mu F_{\upsilon\odot}e^{-\tau_\upsilon/\mu}\right)(-k_\upsilon\rho_\upsilon) \Rightarrow Q = (k_\upsilon\rho_\upsilon F_{\upsilon\odot})e^{-\tau_\upsilon/\mu} \qquad [39]$$

Initially, the value of Q in eqn [39] increases downward as the term $k_\nu\rho_\nu$ in the curved brackets increases because τ_ν is small at the top of the atmosphere and the exponential factor is near 1. Eventually, the optical depth becomes significant, so the term exp $(-\tau_\upsilon/\mu)$ begins to dominate over the downward increase of $k_\nu\rho_\nu$, and Q begins to decrease exponentially downward toward zero. We deduce that Q has a single maximum at some altitude in between.

We find the maximum in Q by differentiating w.r.t. z, using the product rule and setting $dQ/dz = 0$

$$\frac{dQ}{dz} = 0 = \left(k_\upsilon\rho_\upsilon\right)\left(\cancel{F_{\upsilon\odot}e^{-\tau_\upsilon/\mu}}\frac{\left(k_\upsilon\rho_\upsilon\right)}{\mu}\right) + \cancel{F_{\upsilon\odot}e^{-\tau_\upsilon/\mu}}\frac{d\left(k_\upsilon\rho_\upsilon\right)}{dz}$$
$$\Rightarrow -\frac{d\left(k_\upsilon\rho_\upsilon\right)}{dz} = \frac{\left(k_\upsilon\rho_\upsilon\right)^2}{\mu} \Rightarrow \frac{d^2\tau_\nu}{dz^2} = \frac{1}{\mu}\left(\frac{d\tau_\nu}{dz}\right)^2 \qquad [40]$$

In the last step, we use $d\tau_\upsilon/dz = -k_\upsilon\rho_\upsilon$ from the definition of optical depth (eqn [31]). Because the density of absorbing gases usually drops exponentially with increasing height and the absorption coefficient is either constant or an approximate power law relationship with pressure, optical depth should vary approximately exponentially with altitude, that is, $\tau_\upsilon = \tau_{\upsilon 0}$ exp (z/H_τ) where H_τ is a scale height for the optical depth. If this expression for τ_υ is inserted into eqn [40], after a little manipulation, an important result is obtained that $dQ/dz = 0$ occurs where

$$\tau_\upsilon \sec\theta = 1, \quad \text{or} \quad \tau_\upsilon = 1 \quad \text{when zenith angle } \theta = 0 \qquad [41]$$

Thus, at any frequency, the maximum volume heating rate Q, or related effect such as dissociation or ionization, occurs where the optical depth is unity for normal incidence radiation. The altitude is higher by factor sec θ for solar radiation incident at zenith angle θ. Also, the characteristic width of activity is $\sim H_\tau$. Such a vertical structure is called a 'Chapman layer'.

A similar insight about the importance of unity optical depth applies in the thermal IR for atmospheres that are

optically thick at depth, that is, when we cannot see the surface emission looking downward from space. In our expression for upward intensity from an atmosphere (eqn [37]), we neglect the first term due to surface radiation, extend the integral to the whole atmosphere, and assume blackbody emission. Then,

$$I_\nu(\infty)\uparrow \approx \sec\theta \int_0^\infty k_\nu \rho_a B_\nu \exp\left[-\sec\theta \int_z^\infty k_\nu \rho_a dz'\right] dz$$
$$\Rightarrow I_\nu(\infty)\uparrow = \sec\theta \int_0^\infty B_\nu W_\nu \, dz \qquad [42]$$

where W_ν is a weighting function, defined by

$$W_\nu(z) \equiv k_\nu(z)\rho_a(z)\exp\left[-\sec\theta \int_z^\infty k_\nu(z')\rho_a(z')dz'\right] \qquad [43]$$

Equation [42] says that the radiance to space is a weighted vertical integral of the Planck function. The weighting function W_υ is mathematically similar to heating rate Q in eqn [39]. Just like Q, function W_υ is zero at the bottom of the atmosphere where the exponential reaches zero, W_υ is zero at the top of the atmosphere where density is zero, and W_υ has a maximum in between. As a result, the monochromatic IR radiance comes from a layer with characteristic thickness that is a scale height in optical depth or smaller and centered where optical depth has exactly the same $\tau_\upsilon \sim 1$ condition as eqn [41]. For frequencies with large $k_\upsilon \rho_a$ that are highly absorbing, the $\tau_\upsilon \sim 1$ peak of the weighting function W_υ will be high up (large z), given that τ_υ is the integral of $k_\upsilon \rho_a$ from z to ∞. This is seen in a planetary IR spectrum such as **Figure 5(a)** in dips where greenhouse gases absorb. The dependence of $I_\nu(\infty)\uparrow$ on gas composition and wavelength in eqn [42] is also how we deduce the temperature and chemical structure of planetary atmospheres using remote sensing, for example, from orbiters around other planets or ground-based telescopes.

10.13.3.4 Radiative–Convective Equilibrium

Combining the theory of convection (**Section 10.13.2.4**) and radiation (**Sections 10.13.3.1–10.13.3.3**) allows us to understand the average vertical structure of planetary atmospheres quantitatively given that it is primarily controlled by these processes.

A hypothetical atmospheric structure determined only by radiation balance (ignoring convection) will generate an unrealistic temperature profile in an IR-opaque troposphere with a steep temperature gradient that is actually unstable to convection. Conceptually, a temperature profile for purely radiative transfer for a stratosphere and upper troposphere has to be joined to a convective profile below with both continuities of temperature and flux. How do we calculate this? For analytic calculations, three approximations are made, as follows:

- The first is a gray approximation, where the thermal opacity of the atmosphere is assumed to be independent of wavelength and represented by a single, broadband value. 'Gray opacity' should be viewed as a fitting parameter to match an observed thermal structure. It rarely makes sense to laboriously compute gray opacities from spectral averaging, and it is a misconception to consider gray opacities as 'real' properties of atmospheres, given that the real opacity is wavelength-sensitive. Instead, a gray optical property gives a characterization of an atmosphere that is useful for semi-quantitative comparison of planetary atmospheres.
- The second is that the diffuse approximation is implemented. This replaces radiances I and B in Schwarzschild's radiative transfer equation with fluxes, with the optical depth scaled by a factor D, called the diffusivity factor to account for the integration of the radiances over a hemisphere. A value of $D = 1.66$ is close to numerical results (Armstrong, 1968; Rodgers and Walshaw, 1966) and equivalent to assuming an average zenith angle of 53°, that is, $1/\mu = \sec\theta = 1.66$, in eqn [34]. Others set $D = 3/2$ (Goody and Yung, 1989; Weaver and Ramanathan, 1995) or $D = 2$.
- The third simplification is to handle thermal IR with a two-stream approximation, in which upward (F^+) and downward (F^-) fluxes are treated separately.

Radiative–convective equations are easiest to formulate with optical depth τ as the vertical coordinate but can be converted into physical space using a relationship between τ and pressure. In a plane-parallel atmosphere, Schwarzschild's equation (eqn [34]) for the upwelling and downwelling thermal radiative fluxes (F^+ and F^-, respectively) can be written as

$$\frac{dF^+}{d\tau} = D(F^+ - \pi B), \quad \frac{dF^-}{d\tau} = -D(F^- - \pi B);$$
$$\text{where } \pi B(\tau) = \sigma T^4(\tau) \qquad [44]$$

Equation [44] allows calculation of upwelling and downwelling thermal fluxes if $T(\tau)$ is specified. The net thermal flux is $F_{net} = F^+ - F^-$. Subtracting $dF^-/d\tau$ from $dF^*/d\tau$ in eqn [44], we get

$$\frac{dF_{net}}{d\tau} = D(F^+ + F^- - 2\pi B) \qquad [45]$$

and differentiating w. r. t. τ gives

$$\frac{d^2F_{net}}{d\tau^2} = D\left(\underbrace{\frac{d(F^+ + F^-)}{d\tau}}_{DF_{net}} - 2\pi\frac{dB}{d\tau}\right) \Rightarrow \frac{d^2F_{net}}{d\tau^2} - D^2F_{net} = -2\pi D\frac{dB}{d\tau} \qquad [46]$$

In the last step, addition of $dF^-/d\tau$ and $dF^+/d\tau$ from eqn [44] gives $d(F^+ + F^-)/d\tau = DF_{net}$. Equation [46] can be solved for blackbody radiance $B(\tau)$ and the atmospheric temperature profile using the Stefan–Boltzmann law if $F_{net}(\tau)$ and a boundary condition are known.

Boundary conditions involve the solar flux. In the solar system, atmospheres absorb solar radiation in the troposphere or at the surface and partly in stratospheres. The latter often leads to stratospheric temperature inversions (**Figure 2**), while absorption in tropospheres can stabilize upper tropospheres against convection, as happens on Titan. Exponential attenuation is a reasonable approximation for solar radiation, so the net absorbed stellar flux $F^\odot_{net}$ can be written as (Robinson and Catling, 2012)

$$F^\odot_{net}(\tau) = \underbrace{F^\odot_{net} e^{-k_{tropo}\tau}}_{\text{tropospheric (and surface) solar absorption}} + \underbrace{F^\odot_{strato} e^{-k_{stratio}\tau}}_{\text{stratospheric solar absorption}} \qquad [47]$$

Here, $F^\odot_{strato}$ and $F^\odot_{tropo}$ are the top-of-atmosphere net absorbed stellar fluxes in the stratosphere and troposphere (including

the surface for planets with surfaces), respectively. Parameters $k_{\text{strato}} = \tau_{\text{sws}}/\tau$ and $k_{\text{tropo}} = \tau_{\text{swt}}/\tau$ control the attenuation of solar flux in two channels, where τ_{sws} and τ_{swt} are shortwave optical depths and τ is the gray thermal IR optical depth. At the top of the atmosphere, where $\tau = 0$, the net absorbed stellar flux must be (eqn [23])

$$F^{\odot}_{\text{net}}(\tau = 0) = (1 - A)\frac{F^{\odot}}{4} \qquad [48]$$

where A is the planet's Bond albedo and $F^{\odot}$ is the solar flux incident at the top of the atmosphere. The overall energy balance at any atmospheric level is between the net thermal flux with the absorbed stellar flux and any internal energy flux, F_{i} from a planet's interior (relevant for giant planets):

$$F_{\text{net}}(\tau) = F^{\odot}_{\text{net}}(\tau) + F_{\text{i}} \qquad [49]$$

By combining eqn [47] with eqn [49] and inserting into eqn [46], we obtain

$$\frac{\mathrm{d}\sigma T^4}{\mathrm{d}\tau} = \frac{1}{2D}\left[\left(D^2 - k^2_{\text{tropo}}\right)F^{\odot}_{\text{tropo}}\mathrm{e}^{-k_{\text{tropo}}\tau} + \left(D^2 - k^2_{\text{strato}}\right)F^{\odot}_{\text{strato}}\mathrm{e}^{-k_{\text{strato}}\tau} + D^2 F_{\text{i}}\right] \qquad [50]$$

which integrates to

$$\sigma T^4(\tau) = \sigma T^4(0) + \frac{1}{2D}\left[\frac{D^2 - k^2_{\text{tropo}}}{k_{\text{tropo}}}\left(1 - \mathrm{e}^{-k_{\text{tropo}}\tau}\right)F^{\odot}_{\text{tropo}} + \frac{D^2 - k^2_{\text{strato}}}{k_{\text{strato}}}\left(1 - \mathrm{e}^{-k_{\text{strato}}\tau}\right)F^{\odot}_{\text{strato}} + D^2 F_{\text{i}}\tau\right] \qquad [51]$$

The flux at the top of the atmosphere in this equation ($\sigma T^4(0)$) can be eliminated by applying the boundary condition that there is no downwelling thermal radiation at the top of the atmosphere where $\tau = 0$. We first use the definition $F_{\text{net}} = F^{+} - F^{-}$ to rewrite eqn [45] as

$$\frac{\mathrm{d}F_{\text{net}}}{\mathrm{d}\tau} = D\left(F_{\text{net}} + 2F^{-} - 2\sigma T^4\right) \qquad [52]$$

and, second, we solve for σT^4 using eqns [49] and [47]:

$$\sigma T^4(\tau) = F^{-}(\tau) + \frac{1}{2}\left[\frac{D + k_{\text{tropo}}}{D}F^{\odot}_{\text{tropo}}\mathrm{e}^{-k_{\text{tropo}}\tau} + \frac{D + k_{\text{strato}}}{D}F^{\odot}_{\text{strato}}\mathrm{e}^{-k_{\text{strato}}\tau} + F_{\text{i}}\right] \qquad [53]$$

Third, inserting $\tau = 0$, and noting that $F^{-}(0)$ is zero, gives $\sigma T^4(0)$. Inserting $\sigma T^4(0)$ into eqn [51] gives a final expression for the temperature profile in the radiative part of a gray atmosphere that sits above a radiative–convective boundary and extends into the stratosphere:

$$\sigma T^4(\tau) = \frac{F^{\odot}_{\text{strato}}}{2}\left[1 + \frac{D}{k_{\text{strato}}} + \left(\frac{k_{\text{strato}}}{D} - \frac{D}{k_{\text{strato}}}\right)\mathrm{e}^{-k_{\text{strato}}\tau}\right] + \frac{F^{\odot}_{\text{tropo}}}{2}\left[1 + \frac{D}{k_{\text{tropo}}} + \left(\frac{k_{\text{tropo}}}{D} - \frac{D}{k_{\text{tropo}}}\right)\mathrm{e}^{-k_{\text{tropo}}\tau}\right] + \frac{F_{\text{i}}}{2}(1 + D\tau) \qquad [54]$$

If there are no internal heat ($F_{\text{i}} = 0$) and no solar attenuation (the limit $k_{\text{strato}} = k_{\text{tropo}} \to 0$, applying l'Hôpital's rule), eqn [54] reduces to $\sigma T^4(\tau) = (F^{\odot}_{\text{net}}(0)/2)(1 + D\tau)$, which is a common form for simple radiative models in textbooks (e.g., Andrews (2010), p. 85; Goody and Yung (1989), p. 392). Using $\sigma T^4(\tau)$ in eqn [54], the downwelling flux can also be deduced from eqn [53] and the upwelling flux from a similar expression.

We can now ask: what is required for an atmosphere to have a strong stratospheric temperature inversion and thus a well-developed tropopause minimum? The minimum occurs in the radiative regime, and we can simplify eqn [54] by omitting terms in tropospheric shortwave attenuation, that is, $k_{\text{tropo}} \ll 1$, which is the case for real atmospheres. Then, setting the derivative w.r.t. τ of the resulting expression to zero, the optical depth of the tropopause minimum is (Robinson and Catling, 2014)

$$\tau_{\text{tp}} = \underbrace{\frac{1}{k_{\text{strato}}}}_{\sim 1/100}\underbrace{\ln\left[\underbrace{\frac{F^{\odot}_{\text{strato}}}{F^{\odot}_{\text{tropo}} + F_{\text{i}}}}_{\sim 1/10}\underbrace{\left(\frac{{k_{\text{strato}}}^2}{D^2} - 1\right)}_{\sim 10^3}\right]}_{\sim 5} \qquad [55]$$

The numbers given under parts of eqn [55] are typical averages for the Earth, Titan, and the giant planets, which all have stratospheres and tropopause minima (**Table 4**). Using these numbers, the gray IR optical depth where the tropopause minimum occurs is $\tau_{\text{tp}} \sim 0.05$. This optical depth depends on $F^{\odot}_{\text{strato}}/(F^{\odot}_{\text{tropo}} + F_{\text{i}})$, which is the ratio of the stratospheric absorbed flux relative to that from below and k_{stratio}, which is the ratio of shortwave optical depth to IR optical depth in the stratosphere. Equation [55] only makes mathematical sense if

$$k^2_{\text{strato}} > D^2\left[1 + \left(F^{\odot}_{\text{tropo}} + F_{i}\right)/F^{\odot}_{\text{strato}}\right] \qquad [56]$$

which sets a threshold condition on k_{strato} for a tropopause minimum or, alternatively, the condition for a stratospheric temperature inversion. It tells us that to have a stratospheric inversion, an atmosphere has to have a large k_{strato}, that is, a strong shortwave absorber with a shortwave optical depth that dominates over the IR opacity; otherwise, cooling to space by the IR-active molecules cancels shortwave heating of a stratosphere. Typical flux ratios in the planets of the solar system in eqn [56] mean that k_{strato} must be $\sim 10^2$ for a well-developed tropopause minimum.

The condition for a stratospheric inversion (eqn [56]) is satisfied by some planets but not by others depending on stratospheric composition and the balance of shortwave absorption to IR cooling (**Table 5**). The Earth's stratospheric ozone absorbs strongly in the UV, so k_{strato} is large and heating is not overwhelmed by emission by CO_2 at 15 μm, water vapor, or ozone at 9.6 μm. Consequently, the Earth has a stratospheric inversion. In contrast, CO_2 in the atmospheres of Mars and Venus does not absorb strongly in the visible or solar near-IR; instead, in the upper atmosphere, the 15 μm band of CO_2 radiates heat to space efficiently. Thus, k_{strato} is too small for stratospheric inversions in the global average on Mars and Venus. On the giant planets, dark stratospheric aerosols absorb in the UV and visible, while methane has many

[a]For Titan, $\tau_0 = 2.5$ at $p = 1$ bar.

Parameters inferred from measurements include a tropospheric reference pressure (P_{ref}) and temperature (T_{ref}), an empirical adjustment factor applied to the dry adiabat to account for volatile condensation (α_c) (eqn [59]), an internal energy flux (F_i), and the solar flux absorbed in the stratosphere ($F_{strato}^{\odot}$) and troposphere ($F_{tropo}^{\odot}$). For rocky bodies, $F_{tropo}^{\odot}$ includes surface absorption. For example, the Earth has $F_{strato}^{\odot} + F_{tropo}^{\odot} = 240\,\mathrm{W/m^2}$, the global mean absorbed solar flux. Parameters that control solar energy attenuation in the stratosphere and troposphere are $K_{strato} = \tau_{sws}/\tau$ and $K_{tropo} = \tau_{swt}/\tau$, where τ_{sws} and τ_{swt} are shortwave optical depths and τ is the gray thermal IR optical depth at any atmospheric level (eqn [47]). The gray IR optical depths at the reference pressure, radiative–convective boundary, and tropopause are τ_0, τ_{rc} and τ_{tp}, respectively.

A comparison of τ_0 values shows that IR optical depth is somewhat larger on the giant planets than the Earth or Titan. Also, Titan has the largest fraction of solar radiation absorbed in its stratosphere.

absorption bands in solar near-IR. A collision-induced absorption (CIA) continuum of H_2–H_2 and H_2–He and thermal IR emission bands of acetylene (C_2H_2, 13.7 μm) and ethane (C_2H_6, 12.1 μm) and methane (7.6 μm) cool these stratospheres inefficiently (Yelle et al., 2001; Zhang et al., 2013). Overall, k_{strato} is large, and all the giant planets have stratospheric inversions. On Titan, a thick stratospheric haze absorbs visible and UV radiation, along with stratospheric absorption in the near-IR by methane. The results are a large k_{strato} and a pronounced stratospheric inversion.

The aforementioned is radiation only; the other part of the radiative–convective problem to consider is the convective regime. Equation [14] describes a dry adiabat, which we can rewrite as temperature as a function of pressure,

$$T = T_{ref}\left(\frac{p}{p_{ref}}\right)^{\overline{R}/c_p} \Rightarrow T = T_{ref}\left(\frac{p}{p_{ref}}\right)^{(c_p - c_v)/c_p} \Rightarrow T = T_{ref}\left(\frac{p}{p_{ref}}\right)^{(\gamma-1)/\gamma} \quad [57]$$

Here, T_{ref} is a reference temperature at a reference pressure p_{ref} (e.g., 1 bar), while γ is the ratio of specific heats c_p/c_v. Kinetic theory relates γ to the degrees of freedom, N_{dof}, for the primary atmospheric constituent(s), where

$$\gamma = 1 + \frac{2}{N_{dof}} \quad [58]$$

For atmospheres of linear diatomic gases, such as N_2–O_2 (Earth), H_2 (giant planets), or N_2 (Titan), the molecules have

3 translational and 2 rotational degrees of freedom, so that $N_{dof}=5$ and $\gamma=7/5=1.4$. For CO_2-dominated atmospheres (Venus and Mars), there are 3 translational, 2 rotational, and ~0.3 vibrational degrees of freedom, so $N_{dof}=6.3$ and $\gamma=1.3$ (Bent, 1965). With these γ values, a tropospheric temperature T is proportional to $p^{0.3}$ and $p^{0.2}$ for diatomic and triatomic planetary atmospheres, respectively. However, no observed troposphere follows a dry adiabat because condensables release latent heat and lower the lapse rate. Following Robinson and Catling (2012), a semiempirical approximation adjusts the convective tropospheric temperature structure as follows:

$$T = T_{ref}\left(\frac{p}{p_{ref}}\right)^{\alpha_c(\gamma-1)/\gamma} \quad [59]$$

where α_c is a dimensionless constant, ~0.6–0.9 for planets in the solar system, representing the average ratio of the observed lapse rate to dry adiabatic lapse rate in the planet's convective regime.

Equation [59] gives temperature as a function of pressure in the convective regime, whereas eqn [54] gives temperature as a function of optical depth in the radiative regime, so how is optical depth related to pressure? The gray differential optical depth, $d\tau$, across an elemental layer of vertical thickness dz is the sum of various contributions from N_a sources of opacity, such as absorbing gases:

$$d\tau = -\sum_{i=1}^{N_a} k_i \underbrace{\rho_i}_{\mu_i\rho} dz = -\sum_{i=1}^{N} k_i\mu_i \underbrace{\rho\, dz}_{dp/dz=-g\rho} \Rightarrow d\tau = \sum_{i=1}^{N} k_i\mu_i\frac{dp}{g}$$
$$= \sum_{i=1}^{N} k_i(p_{ref})\mu_i(p_{ref})\left(\frac{p}{p_{ref}}\right)^{a_i+b_i}\frac{dp}{g} \quad [60]$$

Here, k_i is the mass absorption coefficient for absorber i, which generally depends on pressure and temperature, while $\rho_i=\mu_i\rho$ is the corresponding density of the ith absorber, where μ_i is the mass mixing ratio (eqn [4]). In the second step, we substitute for the hydrostatic eqn [5]. In the last step, we use the fact that the profiles of μ_i and k_i are generally power laws of pressure:

$$\mu_i(p) = \mu_i(p_{ref})\left(\frac{p}{p_{ref}}\right)^{a_i}, \quad k_i(p) = k_i(p_{ref})\left(\frac{p}{p_{ref}}\right)^{b_i} \quad [61]$$

Water vapor is the main source of opacity in the Earth's atmosphere, whereas in other atmospheres, gases have similar pressure dependence of opacity and mass mixing ratio, such as N_2 and CH_4 on Titan. Furthermore, the sum over $k_i\mu_i$ in eqn [60] could be replaced with a single weighted-mean absorption coefficient k. Thus, we can integrate and normalize eqn [60] to get a power law dependence of optical depth on pressure, where the power is $n_p=a+b+1$,

$$dt \propto \left(\frac{p}{p_{ref}}\right)^{a+b} dp \Rightarrow \tau = \tau_0\left(\frac{p}{p_{ref}}\right)^{a+b+1}, \text{ or } \tau = \tau_0\left(\frac{p}{p_{ref}}\right)^{n_p} \quad [62]$$

Here, τ_0 is the gray IR optical depth at reference pressure p_{ref}, such as 1 bar. In tropospheres and lower stratospheres, often a well-mixed gas ($a=0$) with an absorption coefficient linearly dependent on pressure ($b=1$) occurs, such as H_2 in giant-planet atmospheres. In that case, $n_p=2$. The Earth's atmosphere is complicated, with a 8–12 μm window, a steep ($n_p=4$–5) τ–p scaling for the 6.3 μm water absorption band and water bands beyond about 20 μm, and an $n_p=2$ scaling for the 15 μm CO_2 band. But it turns out that $n_p=2$ is a good approximation for tropospheres and lower stratosphere for all the planets with thick atmospheres in the solar system, validated by comparison of numerical calculations (Robinson and Catling, 2012, 2014).

An $n_p=2$ power law in eqn [62] also has a physical basis. The primary absorption processes that cause IR opacity in thick tropospheres are pressure broadening and CIA (see **Section 10.13.3.5**). Because both processes rely on collisions, they tend to have an absorption coefficient $k_i \propto p$, so by integration of $d\tau \propto p$, it follows that $\tau \propto p^2$.

With an opacity–pressure power law scaling of eqn [62], we can rewrite our tropospheric convective profile with opacity as the vertical coordinate instead of pressure:

$$T = T_{ref}\left(\frac{\tau}{\tau_0}\right)^{\alpha_c(\gamma-1)/n_p\gamma} = T_{ref}\left(\frac{\tau}{\tau_0}\right)^{\beta/n_p} \quad [63]$$

This equation can be inserted into Schwarzschild's differential equation that describes the upwelling thermal radiative flux (eqn [44]) to give a differential equation in $dF^+/d\tau$, which can be solved (see the Appendix of Robinson and Catling (2012)) to give an analytic solution for the convective upwelling flux below the radiative–convective boundary in a gray troposphere:

$$F^+(\tau) = \underbrace{\sigma T_{ref}^4 e^{-D(\tau_0-\tau)}}_{\text{attenuated upwelling flux from } \tau_0 \text{ level}}$$
$$+ \underbrace{\frac{\sigma T_{ref}^4 e^{D\tau}}{(D\tau_0)^{4\beta/n_p}}\left(\Gamma_u\left(1+\frac{4\beta}{n_p}, D\tau\right) - \Gamma_u\left(1+\frac{4\beta}{n_p}, D\tau_0\right)\right)}_{\text{flux contribution from atmosphere above the reference level}} \quad [64]$$

Here, Γ_u is an upper incomplete gamma function, which is a mathematical function defined by

$$\Gamma_u(a,x) \equiv \int_x^\infty t^{a-1}e^{-t}dt \quad [65]$$

Although this looks complicated, from a practical perspective, the incomplete gamma function is evaluated as simply as a sine or cosine in computer programs, such as MATLAB, IDL, or Python. Thus, the thermal flux in eqn [64] can be instantly computed as a function of optical depth, if input parameters (n_p, β) and variables (T_0, τ_0) are specified.

In the preceding text, we have written analytic equations that govern radiative–convective equilibrium in planetary atmospheres with the gray approximation. The temperature follows a convective profile according to eqn [63] up to a radiative–convective boundary, where the temperature then obeys eqn [54] according to radiative equilibrium. There will be a tropopause temperature minimum above the radiative–convective boundary at an IR optical depth given by eqn [55] if the stratospheric shortwave absorption is large compared to IR opacity, that is, the condition of large k_{strato} in eqn [56]. **Figure 6(a)** is a schematic profile

that shows a purely radiative–convective equilibrium for an atmosphere without a stratospheric shortwave absorber. The temperature asymptotes to an isothermal stratosphere with a so-called skin temperature. The skin temperature is given by eqn [53] with $\tau = 0$, no downward thermal flux, and no solar atmospheric absorption. If we also neglect the internal heat flux, we get

$$\sigma T_{\text{skin}}{}^4 = \frac{F^{\odot}_{\text{tropo}} + F^{\odot}_{\text{strato}} + \cancel{F_i}}{2} \Rightarrow T_{\text{skin}}{}^4 = \frac{(\text{absorbed solar flux})}{2\sigma} = \frac{\sigma T_e{}^4}{2\sigma} \quad \Rightarrow T_{\text{skin}} = \frac{T_e}{2^{1/4}} \qquad [66]$$

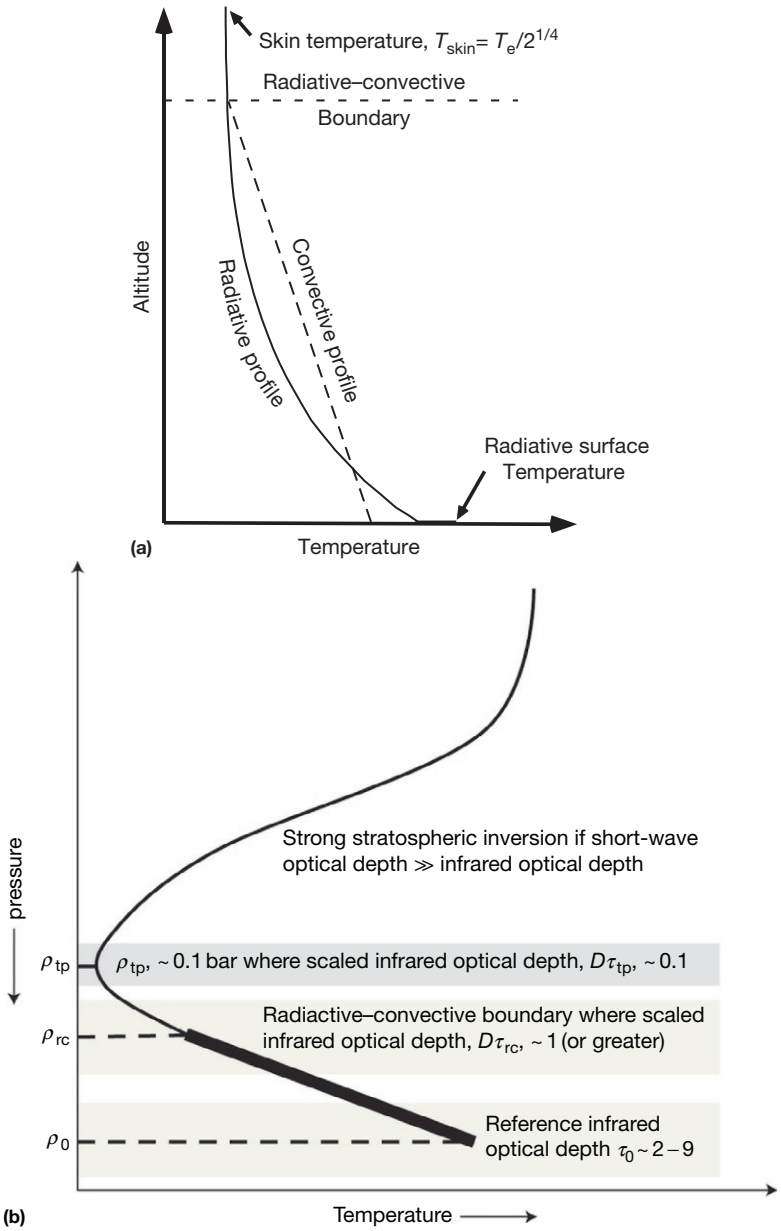

Figure 6 (a) A schematic profile of a radiative–convective equilibrium for an atmosphere without a shortwave absorber. A purely radiative profile (solid line) is unphysical. It is unstable to convection and has a discontinuity at the surface, so turbulence ensues and an adiabatic (i.e., convective) profile (dashed line) is established. The convective profile intersects the radiative profile at a level called a radiative–convective boundary with continuity of net flux and temperature. Without a stratospheric inversion, there is no tropopause minimum. In the absence of significant internal heat from the planet, the temperature asymptotes at altitude to a skin temperature that is a simple function of the effective temperature T_e, as shown. In our solar system, this schematic radiative–convective profile is roughly representative of the global mean profile of Venus. (b) A more general radiative–convective equilibrium profile where a strong shortwave stratospheric absorber is present. The conditions for the stratospheric inversion, tropopause minimum, and typical IR optical depths are shown (applicable for the Earth, Titan, and the giant planets). D is the diffusivity factor (see text). Reproduced from Robinson TD and Catling DC (2014) Common 0.1 bar tropopause in thick atmospheres set by pressure-dependent infrared transparency. *Nature Geoscience* 7: 12–15.

where T_e is the effective temperature. Thus, the skin temperature of an Earth-like world without the properties that give it a stratospheric inversion would be $255\,\mathrm{K}/2^{1/4}$, which is 214 K. Although simple, the skin temperature actually gives a rough estimate for the tropopause minimum temperature; on Earth, the observed global mean tropopause temperature is 208 K (Han et al., 2011). **Figure 6(b)** shows a schematic for the more general case for an atmosphere with a stratospheric inversion.

Of course, gray radiation is an approximation, and numerical nongray calculations are required to replicate the details of atmospheres, for example, Goody and Yung (1989), p. 404–407; Thomas and Stamnes (1999), p. 450–453; and Satoh (2004), p. 380–383. Such models were first pioneered for the Earth by Manabe and coworkers (**Figure 7**) (Manabe and Strickler, 1964; Manabe and Wetherald, 1967). Since then, radiative and radiative–convective models have been applied to Venus (Bullock and Grinspoon, 2001; Crisp, 1986, 1989; Meadows and Crisp, 1996), Mars (Kasting, 1991; Marinova et al., 2005), Jupiter and Saturn (Appleby and Hogan, 1984), Uranus and Neptune (Appleby, 1986), Titan (McKay et al., 1991, 1999), and exoplanets (Heng et al., 2012; Robinson and Catling, 2012).

10.13.3.5 Absorption and Emission by Atmospheric Gases

In the previous subsection, we implicitly assumed that some gases absorb or scatter radiation at certain wavelengths (described as optically *or* radiatively active gases), whereas others do not (optically inactive). Why this is so involves an understanding of molecular spectroscopy.

In a spectrum from a planetary atmosphere, we see discrete lines, groups of lines called bands, windows of weak spectral absorption, and a continuum of smoother varying absorption. Our starting point recognizes that the total internal energy of a gas molecule can be written as

$$E_{\mathrm{total}} = E_{\mathrm{electronic}} + E_{\mathrm{vibrational}} + E_{\mathrm{rotational}} + E_{\mathrm{translational}} \qquad [67]$$

where $E_{\mathrm{electronic}}$ is the energy associated electron orbits and other terms represent vibrational energy, rotational KE, and translational KE, respectively. Molecular collisions depend on temperature through $E_{\mathrm{translational}}$ and redistribute energy between the various forms (if the air is dense enough) to establish local thermodynamic equilibrium where a local volume behaves like a blackbody. This was the assumption in the radiative transfer discussed in **Sections 10.13.3.3** and **10.13.3.4**.

A photon can be absorbed if its energy is close to a quantized energy jump within a molecule or it can be scattered by changing phase or direction. Transitions in rotational speed require less energy than vibrational ones, while electronic transitions require the most. Planck's law for photon energy, $E = h\nu = hc/\lambda$, indicates that types of transition correspond to general wavelength ranges (**Table 6**). However, absorption often occurs as combinations of transitions, such as rotational and vibrational.

An electric dipole moment due to separated positive charge and negative charge determines whether a molecule undergoes certain rotational or vibrational transitions. For example, the slight positive charge on hydrogen relative to oxygen in H_2O produces an electric dipole moment. The electric field in electromagnetic radiation torques the electric dipole and induces rotation. Isolated homoatomic molecules such as H_2 do not possess electric dipoles but dipoles can be induced by collisions. CH_4 and CO_2 also have no electric dipoles, but their bonds can bend, allowing a temporary electric dipole with associated rotational–vibrational transitions.

Some molecules possess a magnetic dipole moment. The magnetic field in an electromagnetic wave can torque a molecule with a magnetic dipole moment into rotation, analogous to a torqued needle on a compass. Many molecules do not have significant magnetic moments because electrons of opposite spin pair up. O_2 notably has two unpaired electrons and a magnetic dipole, which allows rotational bands in the microwave. In fact, satellite sensing of microwave emission from O_2 measures the Earth's atmospheric temperature over broad altitudes according to instrument weighting functions like those discussed in **Section 10.13.3.2** (Shine et al., 2008; Yang et al., 2013).

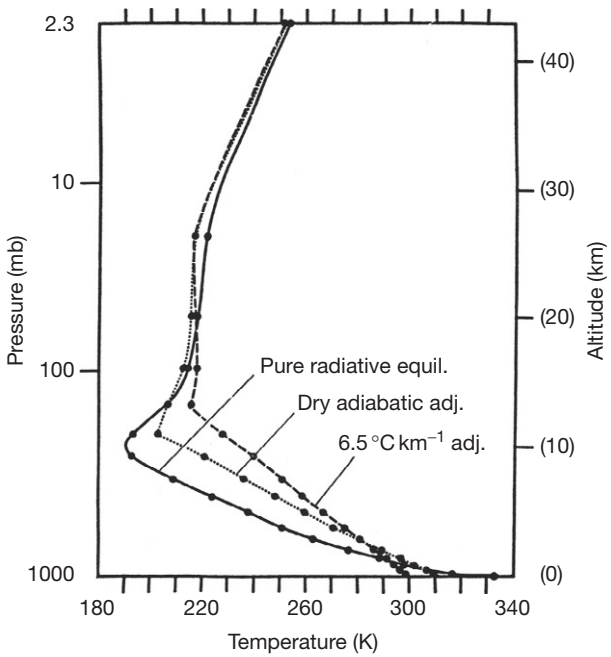

Figure 7 Results from radiative transfer modeling for the Earth that includes the effects of stratospheric ozone that causes a temperature inversion above a tropopause minimum. Three models are shown: purely radiative equilibrium, radiative–convective equilibrium with a dry adiabat, and radiative–convective equilibrium with a typical adiabat modified by water vapor. Reprinted from Manabe S and Strickler RF (1964) Thermal equilibrium of the atmosphere with a convective adjustment. *Journal of Atmospheric Sciences* 21: 361–385, with permission from the American Meteorological Society.

Table 6 Typical wavelength ranges of molecular transitions

Dominant transition	*Wavelength range*	*Band*
Electronic	<1 μm	X-ray to UV to visible
Vibration	1–20 μm	Near-IR to far-IR
Rotation	>20 μm	Far-IR to microwave[a]

[a]H_2 can have rotational transitions at shorter wavelengths in warm, dense atmospheres (Wordsworth and Pierrehumbert, 2013).
IR, infrared; UV, ultraviolet.

For IR opacity and climate, the most important transitions are vibrational and rotational, so we discuss these next.

10.13.3.5.1 Rotational transitions

Rotating molecules have a rotational frequency that is quantized analogous to a household fan spinning at set speeds. A molecule's rotational KE is $^1/_2 I\omega^2$, where I is the moment of inertia. In general, there are three principal moments of inertia about three axes of symmetry through the center of mass of a molecule, denoted l_A, l_B, and l_C from smallest to largest. However, in many simple molecules, some moments of inertia are equivalent or zero. For example, the axis through the atoms of CO_2, a linear molecule (O=C=O), has $l_A \approx 0$, while the moments of inertia around two perpendicular axes are equal and can be designated as l. In quantum theory, the quantized total rotational angular momentum L, associated with a so-called linear rotor such as CO_2, is

$$L = \frac{h}{2\pi}\sqrt{J(J+1)} \qquad [68]$$

where $J = 0, 1, 2, \ldots$ is the rotational quantum number. The rotational KE for number J is

$$E_J = \frac{1}{2}I\omega^2 = \frac{(I\omega)^2}{2I} = \frac{L^2}{2I} = \frac{h^2}{8\pi^2 I}(J(J+1)) = hB(J(J+1)) \quad \text{where } B = \frac{h}{8\pi^2 I} = \text{rotational constant}$$

Only transitions between adjacent states J and $J+1$ are allowed, giving an energy change,

$$\Delta E = hB[(J+1)(J+2) - J(J+1)] = hB\left[J^2 + 3J + 2 - J^2 - J\right] = 2hB(J+1)$$

Thus, the photon frequency needed to cause a rotational transition in a linear rotor is

$$\nu = \frac{\Delta E}{h} = 2B(J+1) \qquad [69]$$

Consequently, a pure rotational absorption spectrum has a series of lines separated by frequency differences $\Delta\nu = 2B$. As a molecule rotates with increasing J, centrifugal force causes bonds to stretch, which requires a more complex treatment. Also, similar expressions can be derived for more molecules with many moments of inertia.

10.13.3.5.2 Vibrational transitions

Molecular bonds behave like springs, so a diatomic molecule has a classical simple harmonic resonant frequency ν_0. In quantum mechanics, however, the oscillation frequency and associated energy levels of a diatomic molecule are quantized as

$$\nu = \left(\mathrm{v} + \frac{1}{2}\right)\nu_0, \quad E_\mathrm{v} = h\nu_0\left(\nu + \frac{1}{2}\right)$$

where the letter 'vee,' $\mathrm{v} = 0, 1, 2, \ldots$, is a vibrational quantum number. The $\mathrm{v} = 0$ state has a finite zero point energy, $E_0 = h\nu_0/2$, and a transition from this state to the next highest, or vice versa, is the fundamental, which typically produces the strongest line because at atmospheric temperatures and pressures, most molecules are in the ground state. Large displacements of atoms in molecules corresponding to $\Delta\mathrm{v} = \pm 2, \pm 3, \ldots$ produce less intense overtones.

The frequency of combined vibrational and rotational transitions is slightly lower or higher than the pure vibration. Consequently, rotational–vibrational spectra have lines on either side of a pure vibrational frequency. The *P branch* is the low-frequency side corresponding to changes $\Delta J = -1$, while the *R branch* is the higher-frequency side with $\Delta J = +1$. The central frequency line with $\Delta J = 0$ is called the *Q branch*, which may not exist if quantum mechanics requires $\Delta J \neq 0$. Lines in the *P* and *R* branches are labeled according to the initial rotational quantum number J, that is, R(0), R(1),..., and P(0), P(1), etc. Superposed $\Delta J = -2$ or +2 electric quadrupole transitions can also occur. Instead of a PQR branch structure, there are the *O branch* ($\Delta J = -2$) and *S branch* ($\Delta J = +2$). Giant-planet atmospheres have electric quadrupole absorption lines of H_2 in the far-IR, for example.

Vibrational bands of CO_2 are important on Venus, Earth, and Mars. The bending of CO_2 produces a 15 μm rotation–vibration band – actually a PQR branch structure but individual lines are hidden by pressure broadening (see the succeeding text). The 4.3 μm asymmetrical stretch CO_2 band is important on Venus for absorbing a large amount of outgoing IR at depth because of Venus's high temperature. A vibration–rotation band of methane at 7.6 μm contributes IR opacity in the Earth's atmosphere but appears in emission in spectra of the giant planets and Titan due to warm CH_4-containing stratospheres.

10.13.3.5.3 Collision-induced absorption

Homoatomic molecules such as H_2 or N_2 lack permanent electric dipoles, but collisions at high-pressure distort the electronic structure and produce a temporary electric dipole, allowing vibrational and rotational transitions (Trafton, 1966; Trafton et al., 1998). CIA in various pairs of molecules creates significant IR continuum opacity in several planetary atmospheres: H_2–H_2 and H_2–He on the giant planets, N_2–N_2 and N_2–CH_4 in Titan's atmosphere (McKay et al., 1989), and CO_2–CO_2 on Venus (Moskalenko et al., 1979) or the early Earth (Kasting and Ackerman, 1986; Wordsworth et al., 2010). As first noted by Sagan (1977) H_2–N_2 and H_2–CO_2 CIA may have been important on prebiotic Earth (Wordsworth and Pierrehumbert, 2013) and early Mars (Ramirez et al., 2014). At Earth-like temperatures, H_2 is a strong greenhouse gas because its small moment of inertia causes widely spaced rotational energy levels (eqn [69]) that absorb across the thermal IR.

10.13.3.5.4 Broadening

Broadening processes are critical for planetary climates because otherwise, IR absorption lines would be delta-functions with negligible climatic effect. The three processes are the following:

- *Natural broadening*, in which a finite time for absorption or emission causes energy and frequencies to spread by Heisenberg's uncertainty principle. Apart from the UV, this broadening is tiny compared to the other two processes in the succeeding text.
- *Doppler broadening*, where random motion of molecules relative to the radiation source causes absorption and emission at frequencies that are Doppler-shifted relative to the

rest position of a line. This broadening tends to dominate in upper stratospheres and higher.

- *Pressure (or collisional) broadening*, where collisions add or remove energy during radiative transitions allowing emission or absorption over a broader range of photon energies. Pressure broadening is a key source of IR opacity in tropospheres (Section 10.13.3.4).

Pressure broadening produces a characteristic line shape called the *Lorenz profile* allowing absorption and emission far from the line center (Petty, 2006). A key property is that pressure-broadened lines have a width linearly proportional to pressure (i.e., the mass absorption coefficient relationship $k_\nu \propto p$, as assumed in Section 10.13.3.4 for tropospheres) unlike Doppler broadened lines, but both Doppler line broadening and pressure line broadening depend on temperature.

10.13.3.5.5 Continuum

A CIA continuum for giant planets and Titan was mentioned in the preceding text. For Earth, weak continuum absorption from 12.5 to 8 μm is mainly due to water vapor with absorption coefficient proportional to the square of the water vapor density. This absorption may be caused by the distant wings of very many lines in the far-IR or by dimers (H_2O•H_2O), trimers, and polymers of H_2O molecules, but the problem is not fully resolved. At shorter wavelengths, continuum absorption arises from well-known processes, including photoionization and photodissociation.

10.13.3.5.6 Numerical radiative transfer

Although gray models like those in Section 10.13.3.4 are indispensable for intuitive understanding, numerical radiative transfer calculations are needed for realism, which deal with hundreds of lines that often overlap. Line-by-line calculations explicitly sum the effects of all the contributions of individual lines. This accurate method is very computationally demanding for climate models. Consequently, two more practical approaches have been developed (Goody and Yung, 1989; Liou, 2002; Petty, 2006; Thomas and Stamnes, 1999; Vardavas and Taylor, 2007):

- *Band models* use an analytic form for the positions and strengths of lines. Over a spectral interval, lines can be represented by a mean line strength and spread in a random distribution or by some other spacing that is amenable to analytic formulation.
- The *correlated k-distribution method* is a statistical representation of the apparently haphazard variation of absorption coefficients k_ν over spectral interval $\Delta\nu$ with a smooth cumulative probability function of the occurrence of k_ν. Within $\Delta\nu$, the Planck function can be considered a function of temperature without frequency dependence. The order in which the k_ν's are summed then does not matter. In this way, integration can be done using bigger spectral intervals than in the detailed line-by-line spectrum.

Line-by-line calculations validate the aforementioned two methods and constrain the region of parameter space where the inherent assumptions are valid.

10.13.4 Photochemistry

10.13.4.1 Basic Principles of Chemical Kinetics

Clearly, through molecular properties like those discussed in the preceding text, atmospheric composition sets and controls planetary climates and atmospheric structures. But what sets composition? The concentration of any gas is determined by chemical kinetics, that is, a competition between source and sink fluxes, which depends on reaction rates. In general, atmospheres are never in chemical equilibrium because of the free energy from sunlight (or starlight for exoplanets), as well as interior or tidal energy fluxes. However, giant-planet atmospheres that convect air to pressurized, hot interiors, where reactions are efficient, are far closer to chemical equilibrium than shallower atmospheres on rocky planets such as the Earth or Mars. One can think of chemical equilibrium as telling you what 'should happen' if everything fully reacted, whereas kinetics determines what actually happens according to the speed of reactions. Thus, the starting point for atmospheric chemistry is to consider reaction rates. Then, we consider other principles before discussing specific planetary atmospheres.

A general two body reaction can be written as

$$bB + cC \rightarrow gG + hH \qquad [70]$$

The number of reactions per unit volume and unit time is given by the reaction rate,

$$R_r = k_r {n_B}^m {n_c}^n \qquad [71]$$

where n_i is number density (molecules cm^{-3}) of species i. Here, the exponents are related to the order of the reaction $m+n$ and are determined experimentally. A rate coefficient or rate constant k_r is established in the lab by mixing reactants and measuring reaction rates. The units of k_r depend on the order of the reaction and the concentration units. If $m=1$ and $n=0$, the reaction would be first order with k_r in units of s^{-1}; if $m=n=1$, the reaction would be second order with k_r in units of cm^3 $molecule^{-1}$ s^{-1}; and so on. The rates of change of species are related:

$$\frac{dn_B}{dt} = -b \times \text{rate} = -bR_r, \quad \frac{dn_G}{dt} = gR_r, \text{ etc., so}$$
$$-\frac{1}{b}\frac{dn_B}{dt} = -\frac{1}{c}\frac{dn_C}{dt} = \frac{1}{g}\frac{dn_G}{dt} = \frac{1}{h}\frac{dn_H}{dt} \qquad [72]$$

We can consider an example, oxidation of methane by a hydroxyl (OH) species:

$$OH + CH_4 \rightarrow CH_3 + H_2O \qquad [73]$$

The Earth's troposphere has concentrations $n_{OH} \sim 8 \times 10^5$ molecules cm^{-3} and $n_{CH_4} \sim 4.3 \times 10^{13}$ molecules cm^{-3}, while an average tropospheric rate constant for eqn [73] is $k_{rCH_4} = 3.6 \times 10^{-15} cm^3$ $molecule^{-1}$ s^{-1}. The units indicate a first-order reaction. By applying eqn [71], we can estimate the chemical lifetime of CH_4, that is, the average time a CH_4 molecule spends in the atmosphere before destruction:

$$\tau_{CH_4} = \frac{n_{CH_4}}{\text{destruction rate}} = \frac{n/_{CH_4}}{k_{rCH_4} n_{OH} n/_{CH_4}}$$
$$= \frac{1}{\left(3.6 \times 10^{s-15} cm^{-3} \text{ molecules} s^{-1}\right)\left(8 \times 10^5 cm^{-3}\right)}$$
$$\sim 12 \text{ years}$$

Thus, methane would be removed rapidly without resupply. Methane attains a nonnegligible abundance of ~1.8 ppmv in the Earth's present atmosphere because of a significant source flux: ~80–90% is from the Earth's microbial biosphere, and the rest is from geothermal sources (Kirschke et al., 2013). On Mars – with another oxidizing atmosphere – the lifetime of methane is ~300 years (Lefevre and Forget, 2009; Zahnle et al., 2011), so methane sources are very limited or nonexistent given in situ measurements of <1 ppbv CH_4 (Webster et al., 2013).

Generally, we deduce that a lifetime is related to chemical sinks as follows:

$$\begin{aligned} &X + Y_1 \xrightarrow{k_{r1}} \\ &X + Y_2 \xrightarrow{k_{r2}} \text{ products}, \quad \Rightarrow \text{chemical lifetime of X} = \tau_x = \frac{1}{\sum_i k_{ri} n_{Yi}} \\ &\text{etc.} \xrightarrow{k_{ri}} \end{aligned} \qquad [74]$$

Three-body (termolecular) reactions are also important in planetary atmospheres, for example, the formation of ozone (O_3) in the Earth's stratosphere from $O + O_2 +$ a third body. When two gases, A and B, combine, bond formation releases energy that must be removed to prevent the *adduct* (the form AB) from splitting. A third body 'M' takes away the energy, where 'M' represents any atmospheric gas, usually the most abundant one:

$$A + B + M \rightarrow AB + M \qquad [75]$$

Because a third body is needed, termolecular reactions are pressure-dependent up to a high-pressure limit, where the exact concentration of M no longer matters. Also, termolecular reactions are usually faster at lower temperatures because the molecules approach each other at slower speeds.

More generally, rate constants have an Arrhenius dependence on thermal energy kT, as

$$k_r = A\exp(-E_a/kT) \qquad [76]$$

where a pre-exponential factor A and activation energy E_a are determined experimentally. A few useful rules are the following: (i) Reactions between molecules and radicals (species with unpaired electrons, see Section 10.13.4.2) usually have positive E_a so that k_r increases with temperature. (ii) Fast reactions between two radicals generally have negative activation energy E_a so that k_r decreases with temperature. (iii) Reactions between nonradical molecules are normally very slow unless they react on particle surfaces. (iv) Favored reactions tend to be exothermic.

10.13.4.2 Why Free Radicals Are So Important

Appreciably fast atmospheric reactions, with few exceptions, involve at least one radical species. A free radical has an unpaired electron in its outer shell (e.g., atomic chlorine, Cl) and reacts strongly to obtain more stable bonding. An exception is ground-state atomic oxygen (O), a biradical that has eight electrons of which two are unpaired. Some literature indicates radicals with dots, for example, HO·.

Photochemistry is initiated by the Sun, loosely analogous to the spark plugs of an engine. Photons break up molecules (Section 10.13.4.3), creating radicals that transmit the free energy. Reactions of radicals with nonradical molecules make further radicals because electrons do not pair up, that is,

$$\begin{aligned} &\text{radical} + \text{nonradical} \rightarrow \text{radical} + \text{nonradical} \\ &\left(\text{e.g.,} \ \underbrace{\text{CN}}_{\text{nitrile radical}} + CH_4 \rightarrow \underbrace{CH_3}_{\text{methyl radical}} + \begin{array}{c}\text{HCN, formation of} \\ \text{hydrogen cyanide on Titan}\end{array} \right) \end{aligned} \qquad [77]$$

However, radical–radical reactions remove radicals in two ways: disproportionation into nonradicals

$$\begin{aligned} &\text{radical} + \text{radical} \rightarrow \text{nonradical} + \text{nonradical} \\ &\left(\text{e.g.,} \ \underbrace{C_2H_3}_{\text{vinyl (or ethenyl) radical}} + C_2H_3 \rightarrow \underbrace{C_2H_4}_{\text{ethylene}} + \underbrace{C_2H_2}_{\text{acetylene}}, \ \begin{array}{c}\text{a reaction at} \\ \sim 200\,\text{km} \\ \text{altitude on Titan}\end{array} \right) \end{aligned} \qquad [78]$$

and recombination with the formation of a single molecule

$$\begin{aligned} &\text{radical} + \text{radical} + M \rightarrow \text{nonradical} + M \\ &(\text{e.g., } NO_2 + OH + M \rightarrow HNO_3 + M, \text{ formation of nitric acid on Earth}) \end{aligned} \qquad [79]$$

By removing radicals, a chain of photochemical reactions initiated by sunlight is terminated. The net effect of all reactions is polymerization in reducing atmospheres, which can produce particles of hydrocarbons, sulfur, phosphorus, and so on, depending on the gas mixture, while in oxidizing atmospheres, the outcome is analogous to combustion, for example, full oxidation of CH_4 to water and CO_2 or oxidation of sulfur gases to sulfate aerosols (Hu et al., 2012, 2013).

Certain gas species can also be lost to planetary surfaces. 'Dry deposition' is interception with the surface and loss without the aid of precipitation, although the surface could be wet or dry. 'Wet deposition' is when raindrops, snow, or cloud or fog particles scavenge gases to the surface. For example, nitric acid formed in eqn [79] is dry-deposited onto the driest desert on Earth, the Atacama Desert (Catling et al., 2010; Michalski et al., 2004), whereas elsewhere, it usually dissolves in rain that falls to the surface. Deposition is how atmospheric chemistry can alter the geochemistry of a planetary surface. For example, the surface of Mars has accumulated sulfate salts that formed in its atmosphere from the oxidation of volcanic sulfur (Settle, 1979; Smith et al., 2014).

10.13.4.3 Photolysis

If species A is photolyzed, its number density n_A (molecules cm^{-3}) declines with a photodissociation rate,

$$A + h\nu \rightarrow \text{products}, \quad \text{rate} = \frac{\partial n_A}{\partial t} = -j_A n_A \qquad [80]$$

where j_A is the photolysis rate (or photodissociation) coefficient (s^{-1}). The probability Ψ_i per second for a molecule i to absorb radiation is related to j_i, as follows:

$$\Psi_i = \int_\lambda \sigma_{i\lambda} I_\lambda d\lambda \ \ s^{-1}, \quad j_i = \int_\lambda q_{i\lambda} \sigma_{i\lambda} I_\lambda d\lambda \ \ s^{-1} \qquad [81]$$

Here, $\sigma_{i\lambda}$ is the absorption cross section for species i (usually cm^2 $molecule^{-1}$), and $l_\lambda d\lambda$ is the photon flux crossing 1 cm^2 in spectral interval λ to $\lambda + d\lambda$. Absorption of a photon may sometimes lead to a different process (collisional deactivation, radiation, or breaking of a different bond), so $q_{i\lambda}$ is a dimensionless quantum yield for the photodissociation of interest.

10.13.4.4 Earth's Atmospheric Composition and Chemistry

With the principles in the preceding text, we can understand the Earth's atmosphere. The two key constituents responsible for its chemical character are very large amounts of O_2 and H_2O vapor compared with any other known atmosphere. The oxidizing chemistry caused by radicals associated with O_2 and H_2O is critical for radiative transfer because it renders the Earth's troposphere largely transparent to visible sunlight. At the same time, O_2 causes the creation of the ozone layer, shielding the Earth's surface from biologically harmful UV radiation with wavelengths less than about 300 nm.

In the stratosphere, the basic scheme for making O_3 from the O atoms of O_2 was deduced by Sydney Chapman in 1930 with the so-called Chapman reactions:

$$O_2 + h\nu(\lambda \leq 242\,\text{nm}) \rightarrow O + O \quad [82]$$

$$O + O_2 + M \rightarrow O_3 + M \quad [83]$$

$$O_3 + h\nu\,(\lambda \leq 1140\,\text{nm}) \rightarrow O + O \quad [84]$$

$$O_3 + O \rightarrow 2O_2 \quad [85]$$

Energy absorbed in ozone photolysis (eqn [84]) heats the stratosphere, causing its temperature inversion. O atoms derived from ozone photolysis cycle around to reform ozone via eqn [83]. But O_3 and O (the so-called odd oxygen species) return to stable O_2 molecules via eqn [85].

Chapman's scheme overpredicted the abundance of stratospheric O_3 compared to observations. In the 1970s, it was realized that minor constituents catalyze the removal of odd oxygen,

$$\begin{array}{l} X + O_3 \rightarrow XO + O_2 \\ \underline{XO + O \rightarrow X + O_2} \\ O_3 + O \rightarrow O_2 + O_2 \end{array} \quad [86]$$

where X is a radical: NO, OH, Cl, Br, or H.

In the 1980s, it was further shown that heterogeneous reactions (gas–solid) on particles in polar stratospheres could deplete the ozone, as opposed to the homogeneous reactions (gas–gas) reactions such as eqns [82]–[86]. In Antarctica, an ozone hole of low ozone column abundance appears each southern spring. Chlorine radicals released from the UV decomposition of anthropogenic CFCs are responsible (Russell et al., 1996). It was deduced that heterogeneous reactions convert unreactive forms of chlorine, such as HCl and chlorine nitrate into Cl_2 on polar stratospheric cloud particles:

$$\underbrace{ClONO_2}_{\text{chlorine nitrate}} + HCl \rightarrow Cl_2 + \underbrace{HNO_3}_{\text{nitric acid}} \quad [87]$$

This reaction sequesters odd nitrogen ($NO_x = NO + NO_2$, pronounced 'nox') into unreactive nitric acid, which prevents NO_x from turning reactive chlorine back into unreactive chlorine nitrate via

$$ClO + NO_2 + M \rightarrow ClONO_2 + M \quad [88]$$

Nitric oxide (NO) is naturally present because biogenically produced nitrous oxide (N_2O) reacts with an energetic oxygen atom (denoted $O(^1D)$) to generate two NO radicals.

In Antarctica, springtime sunlight releases Cl_2 from particles, which photolyzes into Cl radicals, causing ozone depletion via eqn [86]. The process is encouraged by a springtime stratospheric vortex of eastward winds that prevents inflow of new odd nitrogen or ozone from lower latitudes. Unlike Antarctica, buoyancy waves associated with north–south mountain ranges disrupt the development of a coherent Arctic vortex, so the Arctic lacks an equivalent ozone hole.

One aspect of the Earth's stratosphere that bears some commonality to other oxidizing atmospheres (e.g., Venus and early Mars) is that sulfur gases (sulfur dioxide, SO_2, and carbonyl sulfide, OCS) are oxidized into sulfate aerosols that make a thin haze called the Junge layer (at ~20–25 km altitude). The Junge layer scatters sunlight back to space and cools the Earth. The Junge layer is a photochemical haze of sulfates, analogous to Venus' clouds, although far thinner because the Earth's sulfur is mostly not gaseous but tied up in the form of sulfate and sulfide minerals on or below the Earth's surface. However, it is a general feature of oxidizing atmospheres with sulfur gases to produce sulfate hazes.

We now turn to the Earth's troposphere. All major gases (except Ar) in the Earth's atmosphere are mediated by biological cycles, including O_2, N_2, and CO_2. In addition, various trace gases have significant biological sources, such as CH_4 and bigger hydrocarbons, N_2O, OCS, dimethyl sulfide (CH_3SCH_3 and DMS), and carbon disulfide (CS_2).

A key factor for the Earth's tropospheric chemistry is the role of the dominant oxidizing radical, OH (Levy, 1971; Prinn, 2014). This species arises because of the presence of large amounts of water vapor and O_2, where the latter leads to the generation of tropospheric ozone (~10% of the ozone column abundance) in pathways involving NO_x. In the stratosphere, NO_x destroys ozone, but in the troposphere, NO_x makes ozone (Crutzen, 1979). To create ozone, O_2 and O need to be combined, so O atoms are required. These derive from NO_2, whose progenitor NO comes from lightning, soils, or transport from the stratosphere:

$$NMHC_S + NO + h\nu \rightarrow NO_2 + \text{products [a net reaction of many]}$$

$$NO_2 + h\nu(\lambda \leq 410\,\text{nm}) \rightarrow NO + O \quad [89]$$

NMHCs are nonmethane reactive hydrocarbons (C_2–C_5 compounds plus isoprene (C_5H_8), e.g., butane (C_4H_{10}) and ethylene (C_2H_4)), which have biogenic sources such as marine plankton and vegetation. The O atoms from eqn [89] react with O_2 to form ozone (eqn [83]). Oxidation of methane and carbon monoxide, catalyzed by NO_x, can also produce ozone. Then, ozone photolysis with relatively energetic photons generates exited O atoms that react with water vapor to generate OH radicals:

$$O_3 + h\nu(\lambda \leq 310\,\text{nm}) \rightarrow O_2 + O(^1D) \quad [90]$$

$$H_2O + O(^1D) \rightarrow OH + OH \quad [91]$$

OH is the 'detergent of the atmosphere' because it helps oxidize sulfur-containing gases (SO_2, H_2S, DMS, etc.) into sulfates, removes hydrocarbon gases such as CH_4 and NMHCs by initiating their oxidation, and converts NO_x into nitric acid. Without significant OH, the Earth's atmosphere would accumulate hydrocarbons and sulfurous gases and be very different.

10.13.4.5 CO_2 Atmospheres: Venus and Mars

Venus and Mars both have CO_2-dominated atmospheres and so have some common behavior (Krasnopolsky and Lefevre, 2013). For example, CO_2 does not significantly decompose into CO by photolysis on either planet because catalytic reactions recombine CO_2 from CO and O. Also, both planets have cold thermospheres caused by CO_2 radiative cooling, but Venus' thermosphere is colder, which is counterintuitive given Venus' location. Photochemistry lies behind this situation.

Of course, the recombination of CO_2 relies on radicals. On Mars, OH radicals (derived from water vapor or hydrogen peroxide photolysis) catalyze the recombination of CO and O in cycles (McElroy and Donahue, 1972; Parkinson and Hunten, 1972), for example,

$$\begin{aligned} &OH + CO \rightarrow CO_2 + H \\ &H + O_2 + M \rightarrow HO_2 + M \\ &HO_2 + O \rightarrow OH + O_2 \\ &\text{Net}: \; CO + O \rightarrow CO_2 \end{aligned}$$

Unlike Mars, where the chemistry is largely restricted to C–O–H, seven principal elements are involved on Venus: O–C–S–H–Cl–N–F. Chlorine atoms (derived from HCl photolysis) play an important role in CO_2 recombination on Venus, along with various catalysts:

$$\begin{aligned} &Cl + CO + M \rightarrow ClCO + M \\ &ClCO + O_2 + M \rightarrow ClCO_3 + M \\ &ClCO_3 + X \rightarrow Cl + CO_2 + XO \\ &XO + O \rightarrow X + O_2 \\ &\text{Net}: \; CO + O \rightarrow CO_2 \end{aligned}$$

where X = H, Cl, O, SO, or SO_2.

A fundamental difference of Venus compared with Mars (and Earth) is a total cloud cover. Venus' clouds of sulfuric acid are photochemical, originating from the photolysis of SO_2 and CO_2:

$$\begin{aligned} &SO_2 + h\nu \rightarrow SO + O \\ &CO_2 + h\nu \rightarrow CO + O \\ &SO_2 + O + M \rightarrow SO_3 + M \\ &SO_3 + H_2O \rightarrow H_2SO_4 \end{aligned} \qquad [92]$$

Unlike the Earth's clouds that require updrafts and cooling for condensation, photochemical haze occurs globally on Venus, analogous to Titan's haze. Sulfur on Venus also disproportionates, that is, some gets oxidized, while the rest is reduced. Molecules of sulfur atoms and sulfane (sulfur–hydrogen) absorb visible and UV radiation and may be responsible for cloud coloring.

Venus' upper thermosphere is colder than Mar's (~250 K vs. ~270 K) because O atoms are ~10 times more abundant. There is a greater concentration of O atoms on Venus versus Mars because of more photodissociation of CO_2 and a smaller-scale height (eqn [7]) for the same temperature, given the dependence on gravitational acceleration (Krasnopolsky, 2011). On both planets, chemistry produces vibrationally excited CO_2 (denoted by an asterisk),

$$O + CO_2 \rightarrow CO_2^* + O \qquad [93]$$

which decays and radiates 15 μm photons through an optically thin path to space, causing cooling.

10.13.4.6 Reducing Atmospheres: Giant Planets and Titan

Much could be said about the photochemistry on Titan and the giant planets (e.g., Yung and Demore, 1999), but here, I focus on one general aspect – the fate of hydrogenated gases. Although Titan and the giant planets have reducing atmospheres, hydrogen escapes to space on Titan but not from the giant planets where H_2 is the major constituent. This changes the fate of carbon species on Titan compared to the giant planets and is also relevant for the processing of nitrogen, phosphorus, and sulfur species on the giant planets.

Methane is the most abundant carbon gas in the cold reducing atmospheres of the solar system (although CO is thermodynamically favored in hot Jupiters). Unlike the rapid conversion to CO_2 and water vapor that occurs in oxidizing atmospheres (**Section 10.13.4.1**), methane is destroyed when UV photons with wavelength of <145 nm break C–H bonds. The radicals that are released combine to make bigger hydrocarbons in the following overall schematic net reaction:

$$\begin{aligned} (CH_4 \text{ molecules}) + h\nu &\rightarrow \text{radicals} + \text{hydrogen} \\ &\rightarrow (\text{large hydrocarbons}) + \text{hydrogen} \end{aligned} \qquad [94]$$

On Titan, for example, the lifetime of atmospheric methane against complete photolysis loss is 30–100 My (Yung et al., 1984). The hydrocarbons can be as simple as ethane (C_2H_6) or as complex as polyaromatic hydrocarbons, which are molecules consisting of linked benzene rings. On Titan, organic molecules also incorporate nitrogen to form nitriles (organics with C≡N groups) (Atreya et al., 2009). But on Titan, hydrogen escapes, so the organics accumulate on the surface as solids or liquids, and methane is destroyed (**Figure 8(a)**). However, on the giant planets, hydrogen does not escape and is the main gas. There, hydrocarbons eventually get mixed down to deep, hot (~1000 K) layers where they are hydrogenated and converted back into methane.

Similar cycles occur on the giant planets with nitrogen, phosphorus, and sulfur species. Ammonia (NH_3), phosphine (PH_3), and hydrogen sulfide (H_2S) are photolyzed to make hydrazine, elemental phosphorus, and sulfur-containing solids. However, sedimentation and mixing to depth cyclically reconstitute ammonia, phosphine, and hydrogen sulfide (**Figure 8(b)**).

10.13.5 Atmospheric Dynamics

10.13.5.1 Equations of Motion

Atmospheric dynamics concerns the study of atmospheric motions and their relationship to heating and forces (Holton, 2004; Houghton, 2002; Mak, 2011; Vallis, 2006). Winds are

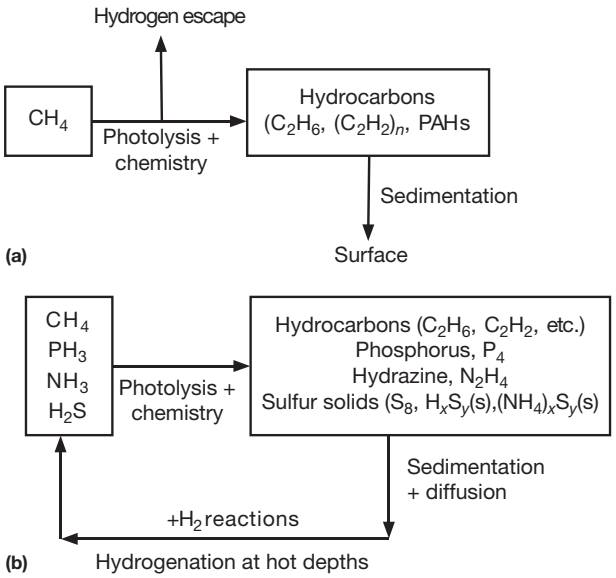

Figure 8 (a) Net hydrocarbon production on Titan, associated with the escape of hydrogen. PAHs are polyaromatic hydrocarbons. (b) The closed cycles of hydrogen-bearing species on giant planets. (Drawn by the author.)

critical for climate because they transport heat (e.g., from tropics to cold poles) and affect the formation of clouds by carrying condensables. Winds also redistribute non-condensables (e.g., O_3 in the Earth's stratosphere), modify surfaces (e.g., dunes on Mars or Titan), and can drive secondary circulations (e.g., ocean currents on Earth).

Atmospheric motions are usually considered from the perspective of an observer corotating with a planet. A rotating frame is accelerating, and in accelerating frames, apparent forces arise in the opposite direction to real accelerations. For example, scales in an upwardly accelerating elevator would incorrectly measure weight without accounting for a downward apparent force. In a rotating frame, centrifugal and Coriolis apparent forces arise. Centrifugal forces are known from everyday experience, but the Coriolis force is less familiar and, consequently, often illustrated by a ball thrown from the center of a merry-go-round to a catcher at its edge. If the merry-go-round does not rotate, the ball reaches the catcher in a straight line, but with counterclockwise rotation, the catcher rotates around and the ball misses him; the ball appears to be deflected to the right of its motion from the viewpoint of the corotating catcher and thrower. The analogy is imperfect because the ball also experiences a radially outward centrifugal force. But the basic picture is analogous to looking down upon a planet spinning west to east: the Coriolis force acts to the right of motion (e.g., a wind vector) such as in the Earth's northern hemisphere. Viewed from below, the merry-go-round's rotation is clockwise and the Coriolis force acts to the left of the motion, akin to the effect on winds in the Earth's southern hemisphere.

Newton's second law for motion on a rotating planet (e.g., see Taylor, 2005) is

$$\underbrace{\mathbf{a}}_{\text{acceleration on co-rotating frame}} + \underbrace{(2\boldsymbol{\Omega}\times\mathbf{v})}_{\text{coriolis acceleration}} + \underbrace{[\boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\mathbf{r})]}_{\text{centripetal acceleration}} = \underbrace{\frac{\mathbf{F}_g}{m}}_{\text{force of gravity}} + \underbrace{\frac{\mathbf{F}}{m}}_{\text{all other forces}} \qquad [95]$$

where $\boldsymbol{\Omega}$ is the planet's angular velocity vector, the acceleration and velocity are measured by a corotating observer, and the last term includes pressure gradient forces, frictional forces, and external tidal forces caused by gravitational interaction with the Sun or parent star, from a moon, or from a planet being orbited if we are considering the atmosphere of a large moon. Usually, the centripetal acceleration is taken to the right-hand side, treated as 'centrifugal force per kg' and, combined with gravity to form an effective, measured gravity g. A modified g vector is valid because rotating planets deform into oblate surfaces as a result of the centrifugal force pulling outward at the equator. Simplifying eqn [95] by neglecting tidal torques, we get the usual basic form of the momentum equation in atmospheric dynamics,

$$\frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t} = \underbrace{\frac{-1}{\rho}\nabla p}_{\text{preesure gradient force/kg}} - \underbrace{(2\boldsymbol{\Omega}\times\mathbf{v})}_{\text{Coriolis force/kg}} - g\mathbf{k} + \mathbf{F}_{\text{vise}} \qquad [96]$$

where $\mathbf{F}_{\text{visc}}$ is the frictional or viscous force per unit mass, $\mathbf{v}$ is the wind vector, and $\mathbf{k}$ is an upward unit vector. It is possible that tidal forces should not be neglected for long-term climate models rather than weather models. But surprisingly little work has been done to examine this issue (Houben, 2013).

Equation [96] can be expanded into local Cartesian (x, y, z) coordinates on a sphere with equations in three velocity components (e.g., see Holton (2004), Chapter 2): a zonal wind u in the west to east or 'zonal' x direction, a meridional wind v in the south-to-north y direction, and a vertical wind w upward in the z direction, that is, $\mathbf{v} = u\mathbf{i} + v\mathbf{j} + w\mathbf{k}$. The resulting momentum equations simplify for large-scale motions, if we ignore friction and vertical motion (given that vertical winds are usually much smaller than horizontal ones) (e.g., see Andrews (2010) or Holton (2004)):

$$\text{Vertical (hydrostatic equation)}: \quad \frac{\partial p}{\partial z} = -g\rho \qquad [97]$$

$$\text{Zonal momentum}: \quad \frac{\mathrm{d}u}{\mathrm{d}t} - \underbrace{\left(f + \frac{u\tan\phi}{a}\right)}_{\text{Coroilis term}\quad\text{Centrifugal term}} \mathrm{v} = -\frac{1}{\rho}\frac{\partial p}{\partial \mathrm{x}} \qquad [98]$$

$$\text{Meridional momentum}: \quad \frac{\mathrm{d}v}{\mathrm{d}t} + \underbrace{\left(f + \frac{u\tan\phi}{a}\right)}_{\text{Coroilis term}\quad\text{Centrifugal term}} u = -\frac{1}{\rho}\frac{\partial p}{\partial y} \qquad [99]$$

Here, a is the planetary radius at the local x, y, z origin, the latitude is ϕ, and f is the Coriolis parameter defined by

$$f = 2\Omega\sin\phi \qquad [100]$$

where Ω is the planet's angular velocity. Specifically, $\Omega = 2\pi/\tau_{\mathrm{d}}$ where τ_{d} is the rotation period (=a sidereal day), for example,

$\Omega = 2\pi/(86\,164\text{ s}) = 7.29\times10^{-5}$ rad s^{-1} for Earth. If put on the right-hand side, terms f_v and $-f_u$ are x and y components of the Coriolis force per kg that act to the right of the wind in Earth's northern hemisphere. Terms $-(u\tan\phi/a)v$ and $+(u\tan\phi/a)u$ are x and y components of cyclostrophic acceleration, which are important on slowly rotating planets (see Section 10.13.5.2).

In eqns [98] and [99], the derivatives in v and u are substantial *or* material derivatives. The dX/dt form is the (Lagrangian) rate of change of flow-field quantity X with respect to time following a fluid parcel, unlike dX/dt, the (Eulerian) rate of change at a fixed point. They are related by

$$\underbrace{\frac{dX}{dt}}_{\text{substantial derivative}} \equiv \underbrace{\frac{\partial X}{\partial t}}_{\text{local derivative}} \underbrace{+u\frac{\partial X}{\partial x}+v\frac{\partial X}{\partial y}+w\frac{\partial X}{\partial z}}_{\text{advective terms}} = \frac{\partial X}{\partial t}+\mathbf{v}\cdot\nabla X \qquad [101]$$

Here, $\mathbf{v}$ is the velocity vector and we remind ourselves that $\mathbf{a}\cdot\mathbf{b} = a_1b_1+a_2b_2+a_3b_3$, while the gradient operator is $\nabla = \partial/\partial x + \partial/\partial y + \partial/\partial z$. For example, if 2-D spatial contours of temperature T are fixed in time ($\partial T/\partial t = 0$) and an observer moves eastward with velocity u in time. Δt between 250 and 270 K contours, then eqn [101] gives $dT/dt = u\nabla T = (\Delta x/\Delta t)\times(\Delta T/\Delta x) = 20\text{ K}/\Delta t$. Alternatively, if the 250 K contour moves with the wind speed and replaces the 270 K downstream contour, $dT/dt = 0$ because the local change $\partial T/\partial t$ ($-20\text{ K}/\Delta t$) is balanced by advection of temperature, $u\nabla T$. 'Advection' (Latin 'carry to') is the transport of an atmospheric property by the velocity field. The difference between advection and convection is that advection usually refers to the predominantly horizontal, large-scale atmospheric motions, while convection describes the mostly vertical, locally induced motions.

10.13.5.2 Balance Regimes: Geostrophic, Cyclostrophic, and Thermodynamic

10.13.5.2.1 Geostrophic balance

On planets that rotate fairly rapidly, such as Earth, Mars, and the giant planets, the Coriolis force is important. In the Earth's northern hemisphere (NH), the Coriolis force acting to the right of large-scale flow is frequently approximately balanced by low pressure to the left and high pressure to the right, that is, a pressure gradient force. Thus, on NH weather maps, winds blow counterclockwise around a 'low' cyclonic system or clockwise around a 'high' anticyclonic system. The balance of Coriolis and pressure gradient forces is called geostrophic balance. Because $f \gg u/\tan\phi$, eqns [98] and [99] provide this balance as

$$u_g = -\frac{1}{f\rho}\left(\frac{\partial p}{\partial y}\right)_z, \quad v_g = \frac{1}{f\rho}\left(\frac{\partial p}{\partial x}\right)_z \qquad [102]$$

The z subscript indicates a partial derivative evaluated along an altitude surface, while the g subscript denotes geostrophic winds. In deriving eqn [102], we assumed $d(u \text{ or } v)/dt \ll f$ to eliminate d/dt terms. This condition is true if the dimensionless Rossby number (Ro), which is the ratio of the Lagrangian acceleration to Coriolis acceleration, is <0.1 or so, where

$$\text{Rossby number, } Ro = \frac{\text{Relative acceleration}}{\text{Coriolis acceleration}} = \frac{U^2/L_h}{fU} = \frac{U}{fL_h} \qquad [103]$$

Equation [103] uses a scale analysis. The variables U and L_h are characteristic wind speeds and horizontal length scales, respectively. For example, Jupiter has $U \approx 100\text{ m s}^{-1}$, $L_h \approx 100\,000\text{ km} = 10^8$ m, and $f \approx 1.8\times10^{-4}\text{ s}^{-1}$ at 45°N. Thus, $Ro \approx 0.01$, so rotation dominates and geostrophy applies. Similarly, $Ro \ll 1$ for other giant planets, Earth, and Mars. But at the equator, $\phi = 0$ and $f \to 0$, so Ro cannot be small. The result is that circulations on rotating planets are more symmetrical with latitude close to the equator but rotation affects flows strongly at higher latitudes, producing big eddies.

Geostrophy predicts that zonal winds should typically increase in speed with altitude. Usually, the distribution of sunlight creates a temperature decrease from equator to pole, so columns of air on average shrink toward the pole because they are cooler, which must create an increasing meridional pressure gradient at higher altitudes. Since $\partial p/\partial y$ grows with altitude, the zonal wind u_g will grow too by eqn [102]. This link between horizontal temperature gradients and the wind shear – that is, change of wind speed and direction with height – is captured in the thermal wind equation, which is derived from eqn [102] by substituting for $\rho = p/\bar{R}T$ from the ideal gas law (eqn [2]), differentiating w.r.t. z and then substituting the hydrostatic eqn [6]:

$$f\frac{\partial v_g}{\partial z} \approx \bar{R}T\frac{\partial}{\partial x}\underbrace{\left(\frac{1}{p}\left(\frac{\partial p}{\partial z}\right)\right)}_{-g/\bar{R}T} = \frac{-g\cancel{\bar{R}}T}{\cancel{\bar{R}}}\frac{\partial}{\partial x}\left(\frac{1}{T}\right) = \cancel{f}\left(\frac{g}{T\cancel{f}}\frac{\partial T}{\partial x}\right)$$
$$= \frac{g}{T}\frac{\partial T}{\partial x}$$

An approximation sign is used for ignoring vertical variations in T. With analogous manipulation of the zonal geostrophic wind equation, the thermal wind equations in u_g and v_g are

$$f\frac{\partial u_g}{\partial z} \approx -\frac{g}{T}\frac{\partial T}{\partial y}, \quad f\frac{\partial v_g}{\partial z} \approx \frac{g}{T}\frac{\partial T}{\partial x} \qquad [104]$$

These equations (or slightly higher approximations) allow calculation of winds on other planets (e.g., Smith et al., 2001). After deriving temperatures from radiances measured by an orbital instrument, eqn [104] implies the geostrophic winds. Often, no surface wind is assumed as a boundary condition at the expense of some accuracy.

10.13.5.2.2 Cyclostrophic balance

The analysis in the preceding text applies to rapidly rotating planets, but for slowly rotating planets, the balance is different. For example, on Venus, $L_h \approx 1000\text{ km} = 10^6$ m, $U \approx 10\text{ m s}^{-1}$, and $f = 2\Omega\sin\phi = 2(2.98\times10^{-7}\text{s}^{-1})(\sin\ 45) = 4.2\times10^{-7}\text{s}^{-1}$ at 45°N, so the $Ro \approx 10$ from eqn [103] and geostrophy is invalid. If the atmosphere itself rotates sufficiently rapidly over some altitude range, the substantial derivatives and f terms are negligible in eqns [98] and [99], and a cyclostrophic balance and a cyclostrophic thermal wind apply, as follows:

$$\text{(a)}\ \underbrace{\frac{u^2\tan\phi}{a} = -\frac{1}{\rho}\frac{\partial p}{\partial y}}_{\text{cyclostrophic balance}};$$

$$\text{(b)}\ \underbrace{\frac{\tan\phi}{a}\frac{\partial(u^2)}{\partial z} \approx -\bar{R}T\frac{\partial}{\partial y}\left(\frac{1}{p}\frac{\partial p}{\partial z}\right) = -\frac{\bar{R}\cancel{T}}{\cancel{\bar{R}}T\cancel{f}}\frac{g}{\cancel{f}}\frac{\partial T}{\partial y} = -\frac{g}{T}\frac{\partial T}{\partial y}}_{\text{cyclostrophic thermal wind equation}} \qquad [105]$$

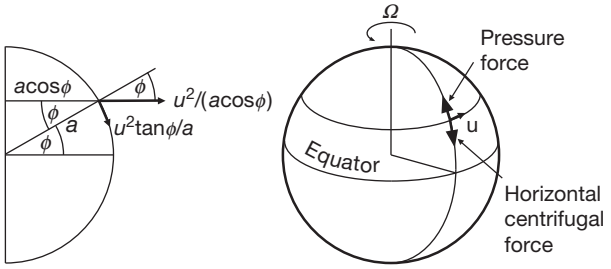

Figure 9 The geometry of cyclostrophic balance and the balance of forces on a slowly rotating planet such as Venus or Titan. Here, ϕ is latitude, a is planetary radius, $\mathbf{u}$ is the zonal wind vector, and Ω is a planetary rotation vector. (Drawn by author.)

Equation [105](a) is a balance between centrifugal force per unit mass and an equator-to-pole pressure gradient force (Figure 9). At latitude ϕ, the centrifugal acceleration due to the zonal wind is $u^2/(a\cos\phi)$, because $a\cos\phi$ is the distance to the rotation axis. On Venus and Titan, wind speeds increase with altitude consistent with a cyclostrophic thermal wind according to Pioneer Venus (Schubert, 1983; Seiff et al., 1980) and Huygens probe (Bird et al., 2005) measurements, respectively. Equation [105] should also apply to slowly rotating exoplanets.

10.13.5.2.3 Thermodynamic balance

Large-scale ascent and descent produce expansion and compression, which can change temperatures from those expected with simple radiative–convective equilibrium (Section 10.13.3.4). The physics derives from the first law of thermodynamics, written $dq = c_p dT - \alpha dp$, where $\alpha = 1/\rho$, from eqn [12]. Dividing by δt and c_p and taking the limit $\delta t \to 0$,

$$\underbrace{\frac{dT}{dt}}_{\text{time variable component}} + \underbrace{w\left(\frac{\partial T}{\partial z} + \frac{g}{c_p}\right)}_{\text{workdone}} \underbrace{-\frac{\alpha}{c_p}\left(\frac{dp}{dt}\right)}_{\approx -g\rho w} = \underbrace{\frac{Q}{c_p}}_{\text{heat gain}} \Rightarrow \underbrace{w\left(\frac{\partial T}{\partial z} + \frac{g}{c_p}\right)}_{\text{static stability}} \approx \underbrace{\frac{Q}{c_p}}_{\text{heat gain}} \quad [106]$$

Here, $Q = dq/dt$ [J kg^{-1} s^{-1}] is the diabatic heating per kg caused by radiation, convection, or conduction. In the middle part of eqn [106], we used eqn [101] to define T' as the horizontal (x, y) and time variable component of temperature and T as a horizontal and time average temperature. Since the term in T' is usually small, we neglect it for the final expression, which is a thermodynamic energy equation. This describes a rate of temperature change (K s^{-1} or K day^{-1}) for a parcel of air with vertical velocity and diabatic heating. We can replace the diabatic heating term with a Newtonian cooling approximation, in which temperature relaxes back to an equilibrium reference temperature field described by T_{eqm} as $Q/c_p = -\alpha_N(T - T_{eq})$, where $\alpha_N = 1/\tau_{rad}$ where τ_{rad} is a radiative time constant. Recognizing static stability (eqn [17]) in eqn [106], we can write thermodynamic balance as

$$w(\Gamma_a - \Gamma) = -\alpha_N(T - T_{eqm}) \quad [107]$$

This equation indicates that heating or cooling from vertical motion is balanced by radiative relaxation back to an equilibrium temperature. The radiative time constant can be estimated as

$$\tau_{rad} = \frac{\text{heat change per m}^2}{\text{absorbed flux per m}^2} = \left(\frac{p_e c_p(\Delta T_e)}{g}\right) \Big/ \left(\frac{(1-A)S_p}{4}\right) = \frac{4p_e c_p(\Delta T_e)}{(1-A)S_p g} \quad [108]$$

where p_e is the pressure at the emission level, g is the gravitational acceleration, ΔT_e is the temperature change forced by the absorption of solar radiation (~2 K for Earth or 80 K for Mars), c_p is the specific heat capacity, A is the Bond albedo, and S_p is the top-of-atmosphere solar flux. This uses eqns [8] and [23].

We can see the effect of eqn [107] in latitude-averaged temperature structures of planetary atmospheres. Static stability $(\Gamma_a - \Gamma)$ is generally positive, so if we measure $T < T_{eqm}$, then w is positive and large-scale ascent produces temperatures colder than equilibrium from cooling by expansion. Conversely, if $T > T_{eqm}$, large-scale descent produces compressional warming. In Mars' equinox atmosphere (Figure 10), one's naive expectation of warmer tropics and colder poles is reversed at pressures below ~0.5 mbar. Large-scale Hadley circulation cells (discussed in the succeeding text) produce descent and compressional warming at high latitudes and ascent and cooling at low latitudes.

10.13.5.3 Zonal Mean Meridional Circulation: Hadley Cells and Thermally Driven Jets

Jet streams or jets are significant features of the circulations of planetary atmospheres, defined as zonal wind maxima, whether eastward or westward. The style of atmospheric circulations is closely connected with jet stream structure, which varies greatly between planets. Jets can be single or multiple in each hemisphere. They may be strong or weak, meandering in latitude or straight. They are generally associated with transient eddies or waves whose zonal wave numbers (the number of complete waves around a latitude circle) vary between planets from wave number one on Venus to wave number >40 on Jupiter.

It is convenient to think of two types of jets: those driven directly by the equator-to-pole temperature gradient (thermally driven jets) and those driven indirectly by eddies (eddy-driven jets), respectively (Lee and Kim, 2003). In large-scale atmospheric dynamics, an eddy means a departure from a steady and uniform east–west flow, which results in variations in pressure with longitude. We consider thermally driven jets first.

The subtropical jet that occurs in the Earth's atmosphere at 30–40° latitude is thermally driven and associated with the descending branch of a large overturning of the tropical atmosphere called the Hadley circulation. This circulation is a large loop of airflow where air warms and rises in the tropics, cools and sinks at higher latitudes, and returns to the tropics near the surface to complete the loop, all under the influence of planetary rotation (Figure 11). George Hadley (1685–1786) invented the concept to explain tropical trade winds (Hadley, 1735). Equatorial-moving air is deflected by the Coriolis force toward the west and produces persistent westward tropical winds. In the subtropics, sinking causes high-pressure zones of dry air that also explain deserts such as the Sahara.

Hadley imagined a circulation symmetrical about the equator, but we know now that the Earth's Hadley circulation is

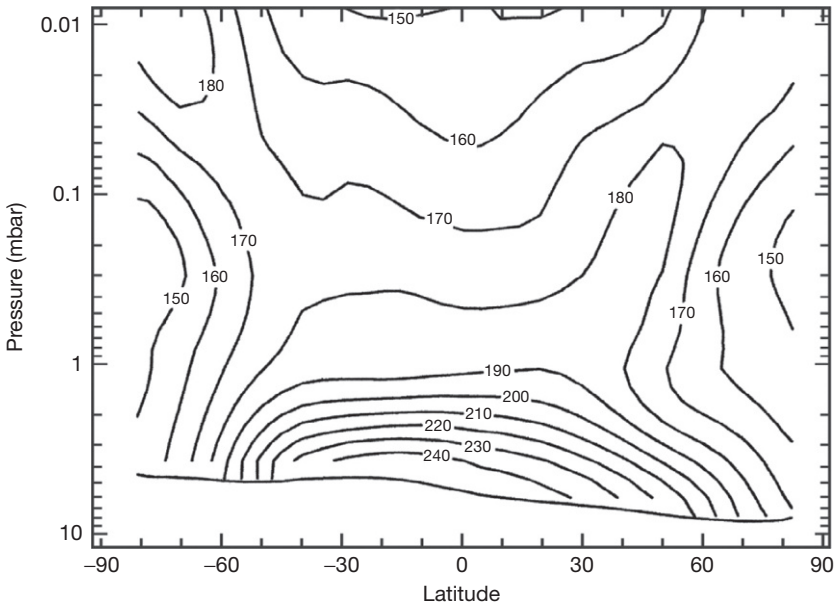

Figure 10 Contours of the zonal mean meridional temperatures (in K) at northern hemisphere autumnal equinox on Mars derived from measurements by the Thermal Emission Spectrometer (TES) instrument on NASA's Mars Global Surveyor orbiter. The solid line at the lower boundary of the temperature contours is the zonal mean atmospheric pressure at the surface. Adapted from Smith MD, Pearl JC, Conrath BJ, and Christensen PR (2001) Thermal Emission Spectrometer results: Mars atmospheric thermal structure and aerosol distribution. *Journal of Geophysical Research* 106: 23929–23945 with permission.

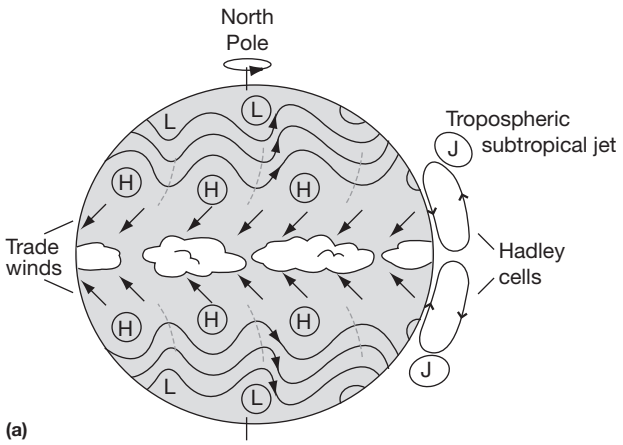

Figure 11 Idealized symmetrical Hadley cells on Earth. Moist air rises near the equator tropics causing a belt of clouds. The air aloft travels poleward, acquiring a fast zonal speed by conservation of angular momentum. This results in a subtropical jet near the descending branch of the Hadley cell. At the surface, air returns to complete the loop, causing westward trade winds in the tropics. In each hemisphere, a different circulation is found beyond the maximum latitudinal extend of the Hadley circulation. In midlatitudes, there are waves that are found in the eastward winds. (Adapted from Wallace JM and Hobbs PV (2006) *Atmospheric Science: An Introductory Survey*, 2nd edn. Burlington, MA: Elsevier Academic Press, International geophysics series. Used with permission.)

symmetrical in neither latitude nor longitude (Cook, 2004; Dima and Wallace, 2003; Lindzen and Hou, 1988). Rising air occurs as relatively small-scale convection associated with heavy rainfall in the intertropical convergence zone (ITCZ) where low-level southwestward trade winds from the northern hemisphere converge with northwestward trade winds from the south. The ITCZ is generally located somewhat off the equator (Figure 12). The descending branches of the Hadley circulation are also not uniform in longitude. Subsidence takes place preferentially in high-pressure areas over the subtropical Atlantic, Pacific, and Indian Oceans.

Monsoons are associated with the Hadley circulation and exist on Earth and Mars. A monsoon is a seasonal reversal of winds associated with latitudinal movement of the ITCZ, and the monsoon behaves as an intensification of the Hadley circulation in particular longitude ranges (e.g., Schneider (2006)). On Earth, the ITCZ is offset from the equator because of planetary obliquity and the distribution of oceans and continents. Surface winds curve across the equator and turn from westward to eastward due to the Coriolis force and become a monsoon circulation. The Martian orbit has a relatively high eccentricity with more incoming solar radiation near the southern summer winter solstice, and there is asymmetrical topography between hemispheres, causing the Hadley circulation to be stronger than during southern winter solstice (Haberle et al., 1993b; Richardson and Wilson, 2002). The lower Hadley branch can be channeled by large-scale topography to form monsoon-like circulations (Joshi et al., 1994, 1995).

A key physical concept behind the Hadley circulation is conservation of angular momentum. In the simplest model, one assumes that angular momentum per unit mass is conserved in the upper branch of the Hadley circulation. At the equator, assuming no zonal wind, the angular momentum per unit mass is Ωa^2, where a is the planetary radius. If angular momentum per unit mass is conserved in transport of air parcels from the equator to latitude ϕ, a zonal wind u is acquired, as follows:

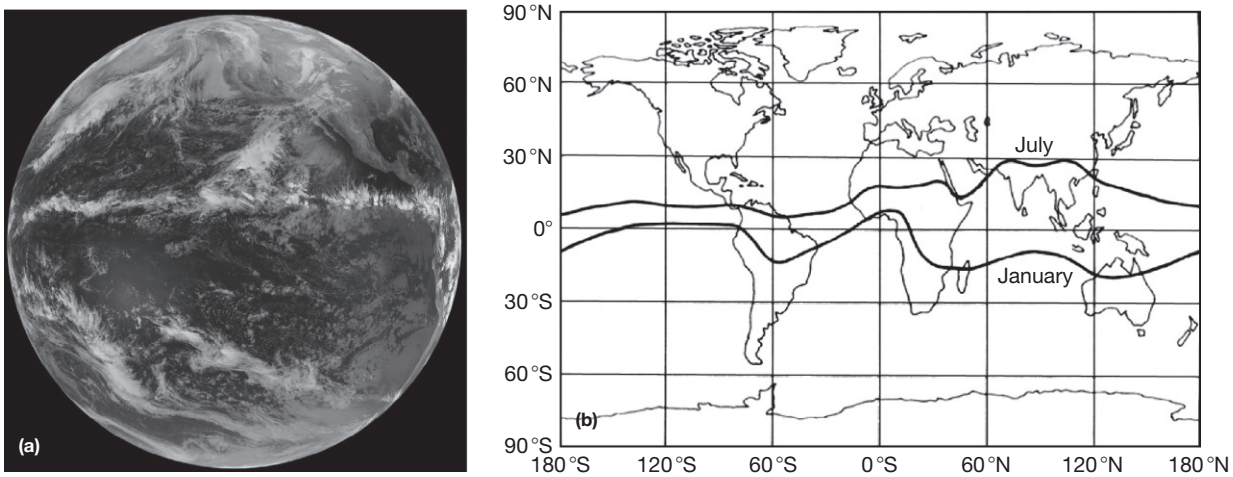

Figure 12 (a) The intertropical convergence zone (ITCZ) of the trade winds is visible on Earth as a band of cloud across the eastern Pacific from west to east (Courtesy: NOAA/NASA GOES project). (b) The latitude of the ITCZ changes seasonally and the annual average latitude of the ITCZ is north of the equator unlike an idealized symmetrical Hadley circulation.

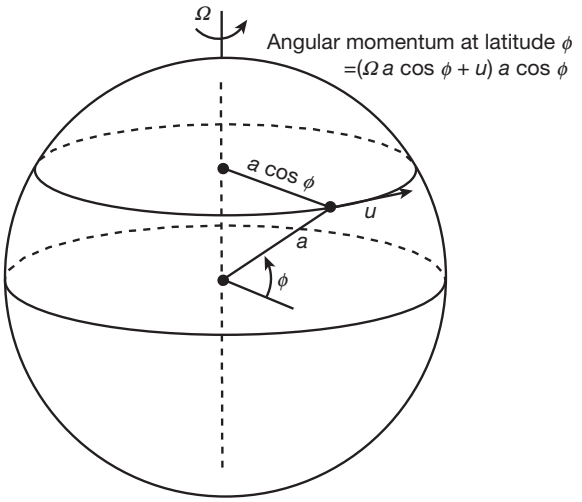

Figure 13 Zonal angular momentum acquired at latitude ϕ in poleward motion of air in the upper branch of the Hadley circulation helps in understanding the Hadley circulation. Rapid zonal wind speeds u are produced, which is responsible for a subtropical jet at the most poleward latitude to which the Hadley circulation extends. (Drawn by the author.)

$$\underbrace{\Omega a^2}_{\text{ang.momentum@equator}} = \underbrace{(\Omega a\cos\phi + u)a\cos\phi}_{\text{angular momentum@latitude }\phi} \Rightarrow u\cos\phi$$

$$= \underbrace{\Omega a\left(1-\cos^2\phi\right)}_{\sin^2\phi} \Rightarrow u = (\Omega a)\frac{\sin^2\phi}{\cos\phi} \qquad [109]$$

A point on the planet's surface at latitude ϕ moves with tangential velocity $\Omega a \cos\phi$, to which we add the zonal wind speed, u (Figure 13). The radius to the planetary rotation axis is $a\cos\phi$, so that angular momentum conservation is given by the first equality, and we solve for u. Imagine air in the upper branch of the Hadley circulation carried from the equator, where $u=0$, to latitude 30°. Equation [109] predicts $u = 134$ m s^{-1} at 30° Thus, we expect strong subtropical eastward winds at altitude.

The subtropical jet core in the upper branch of the Earth's Hadley circulation seasonally reaches ~30–70 m s^{-1} – nowhere as high as predicted in the preceding text because eddies from the midlatitudes provide westward angular momentum that decelerates the upper branch of the Hadley cell (Schneider, 2006). Of course, friction causes slow surface winds, so that winds must increase with altitude near the jet. We can look at the thermal wind eqn [104] in 'reverse': a large wind shear must have a correspondingly big meridional temperature gradient $\partial T/\partial y$ in the vicinity of the jet, unlike the smooth variation of equilibrium temperature with latitude that we might expect. Large-scale ascent is associated with $T < T_{eqm}$ on the equatorial side of the jet. Conversely, large-scale descent occurs on the polar side where $T > T_{eqm}$.

If one assumes that heating and cooling balance across a Hadley cell, then it is possible to derive an equation for the maximum latitude ϕ_H for how far a Hadley cell extends, which varies as $\phi_H \propto g^{0.5}/(\Omega a)$ (Held and Hou, 1980). However, such a theory underpredicts the meridional mass transport (kg s^{-1}) of the Hadley circulation by an order of magnitude. Other models suggest that midlatitude eddies confine the Hadley circulation. Possibly, the Hadley circulation winds and temperatures become unstable, which prevents penetration into midlatitudes. Energy carried from the tropics is transferred from the Hadley cells to eddies and waves characteristic of midlatitudes. Using such ideas, Held (2000) derived a weaker dependence on rotation of $\phi_H \propto (g^{0.5}/(\Omega a))^{0.5}$. Earth-like general circulation model simulations confirm that the Hadley circulation contracts in latitude range with increasing rotation rate (Del Genio and Suozzo, 1987; Navarra and Boccaletti, 2002; Showman et al., 2013). With slow rotation, if the

$Ro \gtrsim 10$, a planet behaves as an 'all tropics' world because Hadley cells extend to high latitudes (Showman et al., 2013).

As slowly rotating bodies, Venus and Titan should have Hadley circulations extending to high latitude, but relatively little evidence proves this. On Venus, ~20 W m^{-2} of sunlight reaches the surface (Titov et al., 2007), so the Hadley circulation must be weak. Surface wind markings from Magellan radar have an equatorward direction at higher latitudes and an east–west direction nearer the equator consistent with a large-scale Hadley circulation (Greeley et al., 1997). Venus absorbs 100 W m^{-2} near its cloud tops (~60–70 km), which should drive a second Hadley-like circulation above the clouds (Baker and Leovy, 1987). A strong temperature gradient and weak maximum in the zonal wind speed at ~55° latitude in both hemispheres indicates this circulation's probable extent. On Titan, low-latitude dunes indicate eastward flow, opposite to the expected trade winds (Jaumann et al., 2009). Possibly, the dunes form during periods when equatorial zonal winds reverse and strengthen (Tokano, 2009, 2010) (see **Chapter 10.12**).

10.13.5.4 Eddy-Driven Jet Streams

In terrestrial midlatitudes, we find an eddy-driven polar jet stream associated with systematically structured eddies superimposed on the zonal mean flow. A familiar example of such eddies are traveling cyclones and anticyclones. There is also a stationary wave structure due to the distribution of oceans and continents. On the giant planets, multiple jets are probably eddy-driven also (Ingersoll, 1990; Williams, 1978) (**Figure 14**). On Mars and Venus, the single, primarily thermally driven jet in each hemisphere is also altered by large-scale stationary and transient eddies.

To understand eddy-driven jets, we introduce concepts of rotation in fluid dynamics. Rather than quantify spin in terms of velocity and distance to a center of rotation, vorticity is used, a single quantity that describes the spin of a fluid element at a point, equivalent to the curl of the wind vector, curl $\mathbf{v} = \nabla \times \mathbf{v}$. In 2-D flows, ignoring the velocity dependence on altitude and the vertical velocity, relative vorticity ζ is a measure of spin about a vertical axis on a planet's surface:

$$\zeta = \nabla_h \times \mathbf{v}_h = \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right) \times (u, v) \quad \Rightarrow \zeta = -\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \qquad [110]$$

The sign of ζ follows a right-hand rule: with fingers in the direction of curved flow, 'thumb up' is positive. Vorticity measures both change of velocity transverse to the flow (horizontal shear) and curvature of the flow. In solid-body rotation, relative vorticity is 2ω (where ω is angular velocity): a shear contribution of the change in tangential velocity with radius, $\partial V/\partial r = \partial(\omega\ \mathrm{r})/\partial r = \omega$, adds to curvature from the change in the tangential velocity with angle, $V(\partial(\text{angle})/\partial(\text{path})) = V(2\pi/2\pi r) = V/r = \omega$. Cyclonic relative vorticity is always in the same direction as the component of the planet's rotation, and a cyclonic vortex is always a low-pressure zone. In the Earth's northern hemisphere, cyclonic flow is counterclockwise but would be clockwise in the southern hemisphere. Anticyclonic relative vorticity is in the opposite direction to the component of planetary rotation.

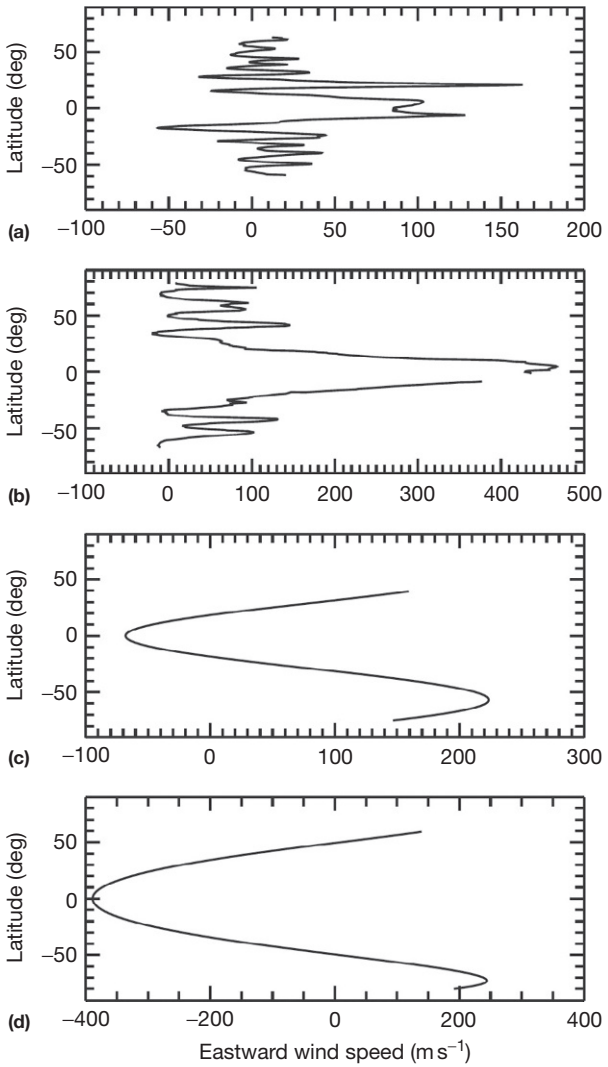

Figure 14 Jet streams on the giant planets are shown in zonal mean zonal winds from cloud tracking on (a) Jupiter, (b) Saturn, (c) Uranus, and (d) Neptune. The peaks, whether eastward or westward, correspond to jets. Jupiter and Saturn have 20 east–west jets, with a strong prograde jet over the equator, while Uranus and Neptune appear to have 3 broad jets, with strong retrograde jet over the equator. Adapted from Showman AP, Cho JYK, and Menou K (2010) Atmospheric circulation of extrasolar planets. In: Seager S (ed.) *Exoplanets*, pp. 471–516. Tucson, AZ: University of Arizona Press.

An element of fluid has a component of the planet's spin as well as any relative vorticity. The solid planet has a vorticity of 2Ω, and its vertical component of $2\Omega\sin\phi$ at latitude ϕ is the planetary vorticity, equivalent to the Coriolis parameter, f (eqn [100]). If we add relative vorticity (ζ) and planetary vorticity (f), we obtain the absolute vorticity η:

$$\eta = \zeta + f = \left(-\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) + f \qquad [111]$$

In adiabatic, inviscid flow in a thin homogeneous layer absolute vorticity, η, is conserved, that is, stays constant with time, if there is no friction or stirring. We denote the latter by a vorticity forcing term S_η:

$$(a)\ \text{no friction or stirring}\ \frac{d\eta}{dt}=0,$$

$$(b)\ \text{with friction or stirring}\ \frac{d\eta}{dt}=S_\eta \qquad [112]$$

Here, the substantial derivative is $d/dt=\partial/\partial t + u\partial/\partial x + v\partial/\partial y$.

Equation [112](b) can be used to understand how jets are forced by eddies. A common technique in fluid dynamics is linearization in which variables are represented by mean values and perturbations and inserted into equations; then certain terms are eliminated to obtain equations that can be solved analytically. Consider a uniform zonal mean flow and an eddy fluctuation deviation that is primed, $u=\overline{u}+u'$, along with a small meridional perturbation $v=v'$. Primed variables represent parts that vary in longitude, associated with eddies. The average of the product of fluctuation components, for example, $\overline{u'v'}$, is the covariance and is nonzero only when u' and v' are correlated, that is, in phase. Thus, applying a perturbation to eqn [112](b), we have

$$\left(\frac{\partial}{\partial t}+(\overline{u}+u')\frac{\partial}{\partial x}+v'\frac{\partial}{\partial y}\right)(\overline{\eta}+\eta')=S_\eta'$$

$$\Rightarrow\left(\frac{\partial}{\partial t}+\overline{u}\frac{\partial}{\partial x}\right)\eta'+v'\frac{\partial}{\partial y}\overline{\eta}=S_\eta' \qquad [113]$$

Here, $\overline{\eta}$ has no dependence on t or x, and we eliminate small terms. If we multiply eqn [113] by η', take the zonal average, and delete terms with a zonal mean of zero, we get an

$$\underbrace{\overline{\eta'\frac{\partial\eta'}{\partial t}}}_{\frac{1}{2}\frac{\partial(\eta')^2}{\partial t}}+\cancel{\overline{u}\overline{\eta'\frac{\partial\eta'}{\partial x}}}+\overline{v'\eta'}\frac{\partial\overline{\eta}}{\partial y}=\overline{S_\eta'\eta'}\Rightarrow \underbrace{\overline{v'\eta'}}_{\text{poleward vorticity transport by eddies}}$$

$$=-\underbrace{\frac{\partial\overline{(\eta')^2}/\partial t}{2\,\partial\overline{\eta}/\partial y}}_{\text{vorticity variance term}}+\underbrace{\frac{\overline{S_\eta'\eta'}}{\partial\overline{\eta}/\partial y}}_{\text{eddy forcing term}} \qquad [114]$$

Examine eqn [114]. Because f increases with latitude and $\partial f/\partial y$ is positive, the meridional gradient of absolute vorticity $\partial\overline{\eta}/\partial y$ is generally >0. So, the generation of vorticity variance by eddy stirring is associated with poleward flux of vorticity across some latitude circle ϕ_1 by the eddies represented by $\overline{v'\eta'}$ at latitude ϕ_1. This increases vorticity in the whole area of the planet poleward of ϕ_1.

It turns out that an increase of vorticity above latitude ϕ_1 can drive a prograde jet at ϕ_1 (here, the word prograde means in the same direction as the rotation of the planet, e.g., eastward for Earth; retrograde means the opposite direction). The vorticity (rotation at a point) is related to the circulation (rotation over an area) around a closed curve enclosing that area by Stokes' theorem. Writing down this theorem and applying it to the whole domical region (a spherical cap) north of latitude ϕ_1, we have

$$\underbrace{\Gamma_C}_{\text{circulation }[m^2s^{-1}]}=\oint\underbrace{V_s}_{\text{velocity along arc ds}}ds=\iint_{\text{area A}}\eta dA$$

$$\Rightarrow 2\pi(a\cos\phi_1)\overline{u}$$

$$=\int_{\lambda=0}^{2\pi}\int_{\phi=\phi_1}^{\pi/2}\eta a^2\cos\phi d\phi d\lambda$$

$$=2\pi[\eta]a^2\int_{\phi=\phi_1}^{\pi/2}\cos\phi d\phi \qquad [115]$$

The result means the following: a poleward vorticity flux by eddies that increases the average vorticity $[\eta]$ in the domical region poleward of ϕ_1 also increases the mean zonal wind $\overline{u}$ at ϕ_1.

Conversely, if eddies drift poleward to another latitude ϕ_2 where there is dissipation, then $\overline{S_\eta'\eta'}$ is negative. At latitude ϕ_2, the eddy vorticity flux will be equatorward (negative), and a retrograde jet will be forced via eqn [115]. Thus, if eddies propagate north or south, prograde and retrograde jets can be generated and multiple jets could form on rapidly rotating planets.

Another way to look at eddy-driven jets is to consider the north–south flux of momentum from the eddies. The northward eddy momentum across a latitude circle is $\rho v'$ (kg m^2 s^{-1}) so that the poleward flux of eastward eddy momentum is $\int\overline{u'(\rho v')}dA$ where the overbar is a zonal average and dA is an element of area of an imaginary great wall around the latitude circle. If the northward eddy wind and eastward eddy wind are correlated, $\overline{u'v'}>0$, and there is northward flux of zonal momentum per unit mass. Negative $\overline{u'v'}$ corresponds to a southward flux. From vector addition of the primed velocities, eddy wind component covariance corresponds to a tendency for tilted eddies. Where $\overline{u'v'}>0$, there is SW to NE tilt of the eddies. Conversely, $\overline{u'v'}<0$ corresponds to systematic NW to SE tilt. So, air parcels traveling along a SW–NE trajectory and then back feed momentum to an eastward jet to the north. More generally, if the shear of the zonal wind along a meridian, $d\overline{u}/dy$, and $\overline{u'v'}$ have the same sign, eddies accelerate jets. Eddies are said to transport momentum upgradient (Held, 1975; Thompson, 1971). This appears to be true on Jupiter (Salyk et al., 2006). On Earth, we find a departure from the symmetrical sinusoid form of waves and a systematic eastward tilt in eddies in midlatitudes so that southward motions have a smaller eastward component than northward motions (Starr, 1948), which causes net angular momentum transport (Figure 15).

10.13.5.5 Planetary Waves and Barotropic and Baroclinic Instabilities

Jets meander in latitude because of waves in the circulation. The most important class of waves in this regard are Rossby waves, which are oscillations that arise primarily in the horizontal because conservation of absolute vorticity acts to restore flows displaced meridionally to the latitude of origin. Consider an air parcel moving eastward with zero relative vorticity ($\zeta=0$) that is perturbed northward, perhaps because of flow over topography. Planetary vorticity f increases northward

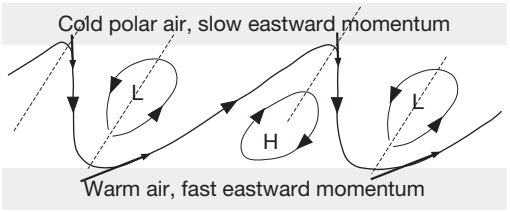

Figure 15 Tilts in the eastward winds cause momentum to be transported from the equator to poles. (These tilts were also drawn on Figure 11 as dashed lines). (Drawn by the author.)

(eqn [100]), so relative vorticity ζ must become negative to keep absolute vorticity constant ($\eta = \zeta + f$). Remembering the right-hand grip rule, negative ζ is anticyclonic curvature (clockwise in the Earth's northern hemisphere), which sends the parcel southward, back to its initial latitude (**Figure 16**). Then, an overshoot beyond the initial latitude will induce cyclonic curvature and send the parcel back northward. The air parcel sinusoidally oscillates as it moves downstream making a Rossby wave. Meanders in the Earth's midlatitude jet stream with typical wave numbers of 4 to 6 are guided by Rossby waves. Low-pressure cyclones tend to form in the troughs of the waves, and high-pressure anticyclones tend to form in the crests. Similar Rossby waves have been observed on Mars in midlatitudes in spring and winter with wave numbers 1–2 (Hollingsworth and Barnes, 1996; Read and Lewis, 2003; Wilson et al., 2002).

The restoring effect due to the gradient in planetary vorticity (f) is called the beta effect where beta $= \beta = \partial f/\partial y$ is the meridional gradient of planetary vorticity. If we assume a zonal mean zonal wind and differentiate absolute vorticity η (eqn [111]) w.r.t. y, we get

$$\frac{\partial \eta}{\partial y} = \beta - \frac{\partial^2 \overline{u}}{\partial y^2}, \quad \text{where } \beta \equiv \frac{\partial f}{\partial y} = \underbrace{\frac{\partial (2\Omega \sin\phi)}{\partial y}}_{\delta y = a\delta\phi,\ \text{spherical geometry}}$$

$$= \frac{1}{a}\frac{\mathrm{d}f}{\mathrm{d}\phi} = \frac{2\Omega\cos\phi}{a} \qquad [116]$$

Usually, β is much larger than $-\partial^2\overline{u}/\partial y^2$ so $\partial\eta/\partial y \approx \beta$ provides the restoring effect.

It is possible to derive sinusoidal functions in x, y, and t that represent Rossby waves. The procedure is to rewrite the vorticity eqn [113] in terms of a single variable, a stream function, ψ, which is a scalar field for a fluid flow with contour lines that are streamlines of the flow, defined as $u = -\partial\psi/\partial y$ and $v = -\partial\psi/\partial x$ (e.g., see Holton (2004), pp. 213–217). The Rossby wave solutions in ψ are found to have a dispersion relation, meaning how the eastward phase speed c of the Rossby wave varies with wavelength, as follows:

$$c = \frac{\omega}{k} = \overline{u} - \frac{\beta}{(k^2 + n^2)}$$

$$= \text{phase speed relative to planet's surface} \qquad [117]$$

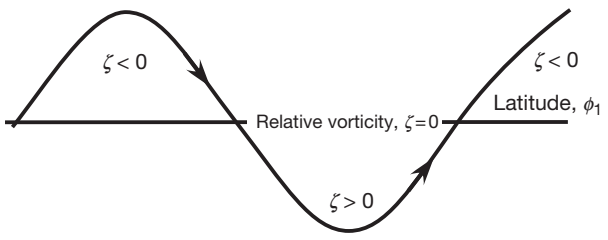

Figure 16 Illustration of the mechanism of Rossby waves in the *x*-*y* plane: a restoring effect caused by the gradient of absolute vorticity. A fluid parcel in the northern hemisphere moves eastward through the wave pattern. As it crosses latitude ϕ_1, the relative vorticity $\zeta = 0$. North of ϕ_1, conservation of absolute vorticity requires $\zeta < 0$, so the trajectory curves to the south anticyclonically. When it shoots over latitude ϕ_1, to conserve absolute vorticity $\zeta > 0$ and the trajectory curves northward cyclonically. (Drawn by the author.)

Here, $k = 2\pi/\lambda_x$ and $n = 2\pi/\lambda_y$ are zonal and meridional wave numbers, where λ_x and λ_y are zonal and meridional wavelengths, respectively. In the simple case where $n = 0$, the waves propagate eastward relative to the planet and westward relative to the zonal wind, at phase speeds that increase with increasing wavelength or smaller k. Setting $n = 0$ and $c = 0$ in eqn [117] gives $k^2 = \beta/\overline{u}$ for stationary waves with a west–east wavelength of $\lambda_x = 2\pi(\overline{u}/\beta)^{0.5}$. For example, in the Earth's middle troposphere at 45°N, $\beta \sim 1.6 \times 10^{-11}\ \mathrm{m^{-1}\,s^{-1}}$, the stationary wavelength is ~7000 km if $\overline{u} = 20\,\mathrm{m\,s^{-1}}$, and four such wavelengths would encircle the Earth.

Strictly horizontal flows with no temperature variations (parallel isobars and isotherms) are called barotropic and such flows are stable when $\beta - \partial^2\overline{u}/\partial y^2 0$. However, if the second term – the curvature of the zonal wind profile with latitude – becomes bigger than β, then instability is produced called the barotropic instability or Rayleigh–Kuo instability. Then, growing unstable eddies derive their energy from the KE of the zonal mean flow. In prograde jets, the zonal wind decreases to the right of the flow where $\partial^2\overline{u}/\partial y^2$ can be large. Barotropic instability produces unstable eddies that propagate to latitudes where they decay and accelerate retrograde zonal mean flow. Numerical simulations of jets forced by the eddies indicate a meridional length scale associated with this instability, characteristic of the width of the jets, called the Rhines radius, $r_{\mathrm{Rh}} \sim (2U/\beta)^{1/2}$, where U is the typical speed of the jet (Rhines, 1975). On giant planets, vortices stop growing at this size in the meridional directional and stretch out east–west, around a circle of latitude. Thus, the number of bands on the face of a gas giant is roughly a semicircle meridian divided by the Rhines radius, $-(\pi a)/r_{\mathrm{Rh}}$ (Menou et al., 2003).

In real atmospheres, we must consider vertical variations. General flows with vertical wind variations, nonzero vertical velocity, and horizontal temperature gradients (thus, mutually inclined isobars and isotherms) are called 'baroclinic.' Instead of vorticity, an analogous quantity, potential vorticity (PV), is introduced to allow for the vertical stretching or shrinking of fluid columns. Shrinking of the radius of a column of spinning fluid increases the spin rate, like an ice skater drawing in their arms. PV is conserved for a fluid element in the absence of mixing with other air parcels or frictional loss of KE and, in a constant density fluid, can be defined as

$$P_{\mathrm{v}} = \frac{\eta}{h} = \frac{(f + \zeta)}{h}\left(\mathrm{m^{-1}s^{-1}}\right) \qquad [118]$$

where h is the height of a short segment of a fluid column (e.g., Wallace and Hobbs, 2006, p. 289). Here, the word potential crops up again. In potential temperature (**Section 10.13.2.4**), we had a quantity remaining the same in adiabatic expansion, although the actual temperature changed. Potential vorticity is conserved for a fluid element, but the element's relative vorticity changes with changing latitude or column height. When density ρ varies with height, a more general version of PV is Ertel's potential vorticity Q_{P}:

$$Q_{\mathrm{P}} = \frac{\eta}{\rho}\frac{\partial\theta}{\partial z} \qquad [119]$$

where θ is potential temperature and the sign of $\partial\theta/\partial z$ indicates static stability (**Section 10.13.2.4**). In adiabatic flow, if static stability $\partial\theta/\partial z$ increases, shrinking and horizontal expansion

of fluid columns causes the absolute vorticity n to decrease according to eqn [119], if Q_P stays constant. The converse also applies. Since Q_P involves potential temperature, it can be generated and dissipated by diabatic heating, stirring, or friction.

Ertel's PV can be calculated from temperature and pressure fields, but analytic approaches often use quasigeostrophic (QG) potential vorticity q_g, which is an approximate form of PV valid when the *Ro* is small and flows are approximately geostrophic. Equations based around QGPV are helpful in studying large-scale motions characteristic of atmospheric circulations. An equation analogous to eqn [113] can be derived but with absolute vorticity η replaced by QGPV, q_g, which again can be written in terms of a single stream function and solved to give 3-D planetary wave solutions (e.g., see Andrews, 2010). The key difference is that such waves have an amplitude perturbation ψ' that depends on height. Analogous to $^1/_2(\text{mass}) \times (\text{velocity})^2$, the wave KE density $\sim \rho\psi'^2$ is independent of height in the absence of dissipation. So, for this quantity to remain constant, the amplitude grows as $\psi' \sim \rho_0^{-0.5}$, where ρ_0 is the background density. Such a relationship is used in photochemical models of planetary atmospheres where turbulence (at least to certain altitudes) is often parameterized proportional to $\rho^{-0.5}$. The same $\rho^{-0.5}$ dependence also applies to the vertical amplitude growth of buoyancy waves (**Section 10.13.5.7**).

The meridional gradient of zonal mean QGPV is somewhat analogous to eqn [116] but has an extra term that depends on the vertical shear of the zonal mean zonal wind (e.g., see Salby (2012), p. 465, or Andrews (2010), p. 128 for derivation of QGPV equations):

$$\frac{\partial \overline{q}_g}{\partial y} = \beta - \frac{\partial^2 \overline{u}}{\partial y^2} + \left(\frac{1}{\rho_0}\right)\frac{\partial}{\partial z}\left[\left(\rho_0 \frac{f_0^2}{N_B^2}\right)\frac{\partial \overline{u}}{\partial z}\right] \qquad [120]$$

Here, f_0 is the value of the Coriolis parameter f at a reference latitude ($f = f_0 + \beta y$), N_B is the Brunt–Väisälä frequency (**Section 10.13.2.4**), and ρ_0 is a height-dependent zonal and time-mean density, that is, $\rho_s \exp(-z/H)$, where H is density scale height and ρ_s a reference density. Just as barotropic instability was caused by a change of sign of $\partial\eta/\partial y$ in eqn [116], so instability arises when $\partial \overline{q}_s/\partial y$ changes sign. When the third term $(1/\rho_0)\partial/\partial z(\rho_0 B \partial \overline{u}/\partial z)$ dominates, a different kind of instability emerges. This is baroclinic instability, which is when flow is driven by the extraction of potential energy from a latitudinal temperature gradient, causing large-scale eddies. If we use the barometric law $\rho_0 = \rho_s \exp(-z/H)$ and differentiate the last term of eqn [120] w.r.t. z using the product rule, we see that this term depends on the vertical wind shear:

$$\left(\frac{1}{\rho_0}\right)\frac{\partial}{\partial z}\left[(\rho_0 B)\frac{\partial \overline{u}}{\partial z}\right] \approx \left(\frac{B}{\rho_0}\right)\left(-\left(\frac{\rho_0}{H}\right)\frac{\partial \overline{u}}{\partial z} + \rho_0 \cancel{\frac{\partial^2 \overline{u}}{\partial z^2}}\right) \propto -\left(\frac{1}{H}\right)\frac{\partial \overline{u}}{\partial z} \qquad [121]$$

Thus, baroclinic instability is most commonly found near the regions of strong vertical shear of the mean zonal wind. On Earth, it occurs when $\partial \overline{u}/\partial z$ exceeds $\sim 1\ \text{m s}^{-1}\ \text{km}^{-1}$. This threshold is small and less than the wind shear predicted from the thermal wind equation with a typical horizontal gradient induced by the spread of sunlight over midlatitudes. Consequently, baroclinic instability is generally predicted on rapidly rotating rocky planets at the appropriate latitudes and occurs on Mars, making associated baroclinic waves (Banfield et al., 2004; Collins and James, 1995; Hinson et al., 2012; Read and Lewis, 2003; Wilson et al., 2002). The net thermal effect of 3-D baroclinic eddies is to transport warm low-latitude air poleward and up and cold high-latitude air equatorward and down. For this reason, the process has been called stantwise (or sloping) convection (Hide and Mason, 1975). As described in **Section 10.13.5.4**, eddies can drive jet streams. However, baroclinic instability should be less important on slowly rotating planets with small horizontal temperature gradients.

The horizontal length scale of the most unstable eddies produced by baroclinic instability is the Rossby radius of deformation:

$$r_{Ro} = \frac{N_B H}{f_0} \qquad [122]$$

where H is the scale height, N_B the Brunt–Vaisala frequency, and f_0 a reference Coriolis parameter. The Rossby radius can be understood as follows. Imagine air rising vertically through a height H and then spreading out perhaps when it reaches the tropopause. Initially, the spreading gas will not 'feel' the effects of the planetary rotation, but after a certain distance, its lateral spread will be converted to rotational motion around a core. This distance is roughly the Rossby radius. In the Earth's midlatitude troposphere, $r_{Ro} \sim 700$ km, using $f_0 \sim 10^{-4}\ \text{s}^{-1}$, $H \sim 7$ km, and $N_B \sim 10^{-2}\ \text{s}^{-1}$. Perhaps as a consequence, only one eddy-driven jet can fit in the Earth's midlatitudes (Schneider and Walker, 2006). On Jupiter, $r_{Ro} \sim [(0.003\text{–}0.02) \times 27]/[2 \times (2\pi/35730) \times \sin(45°)] \approx 325\text{–}2200$ km using a range of N_B values (Magalhaes et al., 2002; Shetty and Marcus, 2010), which is small compared to Jupiter's vast size.

10.13.5.6 Deep and Shallow Atmospheres on Giant Planets

The pattern of strong eastward jets at the equator on Jupiter and Saturn, with alternatively eastward and westward jets at higher latitudes is a puzzle of atmospheric dynamics. Historically, there have been two approaches to explain the jet structure (Vasavada and Showman, 2005):

(i) The observed wind systems are occurring in a shallow layer overlying a horizontally uniform but convective deep interior (Williams, 1978).
(ii) The observed winds somehow reflect the dynamic activity of an active deep atmosphere, and the jets probably represent very deeply rooted systems (Busse, 1976, 1983).

In the first scenario, shallow-layer models can produce eddies (Cho and Polvani, 1996; Huang and Robinson, 1998) – sometimes associated with the moist convection (Lian and Showman, 2010) – that force alternating zonal jets, though many models produce westward jets at the equator. In the second scenario, circulations extend deeply into the interior. The deep interior opacities of giant planets should lead to nearly adiabatic and convective conditions (Nutzman et al., 2009). The jets themselves could perhaps result from the surface manifestation of large circulating cells in systematic alignment with the jets. Galileo probe measurements of a vertical wind profile on Jupiter show nearly uniform strong zonal

winds to great depth from 5 to 20 bar, but consistent with temperature measurements interpreted in the light of the thermal wind equation, these measurements show decay of wind strength upward in the uppermost troposphere (Atkinson et al., 1997). This wind profile supports the deep circulation camp, but because the profile may not be representative, it does not prove it. The probe descended in a 'hot spot' of high IR emission at 5 μm, which emerges from deeper, unusually cloud-free parts of the troposphere (Ortiz et al., 1998).

On Uranus and Neptune (the ice giants), a broad band of strong retrograde winds exist at low latitudes with a single high-latitude prograde jet in each hemisphere (**Figure 14**). Moreover, Neptune's retrograde jet speed exceeds 500 m s^{-1}, the fastest in the solar system. It is unclear why there are such significant circulation differences between the gas giants and Uranus and Neptune. Possibly, convection is weaker on the ice giants and unable to drive the eddies needed for the kind of jet structure seen on the giant planets or only operates to drive prograde jets at high latitudes. Perhaps, a surprising result is that the jet speeds increase going outward in the solar system, which is counterintuitive if one assumes that incident sunlight is important. This puzzle has been called Suomi's paradox after Vern Suomi, who first pointed it out and is not resolved.

10.13.5.7 Buoyancy Waves and Thermal Tides

Besides planetary waves, another class of atmospheric waves that are very important for circulation are propagating buoyancy waves (also called internal gravity waves), which correspond to oscillations primarily in the vertical plane when the square of the Brunt–Väisälä frequency exceeds zero, $N_B^2 > 0$. Given that N_B^2 has the same sign as static stability (eqn [17]), this situation is common in atmospheres. As discussed in **Section 10.13.2.4**, the restoring force of the mean vertical buoyancy gradient acts on vertically displaced fluid parcels to cause oscillations. It is possible to derive a wave equation for buoyancy waves called the Taylor–Goldstein equation and find solutions (e.g., Holton, 2004, pp. 196–201; Nappo, 2002). In the x-z plane, wave perturbations in density, vertical velocity, pressure, and potential temperature vary as $\sim e^{(z/2H)} e^{i(kx-\omega t)}$, where the factor $\exp(z/2H)$ accounts for the vertical variation of atmospheric density, where H is the density scale height.

Such waves are generated mainly by flow over topography and large-scale flow associated with convective cells. Wave amplitude varies with density as $\rho^{-1/2}$, so amplitudes grow upward as density decreases, causing some waves to break aloft, in crude analogy to ocean waves breaking on a beach. Theory shows that buoyancy waves can also be absorbed at lower levels, the so-called critical levels, if the phase speed of the wave c equals the mean zonal wind, that is, $c = \overline{u}$ (Forbes, 2002; Nappo, 2002). Otherwise, the waves continue to propagate vertically and break well above these critical levels. Thus, for example, if an eastward jet exists at altitude, buoyancy waves propagating upward with eastward phase speeds will be absorbed and are said to be filtered out, whereas waves with westward or near-zero relative speed (the speed of the underlying surface) will penetrate higher, break, and dump their westward momentum (Forbes, 2002). The result is that these breaking waves diminish eastward zonal winds aloft, which is called closing off the winds – that is, a jet exists below the breaking altitude and winds diminish upward from the core of a jet. This process is important for shaping jets in general, acts as a drag on the zonal mean flow, and makes upper atmospheres 'feel' the rotation of the underlying planet. Thermal wind balance (eqn [104]) applied to the effect of waves closing off the jets and declining wind speed with altitude is associated with a reverse equator-to-pole temperature gradient in the Earth's stratosphere. In turn, through thermodynamic balance (eqn [107]), this is connected with ascent and descent, where tropospheric air rises into the tropical stratosphere and subsides at the poles – the Brewer–Dobson circulation (Brewer, 1949; Dobson, 1956) – which carries stratospheric ozone from equator to poles.

An important and special class of large-scale buoyancy waves are atmospheric thermal tides, which are global oscillations in pressure and wind fields caused by the heating and cooling associated with the apparent motion of the Sun over a planet (Chapman and Lindzen, 1970). The wave periods are fractions of a solar day, so that the wave with a solar day length is a diurnal tide, while that with half a day length is a semidiurnal tide. Furthermore, the tides divide into migrating tides that move around the planet with the Sun's apparent motion and nonmigrating tides that do not, which are modes generated by migrating tides interacting with planet-scale topography.

A key theoretical result is that global-scale thermal tidal waves only propagate vertically if their angular frequency ω exceeds the Coriolis parameter, that is, $\omega > f$ (Lindzen, 1971). A diurnal tide with $\omega = \Omega$ cannot propagate vertically beyond 30° latitude because $f = 2\Omega\sin(30°) = \Omega$ at that latitude. Thus, on Earth and Mars, the diurnal tide acts as a buoyancy wave only between latitudes ±30° where it propagates vertically and its amplitude increases with height, whereas the semidiurnal tide is a global buoyancy wave from pole to pole with very large vertical wavelength ~100 km. Migrating and nonmigrating tides have been detected on Earth and Mars, and migrating tides have been observed on Venus (Migliorini et al., 2012; Pechmann and Ingersoll, 1984; Peralta et al., 2012; Schofield and Taylor, 1983). In the case of Venus, which rotates every 243 Earth days, the thermal tides in the middle atmosphere reflect atmospheric rotation, clearly not the rotation of the solid planet. The atmosphere near the cloud tops at ~65–70 km altitude rotates at ~110 m s^{-1} past the subsolar point, establishing waves that migrate with the Sun but move opposite to the direction of the mean flow (Gierasch et al., 1997).

Tides are important in atmospheres. On Mars, feedback between tidal surface winds and lifting of dust high in the atmosphere may contribute to the generation of planet encircling dust storms (Leovy et al., 1973), while breaking of tides may be important for mixing atmospheric constituents. On Venus, tides may be implicated in superrotation, which we discuss next.

10.13.5.8 Superrotation

Superrotation is where the equatorial zonal wind speed is persistently greater than the speed of the underlying rotating planet, which applies to Venus (Belton et al., 1991; Peralta et al., 2007), Titan (Bird et al., 2005; Kostiuk et al., 2006), Jupiter (Ingersoll et al., 2004), and Saturn (Del Genio et al., 2009). The angular momentum of a planet's surface is maximal

at the equator, and so, the superrotation cannot be maintained by some simple transport of angular momentum (Hide, 1969, 1970), as, for example, occurs from equator to high latitudes in Hadley cells. Also, since viscosity should tend to dissipate high equatorial winds, superrotation is puzzling.

Generally, it has been proposed that equatorial superrotation might be maintained by eddies with the kind of 'upgradient' transport discussed in **Section 10.13.5.4** (e.g., Gierasch, 1975) (although gravitational torque acting on the atmosphere is an alternative idea (Gold and Soter, 1971; Schubert, 1983)). Eddies could carry prograde momentum systematically toward the jet region, either by motions in the vertical plane with upward and zonal velocities correlated below the maximum wind level and downward and zonal velocities correlated above the maximum or by motions in the horizontal plane with equatorward and prograde winds correlated (Schneider and Liu, 2009). If the former case applies, buoyancy waves may be implicated; in the latter case, Rossby waves. Either way, generation of wave activity by some process near the equatorial wind maximum would be required.

Attempts to model superrotation on Venus have been made with varying degrees of success, and models that work have generally assumed background superrotation below the cloud base (e.g., Del Genio and Zhou, 1996; Hollingsworth et al., 2007; Lebonnois et al., 2010; Yamamoto and Takahashi, 2009). The waves near the superrotating level on Venus may be atmospheric tides (Newman and Leovy, 1992). It is unlikely to be a coincidence that the peak winds occur near a maximum in the vertical profile of solar heating maximum (**Figure 17**) (Gierasch et al., 1997; Leovy, 1987; Pechmann and Ingersoll, 1984; Schofield and Taylor, 1983). However, the underlying physics of equatorial superrotation remains an area of research (Mitchell and Vallis, 2010).

10.13.6 Outstanding Questions

Although the Space Age has greatly improved our knowledge of the atmospheres of the solar system, including the Earth, a long list of unsolved problems remains. Planetary atmospheres as a whole are very undersampled, with no in situ measurements at all for Saturn, Uranus, and Neptune, a possibly unrepresentative descent profile from Jupiter, poor knowledge of the atmosphere of Venus below the clouds, and barely any measurements of winds in all extraterrestrial atmospheres. Even on Earth, matters of basic enquiry remain. These include, for example, how the Hadley circulation interacts with eddies (Levine and Schneider, 2011), how stratospheric circulation and

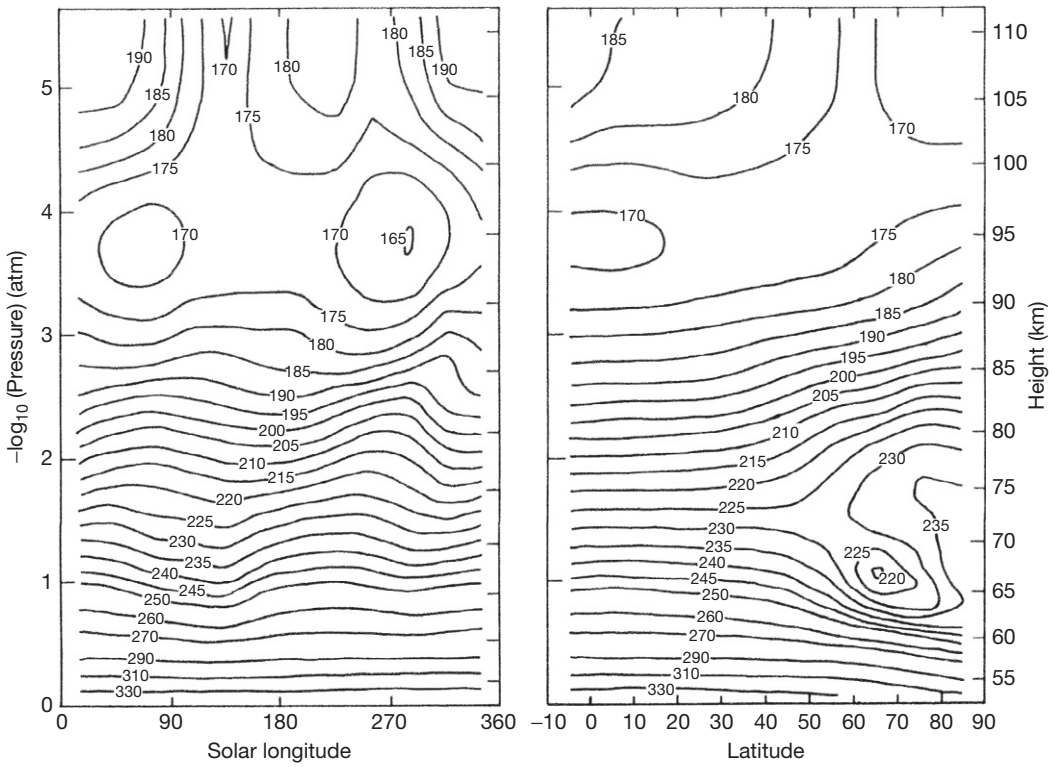

Figure 17 Cross sections of temperature (K) in the atmosphere of Venus above 55 km altitude (Schofield and Taylor, 1983). On the left, the temperature field is averaged between 0 and30°N and shown in Sun-following coordinates where zero longitude is noon and 180° is the antisolar point. There is a minimum temperature of 170 K at 95 km altitude, above which the equator-to-pole temperature gradient is reversed. On the right, temperatures are shown as a zonal mean cross section. From above the cloud tops (70 km) to 95 km, a semidiurnal variation is revealed by waves in the temperature contours with a phase that moves in an eastward direction at higher altitude (left). The phase in the solar longitude plot on the left suggests a Sun-following eastward-propagating oscillation forced at lower altitudes. Gierasch PJ, Goody RM, Young RE, et al. (1997) The general circulation of the Venus atmosphere: An assessment. In: Bougher SW, Hunten DM, and Phillips RJ (eds.) *Venus II*, pp. 459–500. Tucson, AZ: University of Arizona Press.

chemistry affects the troposphere (Thompson et al., 2011), and the response of cloud formation (Boucher et al., 2013) and the stability of ice sheets to climate forcing (McNeall et al., 2011).

After the Earth, Mars has the most observed atmosphere. On Mars, global dust storms occur in some Martian years and not others (Martin and Zurek, 1993). But we do not know why. What are the mechanisms for storm initiation, growth, and decay and how are these storms connected to circulation features such as tides and planetary waves? Also, the role of clouds and surface exchange in the water cycle on Mars and its interaction with the dust cycle remains to be elucidated.

On Venus, winds and temperature fields in the lower atmosphere are essential for understanding the circulation and yet are poorly measured or understood. Clouds play such an important role for Venus' climate that further elucidation of their size distribution, shapes, and composition and the distribution of minor sulfur and chlorine species would also help define chemistry, climate, and dynamics. Also, many reactions relevant to chemistry on Venus that involve elemental sulfur lack laboratory data.

We do not have a fundamental understanding of the differences between the giant-planet atmospheric circulations. There are two main puzzles. The first is the different jet structures on Uranus and Neptune compared with those on Jupiter and Saturn. The latter have several jets in each hemisphere (Jupiter has 5–6 eastward jets and Saturn has 4), whereas the ice giants have only one jet (**Figure 14**). Whereas the equatorial jets are retrograde on the ice giants, they are prograde on the gas giants. Also, the fastest jets are on Neptune, and although Uranus is tipped on its side, its meridional profile of zonal winds is much like Neptune's and vaguely like the Earth's. Clearly, incident sunlight plays less of an overall role than rotation, while obliquity seems strangely unimportant for the jet structure. The second main puzzle is equatorial superrotation on Jupiter and Saturn. The superrotation is so strong on these gas giants that it is probably very deep. Vertical wind shear is required for the buoyancy wave mechanism that may be important for Venus yet appears lacking based on Galileo probe results (**Section 10.13.5.8**). So unlike on Venus, there is no clear mechanism for generating sufficiently strong buoyancy wave momentum fluxes. The horizontal shear zones associated with superrotation on Jupiter and Saturn are much wider than the scales of eddies that might transport momentum horizontally to drive superrotation. What drives superrotation on Saturn and Jupiter? And why is it absent on Uranus and Neptune, which have strong equatorial easterlies?

Finally, this chapter omitted atmospheric evolution for reasons of space. But it is clear from the history of the research literature in planetary science that initial assumptions of Earth-like conditions on the other rocky bodies, Venus and Mars, proved to be drastically erroneous. The reasons are related to great differences in how these bodies evolved, which is another story (Catling and Kasting, in press).

10.14.1 Introduction

10.14.1.1 The Requirements for an Origin of Life and 'Habitability'

Whether or not life originated on Earth, it was certainly present in abundance and at a relatively advanced level of evolution by about 3.5 billion years ago (Ga) (see reviews in Westall and Southam (2006) and Westall (2011)). At this time, the habitable environment of the Earth was very much different than the Earth of today – significantly hotter (Arndt, 1994; Knauth and Lowe, 2003) and more volcanically/hydrothermally active (Hofmann and Bolhar, 2007) and basically without oxygen (<0.2% present atmospheric levels, Catling and Claire, 2005; Kasting, 1993). The low levels of reactive oxygen produced by photolysis (Kasting, 1993) relative to the abundance of reduced chemical species would have resulted in a correspondingly reducing chemistry for the hydrosphere and lithosphere as well. Based on comparisons with the lunar cratering record, the environment was also affected by a short, sharp influx of bolides (the Late Heavy Bombardment (LHB); Gomes et al., 2005) about 3.9 Ga ago that may or may not have evaporated all the surface water (Sleep et al., 1989) and eliminated all life (Maher and Stevenson, 1988). It is commonly believed that the life on Earth today evolved from primitive cells that could only have appeared after the end of the LHB (Lowe and Byerly, 1986; Lowe et al., 2003), that is, after ~3.85 Ga. However, the last decade has seen an enormous advance in our understanding of the limits of life and it is clear that, once started, it is very difficult to eradicate prokaryotes from either the Bacteria or Archaea domains (Woese et al., 1990), especially the latter since they generally occur in environmental conditions that today are considered to be extreme but were common on the early Earth. It is possible, therefore, that life appeared on Earth before ~4.0 Ga and survived the catastrophic LHB in, for instance, a protected subsurface habitat (cf. Russell et al., 2010), to reappear and flourish at the surface once water had recondensed. They may represent the survivors of a 'hot bottleneck' through which the early forms of life had to pass, such as would have existed during a catastrophic impact event. However, whether or not they represent the last universal common ancestor (LUCA) is still debated (Brochier and Philippe, 2002). An alternative hypothesis is that life first appeared on another planet and was transported by panspermia to the Earth (e.g., Cockell, 2008) once habitable conditions had been reestablished at the end of the catastrophic bolide period. However, the other likely contender for an independent origin of life in the inner part of the solar system, Mars, also suffered from the same bolide bombardment.

In order to address the concept of life and habitability in the solar system, we start with a brief overview of the current thinking on the basic requirements for life to originate and the origin of life. In life as we know it, all cells need a source of energy and are composed of water and carbon molecules that include some essential elements (notably hydrogen, oxygen, nitrogen, phosphorus, and sulfur (HONPS)). These are therefore the minimum requirements on a planet (or other type of rocky body) for the appearance of life. Since organic carbon molecules occur in interstellar clouds, as well as in the materials forming the proto-solar system cloud (in the form of the planetesimals that formed the rocky planets, asteroids, meteorites, micrometeorites, and comets), they can be considered to be more or less ubiquitous. Endogenous sources of organic carbon included the primordial, slightly reducing atmosphere (Johnson et al., 2008; Miller, 1953) and active hydrothermal systems where organic carbon is primarily produced via Fischer–Tropsch synthesis (i.e., hydrocarbons containing up

to 29 carbon atoms have been produced from the Rainbow ultramafic hydrothermal system on the Mid-Atlantic Ridge; Holm and Charlou, 2001; see also Russell et al., 2010), which are believed to have been very active on the early Earth. A significant amount of the organic molecules (and other volatiles, such as water) were also delivered from extraterrestrial sources (Chyba and Sagan, 1992; Sephton and Botta, 2008). Carbonaceous chondrite meteorites contain up to 5% organic carbon, and eight of the amino acids that have been identified in them are of the kind used in living cells today; they are the building blocks of life. The present-day flux of carbonaceous micrometeorites (to the Earth) containing up to 2% carbon is estimated between 50 and 100 tons per year, which implies an extraordinary amount equaling 10^{23} g carbon over a 300 My period during the LHB (Maurette et al., 2000; see also Brack, 2004, for a review). Thus, organic carbon on rocky bodies in the young solar system was readily available.

The sources of the other elements essential for an origin of life (HONPS) would likewise be readily available on any rocky planet. A rocky planet is also an excellent source of energy. Living organisms need energy in order to militate against the constant problem of entropy, the increase in disorder or dissipation of chemical energy within a closed system, their entire lives. From a simplistic, energy perspective then, any geologic system that provides geochemical energy, that is, a reaction that can be written possessing a negative ΔG_r, should conceivably have the capacity to support life. However, because water is a necessary ingredient of life as we know it and is therefore also necessary for life to emerge elsewhere in our solar system (or in the universe), this means that the target planetary body should be situated within the habitable zone around its star (see Franck et al., 2006; Kasting et al., 1993; Kopparapu et al., 2013). Habitable conditions are defined by the sum of the physical and chemical conditions, which support the presence of liquid water at the surface of a planetary body. This habitable zone around the Sun has moved outward since the formation of the solar system as luminosity, now about 25–30% >4.6 Ga ago, has increased (Newman and Rood, 1977). While rocky planets within this zone represent ideal potential habitats, rocky bodies with liquid water in contact with rock do exist outside this zone and can thus be considered as being potentially habitable. In the early part of the history of the solar system, a number of planets and satellites had their own internal heat source from decaying radioactive elements, and in the case of Europa, there is convincing evidence that a liquid ocean exists underneath its icy crust (e.g., Hussmann et al., 2014; **Chapter 10.18**) with the energy required to keep the fluid liquid being impacted by the strong tidal forces from Jupiter (Chyba and Phillips, 2001; Hussmann et al. 2014) and the Laplace orbital resonance of the three inner Galilean satellites Io, Europa, and Ganymede. Analysis of the induced magnetic field (Khurana et al., 1998) as well as more recent spectral observation suggests that Europa's ocean is a brine containing Na, K, and Mg salts (Brown and Hand, 2013).

10.14.1.2 The Origin of Life and the First Cells

A working definition of a minimal life-form could be "a structure capable of auto-reproduction including errors that lead to evolution" (Brack, 2005). The basic structure consists of three long chain carbon molecules that are necessary for the functioning of the cell: (1) a lipid membrane enclosing a (2) molecule capable of information transfer (RNA/DNA) and (3) a catalyzing molecule (enzyme) to provide the basic work of the cell. Despite the fact that it has not yet been possible to reproduce a life-form *ex novo* in the laboratory, the last 50 years has seen significant advances in understanding how these basic elements formed from inorganic components.

In the modern cell, membranes are primarily composed of amphipathic phospholipids that are stable in water. These lipids can be formed from fatty acids found in carbonaceous chondrites like the Murchison meteorite (Deamer, 1998). Catalytic reactions in modern, living cells are performed by proteinaceous enzymes, themselves made of homochiral amino acids. As we have noted earlier, these were abundantly available on the early Earth. There are, however, a number of scenarios regarding the condensation or assemblage of simple amino acids into longer chain molecules, such as peptides. These include condensation on mineral surfaces, such as clays (Ferris et al., 1996), thermal condensation (Fox and Dose, 1977), and chemical reactions (Barbier and Brack, 2002). Likewise, the origin of the first information transfer molecules is highly debated. Nucleic acids in modern cells are composed of bases (purine and pyrimidine), sugars (ribose or deoxyribose), and phosphate groups. RNA (ribonucleic acid) is considered to be a likely, primitive replicating molecule because it also has catalytic properties (representing self-replication, mutation, and evolution) and can act as a polymerization template (Zaug and Cech, 1986). However, even RNA is too complicated to have been the first replicating molecule (Schwartz and Orgel, 1985). Nonenzymatic replication has been demonstrated (Inoue and Orgel, 1982), as have autocatalytic reactions involving the reaction of FeS and H_2S on the surface of pyrite (Wächtershäuser, 1988). In the latter scenario, organic molecules forming a network on the surface of the mineral evolve. Other candidates for precursor replication molecules include pyranosyl-RNA and threo furanosyl nucleic acid, though the latter is considered to be more likely because of the greater availability of the carbon precursors of tetrose than ribose on the primitive Earth.

The basic process leading to an origin of life can be envisaged thus (Brack, 2004):

$$\text{CHONPS} + \text{water} \rightarrow \text{catalyzers} \rightarrow \text{RNA world} \rightarrow \text{cells (RNA, proteins, and membranes)}$$

10.14.2 Geology, Life, and Habitability

Based on the previously described criteria for habitability and the origin of life, the key to understanding the potential for the emergence of life, that is, habitability, is the understanding of the history of liquid water on any terrestrial planet or icy moon. Given the necessity of disequilibria conditions in the emergence of life, liquid water needs to be in contact with minerals/rocks, implying liquid water on a rocky planet. The capacity to support life may be transient, that is, it will not be constant for a particular planet over time but will vary based on a wide range of geologic and planetary factors (e.g., Westall et al., 2013). We only have terrestrial life to use as a basis for

discussion of the relationship between geology (including aqueous geochemistry), life, and habitability. Assuming water is available, there is a wide diversity of metabolic strategies that have been developed by terrestrial microorganisms (Barns and Nierzwicki-Bauer, 1997; Pace, 1997; Reysenbach and Shock, 2002), so that they can successfully colonize almost all geologic environments.

In this chapter, we focus on the interaction between geology and prokaryotic life as a way to address the subject of habitability, both from our perspective and from that of the prokaryotes, which have inhabited Earth for far longer than we have. Today, prokaryotic organisms are ubiquitous on Earth, being found in a wide variety of surface and subsurface environments (Colwell et al., 1997; Lovley and Chapelle, 1995; Onstott et al., 2006; Parkes et al., 1994; Stevens et al., 1993), where they are only limited by the availability of water (Navarro-Gonzalez et al., 2003) and temperatures $<121\,^{\circ}C$ (Kashefi and Lovley, 2003). In these natural environments, prokaryotes typically grow as biofilms on mineral surfaces (Marshall, 1988; Wanger et al., 2006). This intimate association of life with its geologic substrate is thought to have occurred for at least the last ~3.5 billion years (see Westall and Southam, 2006; Westall, 2011, for a review) producing molecular to global-scale by-products. During the initial stages of this interaction, the physical and chemical conditions of the early Earth would have controlled the biosphere. However, over time, life exerted an increasing influence over the geosphere. Life serves as a catalyst for a wide array of reactions at geologically low temperatures, doing them faster than would happen abiotically (e.g., Singer and Stumm, 1970).

10.14.2.1 Habitability as Defined by the Physical and Chemical Environmental Constraints on Life

The growth of prokaryotes is affected by the various physical and chemical constraints of the environments in which they are growing (Figure 1). They, in turn, can have a profound effect on their surrounding environment. Understanding the physical and chemical limits of bacteria and their environmental influences allows us to predict the types and distribution of microorganisms that could occur in natural systems.

The range of (and optimum) growth temperatures differentiate prokaryotes into broad groups (Stetter et al., 1990). Psychrophiles grow optimally at or below 15 °C and have even demonstrated activity down to −20 °C (Mykytczuk et al., 2013); viable prokaryotes have been recovered from million-year-old permafrost (Gilichinsky et al., 2007). Psychrotolerant prokaryotes grow optimally between 20 and 40 °C but will grow at temperatures as low as 0 °C. Mesophiles grow optimally between 15 and 45 °C. Thermophiles have optimum growth temperatures above 45 °C and hyperthermophiles grow optimally above 80 °C (Figure 2). While no single microorganism can withstand the full range of temperatures described here, as a group, prokaryotes can be found across any thermal gradient, from ice or permafrost regions all the way up to hydrothermal fluids (121°C).

In all environments, prokaryotes concentrate solutes within their cell envelopes and obtain water through osmosis, thus enabling them to maintain intra-cell turgor pressure (Kunte, 2006). The prokaryote cell envelope is designed to withstand this turgor pressure, which can measure between 2-3 atmospheres in gram-negative bacteria and up to 15 atmospheres in gram-positive bacteria (Beveridge, 1981). The accumulation of water represents a challenge for prokaryotes in the Archaea domain in contemporary (e.g., the Great Salt Lake) and paleo-evaporitic (Bechtel et al., 1996), hypersaline systems. Some of these environments are continually under stress due to low water activity and are therefore considered to be examples of extreme environments, which will only support halophilic (or halotolerant) microorganisms (see Figure 3).

Most natural environments occur as circumneutral pH systems. Therefore, most prokaryotes exhibit optimal activity in the pH range of 6–8. At pH 7, the hydrogen ion concentration is 100 nM. Extreme environments possessing acidic (e.g., pH 2) or alkaline (e.g., pH 11) pH conditions will contain

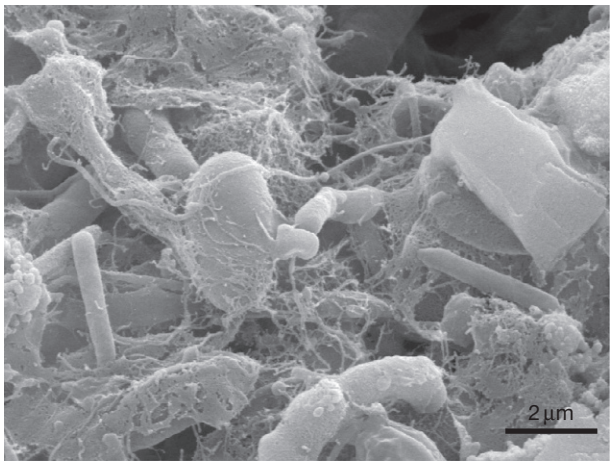

Figure 1 A scanning electron micrograph of a bacterial biofilm collected from a groundwater outflow into an oxygenated mining environment, 3.1 km below land surface in the Witwatersrand Basin, Republic of South Africa. Note the spiderweb-like appearance of the bacterial exopolymer material.

Figure 2 A photograph of a hydrothermal spring in Norris Geyser Basin, Yellowstone National Park. Extreme environments, such as this, are dominated by prokaryotic organisms representing both the Archaea and Bacteria domains. The field of view is ~8 m across.

Figure 3 A photograph of Basque Lake #2, in central BC, Canada. The evaporite minerals in this basin are dominated by epsomite, indicating the hypersaline nature of this environment.

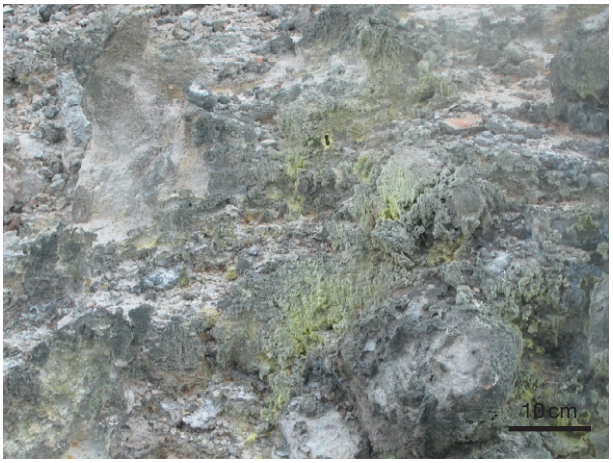

Figure 4 A photograph of a hydrothermal acid hot spring in Shimabara, Japan. In these extreme environments, the geosphere dominates the biosphere.

indigenous microorganisms, that is, acidophilic (acidotolerant) or alkaliphilic (alkalitolerant) prokaryotes, respectively, whose growth parameters are adapted to these extremes in environmental pH (Goodwin and Zeikus, 1987). Note that the word 'extremophile' is an anthropocentric term because for many microorganisms, thiobacilli, an ambient pH of 2 is optimum.

Our modern habitat is characterized by an atmosphere rich in oxygen (which was not the case on the early Earth). The capacity to utilize oxygen as a terminal electron acceptor creates a competitive advantage as well as a challenge for prokaryotes, which are subdivided into aerobic and anaerobic groups based on their oxygen requirements and detoxification strategies (Chapelle, 1993). There are also facultatively anaerobic prokaryotes that utilize oxygen if it is available, becoming anaerobes when the oxygen runs out, that is, they can grow with or without oxygen. The utilization of oxygen as a terminal electron acceptor enables organisms to fully oxidize their respective source(s) of energy and thereby maximize their energy gain from reaction [1]:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O;\ \Delta G^o = -2870\,kJ\,mol^{-1} \quad [1]$$

Any organism that is capable of growing in the presence of oxygen, whether or not it utilizes oxygen as a terminal electron acceptor, must also have the capacity to detoxify the chemically reactive oxygen compounds produced through the stepwise reduction of oxygen to water (hydrogen peroxide, superoxide radical, and the hydroxyl radical; Atlas and Bartha, 1997). Detoxification of these oxygen radicals requires a series of enzymes including superoxide dismutase, catalase, and peroxidase. The ability to tolerate oxygen relates to the presence or absence of each of these enzymes. Measurements of dissolved oxygen and redox potential, which represents the sum reactivity of oxidants and reductants, are important in determining which microbial processes are functioning within natural systems.

Analyses of the physical and chemical limits on prokaryote growth and survival typically focus on one 'stressor' at a time, for example, pH (acidophile vs. neutrophile vs. alkaliphile), temperature (psychrophile vs. mesophile vs. thermophile), salinity (freshwater vs. halophile), or oxygen availability (aerobe vs. anaerobe). On the other hand, there are many examples of prokaryotes that can withstand multiple 'stressors' (see de Vera et al., 2013), for example, thermoacidophiles. It is in these environments (see **Figure 4**) that the diversity of prokaryotes and the limits of life are truly appreciated (see **Table 1**). Nevertheless, other combinations of 'stressors' will be deadly to microorganisms, such as low water activity together with high UV radiation, as on the surface of Mars today (Cockell and Raven, 2004).

10.14.2.2 Building Cells

Modern prokaryotes use a wide range of organic and inorganic nutrients. Organic nutrients, for example, carbohydrates, amino acids, nucleic acids, and hydrocarbons, include nearly every organic monomer or polymer found in the living or diagenetically altered biosphere. Inorganic nutrients include dissolved gases (carbon monoxide, carbon dioxide, hydrogen, nitrogen, and dihydrogen sulfide), soluble cations (sodium, calcium, magnesium, ammonium, and ferrous and ferric iron), base metals (chromium, nickel, copper, cobalt, zinc, lead, and mercury), and soluble anions (chloride, nitrite, nitrate, hydrogen sulfide, sulfite, sulfate, phosphate, selenate, and arsenate). Depending on nutrient requirements, these compounds can be used in assimilation reactions, that is, building new cells, or in dissimilatory processes to generate the energy needed to construct new biomass (discussed in the succeeding text).

Carbon utilization is one of the most important criteria by which prokaryotes are characterized. Heterotrophic prokaryotes require organic carbon for their metabolism and typically couple the oxidation of organic carbon to CO_2 with the reduction of dissolved inorganic species or minerals. The sources of carbon and energy for heterotrophs can range from simple organics such as glucose and asparagine, an amino acid (Goldman and Wilson, 1977), to macromolecular materials such as cellulose (Ljungdahl and Eriksson, 1985).

Table 1 Classification and examples of extremophiles

Environmental parameter	*Type*	*Definition*	*Examples*
Temperature	Hyperthermophile	Growth >80 °C	*Pyrolobus fumarii*, 113 °C
	Thermophile	Growth 60–80 °C	*Synechococcus lividis*
	Mesophile	15–60 °C	*Homo sapiens*
	Psychrophile	<15 °C	*Psychrobacter*, some insects
Radiation			*Deinococcus radiodurans*
Pressure	Barophile	Weight loving	Unknown
	Piezophile	Pressure loving	For microbe, 130 MPa
Gravity	Hypergravity	>1 g	None known
	Hypogravity	<1 g	None known
Vacuum		Tolerates vacuum (space devoid of matter)	Tardigrades, insects, microbes, seeds
Desiccation	Xerophiles	Anhydrobiotic	*Artemia salina*; nematodes, microbes, fungi, lichens
Salinity	Halophile	Salt loving (2–5 M NaCl)	*Halobacteriacea*, *Dunaliella salina*
pH	Alkaliphile	pH > 9	*Natronobacterium*, *Bacillus firmus* OF4, *Spirulina spp.* (all pH 10.5)
	Acidophile	Low pH loving	*Cyanidium caldarium*, *Ferroplasma sp.* (both pH 0)
Oxygen tension	Anaerobe	Cannot tolerate O_2	*Methanococcus jannaschii*
	microaerophile	Tolerates some O_2	*Clostridium*
	aerobe	requires O_2	*Homo sapiens*
Chemical extremes	Gases metals	Can tolerate high concentrations of metal (metalotolerant)	*Cyanidium caldarium* (pure CO_2) *Ferroplasma acidarmanus* (Cu, As, Cd, Zn); *Ralstonia sp.* CH34 (Zn, Co, Cd, Hg, Pb)

Autotrophs are able to obtain their cellular carbon for biomass from inorganic sources (dissolved CO_2/HCO_3^-). Autotrophic organisms direct most of their energy toward the fixation (reduction) of CO_2 into organic carbon, that is, biomass production, and therefore tend to grow at slower rates than heterotrophic organisms. However, autotrophs are extremely important since they serve as the basis of the food chain upon which 'we' heterotrophs thrive. For example, autotrophic bacteria oxidize sulfur (reaction [2]) and synthesize carbohydrates at seafloor hot springs (reaction [3]):

$$2H_2S + O_2 \rightarrow 2S^\circ + 2H_2O;\ \Delta G^o = -441\,kJ\,mol^{-1} \quad [2]$$

$$CO_2 + 2H_2S \rightarrow CH_2O + 2S^\circ + H_2O \quad [3]$$

They are the base of the 'food chain' in these lightless, extreme environments (Cavanaugh et al., 1981).

Nitrogen and phosphorus are the limiting nutrients in most natural systems. However, prokaryotes can easily assimilate all forms of water-soluble inorganic nitrogen, and when the availability of nitrogen is limited, a wide range of prokaryotes possess a nitrogenase enzyme that allows them to fix atmospheric nitrogen (Brill, 1975). Regarding phosphorus-limiting conditions, microorganisms can produce a wide array of organic and inorganic acids that can enhance the weathering of silicate minerals in rocks and thus assimilate phosphate (Rogers et al., 1998; discussed in **Section 10.14.3.1**).

10.14.2.3 Generating Energy

In natural systems, prokaryotes exploit a wide range of redox reactions having negative ΔG_r to support metabolism (Nealson and Stahl, 1997). The requirement of energy for biosynthetic reactions is described according to the electron donor or source of reducing power and by the electron acceptor, that is, a redox couple. Current research on the diversity of life focuses on phenotypic and genotypic studies of geochemical gradients, where thermodynamic calculations highlight possible biogeochemical reactions that could support life, for example, anaerobic methane oxidation at deep-sea cold clathrate vents (Thomsen et al., 2001).

In natural systems, microbially catalyzed redox processes are established through competition for available nutrients (assimilation) and through the efficiency of their respective energy generation mechanisms (Lovley and Klug, 1983). As geochemical conditions become increasingly reducing, the amount of energy (as expressed by ΔG_r) available from each of the predominant biogeochemical reactions (i.e., redox zones) decreases (Lovley and Chapelle, 1995; Lovley and Phillips, 1988) resulting in a concomitant reduction in biomass (Onstott et al., 2006).

Phototrophs utilize sunlight to produce ATP (adenosine triphosphate, the principal energy carrier of all cells) from otherwise chemically stable reduced compounds. Anoxygenic phototrophs were probably already present on the Earth by 3.5 Ga (see reviews in Westall and Southam, 2006; Westall, 2011); contemporary representatives of this group are anaerobic green and purple sulfur bacteria that derive their energy for growth from light and H_2S or Fe^{2+} (Heising and Schink, 1998; Kappler and Newman, 2004), producing elemental sulfur, sulfate, or Fe^{3+} as end products of their metabolism (van Gemerden, 1986). The later-evolved oxygenic phototrophs use light in combination with H_2O as their source of energy (reaction [4]):

$$6CO_2 + 6H_2O + \text{sunlight} \rightarrow C_6H_{12}O_6 + 6O_2 \quad [4]$$

Chemolithotrophs (hydrogen, ammonia, or sulfur oxidizers and methylotrophs) are prokaryotes that utilize inorganic chemicals (H_2, NH_4^+, H_2S, and CH_4) as their energy

sources (electron donors). Lithotrophs grow more slowly than heterotrophs owing to the relatively low levels of chemical energy present in inorganic versus organic compounds (Nealson and Stahl, 1997) (**Figure 5**). Chemoorganotrophs, which utilize organic carbon as their source of reducing power and cellular carbon, include both aerobic and anaerobic prokaryotes.

Prior to the evolution of oxygenic photosynthesis (Dismukes et al., 2001; Kasting, 1993), the extremely low levels of oxygen in the atmosphere (<0.2% of present atmospheric levels, Kasting, 1993) would have resulted in lower overall biological activity (Des Marais, 2000). The capacity of oxygen to help provide abundant energy directly via aerobic respiration would simply not have existed. The small amount of oxygen produced by photolysis of H_2O vapor in the upper atmosphere or by radiolysis of water molecules at the surface of the oceans would have been immediately scavenged by the abundant reduced mineral species that covered the Earth, thus indirectly providing some oxidized inorganic electron acceptors, although nowhere near the quantity that was available ever since the atmosphere was oxidized.

Today, because of the presence of oxygen in our atmosphere and dissolved oxygen in surface and near-surface groundwater (**Figure 6**), aerobic microorganisms dominate the Earth's surface with anaerobic prokaryotes becoming increasingly important with depth below the surface. During the early to mid-Archean, prior to the evolution of oxygenic photosynthetic bacteria, or presumably, on any geochemically reducing planetary body possessing an 'early stage' biosphere, anaerobic organisms would have been the dominant group (Kasting, 1993).

Below the aerobic zone (or at the surface of an anaerobic planet), a progression of different anaerobes (e.g., metal reducers, sulfate reducers, and methanogens) exists (would exist), most of which (from Earth's lessons) utilize organic matter for their metabolism (Lovley and Chapelle, 1995; Lovley and Klug, 1983). Under moderately reducing conditions, Fe- and Mn-reducing bacteria couple the oxidation of organic matter to the reductive dissolution of high-surface-area Fe and Mn oxyhydroxides (Lovley and Phillips, 1988; Myers and Nealson, 1988). At increasingly reduced conditions, sulfate-reducing bacteria oxidize low-molecular-weight organic compounds, utilizing sulfate as the terminal electron acceptor, forming and releasing hydrogen sulfide as a by-product of metabolism (Anderson et al., 1998; Donald and Southam, 1999). Bacterial methane production occurs under even more reducing conditions than microbial sulfate reduction. Methanogenesis (reaction [5]) is also the dominant anaerobic prokaryotic process that cycles inorganic carbon back into the organic carbon pool (reaction [6]):

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O,\ \Delta G^o = -130.2\,kJ\,mol^{-1} \quad [5]$$

$$CO_2 + 2H_2 \rightarrow CH_2O + H_2O \quad [6]$$

Biogenic methane can migrate out of the zone of methanogenesis and become an organic carbon source (electron donor) for heterotrophic bacteria elsewhere. This redox zonation going from aerobic → Fe–Mn–oxide reduction → sulfate reduction → methanogenesis is a universal phenomenon on the present-day Earth, as demonstrated, for example, in marine sediment pore waters (e.g., Drever, 1997).

Since prokaryotes can only transport soluble compounds across their cell envelopes, they have evolved various metabolic ways in which to obtain nutrients from solid substrates, for example, Fe or Mn oxides, to support their growth. The ability to alter the chemistry of their surrounding environment on the scale of 10s to 100s of nanometers (Purcell, 1977) is what enables prokaryotes to promote the dissolution of otherwise 'stable' mineral phases (based on bulk fluid chemistry) or the precipitation of minerals under apparently undersaturated conditions. Remarkably, it has been recently demonstrated that prokaryotes can produce electrically conductive nanowires under electron acceptor-limiting conditions (Gorby et al., 2006), thus demonstrating that biogeochemical cycling, which is not directly evident from fluid chemistry or mineralogy, may still be possible via interspecies electron transfer (Gorby et al., 2006).

10.14.2.4 The Growth of Microorganisms

Their small size (submicrometer to micrometer-scale) and resulting high surface area to volume ratio of bacteria help facilitate their growth. Since access to nutrients is based on diffusion and active uptake transporters at the cell surface, the greater the surface to volume ratio, the greater the capacity to obtain nutrients (Koch, 1996; Pirie, 1973; Purcell, 1977). Also, since individual prokaryotes only possess a mass of $\sim 1 \times 10^{-12}$ g (wet weight; Neidhardt et al., 1990), extremely low amounts of dissolved nutrients can support their growth and survival. On Earth, prokaryotes are critical components of the food chain because they utilize dilute concentrations of inorganic and organic nutrients that are unavailable directly to higher eukaryotic organisms (Fenchel and Jorgensen, 1977). The ability of prokaryotes to metabolize organic compounds in natural systems is dependent on the chemical properties and the composition and mineralogy of the soil (Knaebel et al., 1994). For example, Scow and Hutson (1992) found significant decreases in microbial degradation of organic carbon in the presence of kaolinite, owing to the effects of sorption and reduced diffusion from the clay surface.

While prokaryotes can be planktonic, attachment to a mineral surface is advantageous in that it allows them to persist or hold their position within a presumably, favorable geochemical flow, letting the nutrients come to them (**Figure 5**; Emerson and Revsbech, 1994; Purcell, 1977). Individual prokaryote species often grow as microcolonies (Hall-Stoodley et al., 2004), tens of microns in diameter, and can occur in association with other microcolonies within biofilms. Where freshwater–-hypersaline aquatic conditions are stable for a long periods of time and, where nutrients and favorable redox conditions exist for rapid growth, these 'biofilms' can reach large dimensions, up to centimeters or even meters in plan view and a mm or more in thickness, forming significant microbial mats on sediment/rock surfaces (**Figure 4**; Nealson and Stahl, 1997).

These mats are characterized by the microbial production of copious quantities of extracellular polymeric substances (EPS or capsule, **Figure 1**; Moser et al., 2003; Wanger et al., 2006). EPS serve many purposes, including protecting the colonies from the 'external' environment and providing a unique microenvironment or habitable zone in which the organisms can control the redox and pH conditions (Roden et al., 2004).

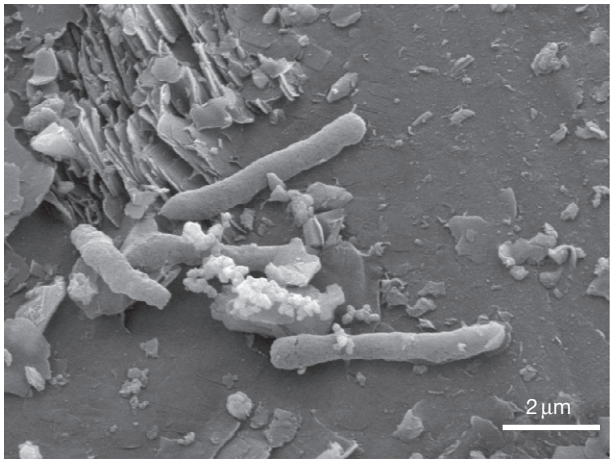

Figure 5 A scanning electron micrograph of a natural fracture face collected 2.8 km below land surface demonstrated that the deep subsurface possesses very sparse bacterial 'biofilms' (see Wanger et al., 2006).

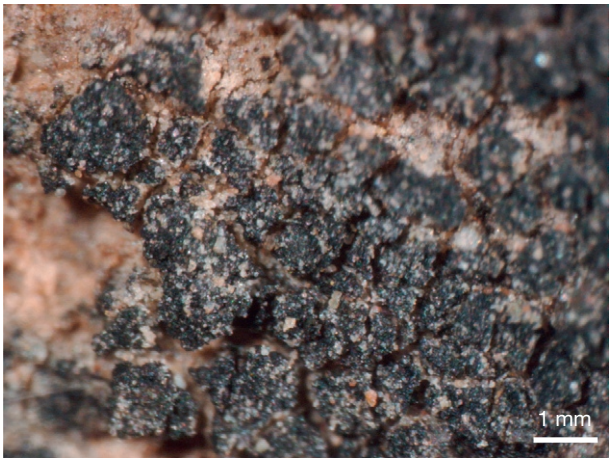

Figure 7 A photograph of an endolithic bacterial colonization (the blackening) of aeolian sandstone in potholes at Bartlett Wash, near Moab, NM (see Chan et al., 2005).

Figure 6 A photograph of microbial mats growing near Atlin, BC, Canada. Prior to the evolutionary development of predators, approximately one-half billion years ago, much of the photic biosphere on Earth presumably looked similar to this.

EPS-rich biofilms can also play an important role in the stabilization of sediment surfaces by cementing mineral particles together (see **Figures 1** and **3**; Stahl, 1994), thus prolonging the stability of a particular habitat.

Under arid environmental conditions where water activity is limited, for example, hot and cold desert environments (Friedmann and Ocampo, 1976), habitable endolithic microenvironments are found within soil or within rock. Endolithic microbial communities display an intimate relationship with the substrate they inhabit, also producing protective and nutritive EPS (**Figure 7**).

10.14.3 Geology and Life

10.14.3.1 Lithotrophy

Lithotrophic or 'rock-eating' prokaryotes are broadly characterized as organisms capable of utilizing inorganic compounds, for example, H_2S or minerals to generate energy, and can produce geologically significant phenomena. For instance, metal sulfide oxidation produces acidic environments as in acid mine drainage systems (Nordstrom and Southam, 1997; Singer and Stumm, 1970) and supergene copper deposits (Enders et al., 2006).

Microorganisms are also active agents of chemical weathering of silicate minerals (e.g., Brantley et al., 2001; Hiebert and Bennett, 1992; Rogers et al., 1998; **Figure 3**), and if reactive organic matter is abundant, mineral dissolution can occur very rapidly. Silica weathering (both as grains and as cement) is a general phenomenon resulting from microbial corrosion in order to concentrate elements limited in their environment, for example, iron and phosphate (Banerjee et al., 2000), and micronutrients, such as Fe, Co, Zn, Mo, Cu, and Ni, which are represented in trace amounts in most terrestrial materials (Bennett et al., 1996). Moreover, if apatite occurs in a silicate rock, it will be the first mineral to be dissolved out because phosphate is a biolimiting nutrient (Taunton et al., 2000). An added advantage of silicate weathering is the creation of suitable habitats for the growth of endolithic microbial communities in water-limited ecosystems (Chan et al., 2005; Friedmann, 1980, 1982). This process also results in the exfoliation of silicate rocks that is typical of hot or cold desert environments, whereby the metabolic activity of microbes inhabiting the protective microhabitat beneath the exposed surface of the rocks weakens the rock in layers parallel to its surface (Parnell et al., 2004).

The importance of mineral weathering in supporting the biosphere has led to the general hypothesis that life on Earth or any other rocky planetary body would ultimately be limited in the long term without some form of plate tectonics or lithospheric renewal providing nutrients from the more reduced lithosphere below. However, once established, subsurface colonization of planetary bodies would extend life for much longer periods of time as the planet cools, allowing the deeper penetration of life into the lithosphere. For example, Hoening et al. (2013) modeled the evolution of the continental surface coverage and the mantle water content with and without

biologically enhanced weathering rates. These authors speculated that the mantle would be significantly drier and the aerial surface coverage by continents smaller than observed if the Earth had no biosphere. The Earth may even lack plate tectonics altogether under these circumstances!

10.14.3.2 Microorganisms and Mineral Formation

Given sufficient mineral ions in the aqueous medium, microorganisms and their biofilms or mats can be rapidly fossilized (**Figure 2**; Schultze-Lam et al., 1995; Westall et al., 1995). Fossilization takes place either (i) by the complexation of mineral ions to functional groups in the organic material, gradually replacing the organic structure and, at the same time, trapping the degrading organic molecules in the polymerizing mineral matrix, or (ii) when amorphous minerals formed in the aqueous phase bind to the cell envelope (Konhauser et al., 2003; Rancourt et al., 2005). The organic matter in the fossilized microorganisms becomes rapidly degraded (e.g., Orange et al., 2013), but the degradation products may remain trapped in the encapsulating mineral matrix. Alternatively, in modern oxidizing hydrothermal environments, the organic matter can be completely oxidized, although the microbial cast still remains (Konhauser, 1998).

The formation of many secondary minerals catalyzed by microorganisms occurs in both natural and laboratory systems (**Figure 8**; see Lowenstam, 1981). Metal sorption and mineral nucleation onto microbial cell envelopes are two different passive mineralization processes. Metal sorption occurs via ion-exchange reactions through competition between hydronium ions, alkaline earth ions, and heavy metals for anionic reactive sites on microbial surfaces (Beveridge, 1981; Urrutia and Beveridge, 1994). Many cell envelope polymers have a demonstrated capacity to bind metallic ions and promote mineral nucleation (Beveridge, 1981; Fein et al., 1997).

Active surface-mediated mineralization occurs either by the direct transformation of metals into unstable forms (Lovley et al., 1991) or by the formation of metal-reactive by-products (Fortin et al., 1994). For example, cyanobacteria have the capacity to precipitate carbonates (Thompson and Ferris, 1990; Thompson et al., 1997) via the creation of alkaline conditions immediately around the cell from photosynthetic activity (**Figure 6**). However, the formation of unstable forms or metal-reactive by-products depends on the geochemical environment in which they are formed. One hypothesis for the deposition of banded iron formations in the late Archean is that iron oxide precipitation was mediated by the metabolic activity of oxygenic photosynthetic cyanobacteria (although there are a number of BIFs that formed by abiotic processes on the early, anoxic Earth before the advent of oxygenic photosynthesis). Today and since the oxygenation of Earth's atmosphere, the oxidation of iron (reaction [7]) occurs within the aerobic/anaerobic interface of the Earth surface where the reduced iron encounters oxidizing conditions:

$$Fe^{2+} + \tfrac{1}{4}O_2 + H^+ \rightarrow Fe^{3+} + \tfrac{1}{2}H_2O,\ \Delta G^o = -40.1\,kJ\,mol^{-1} \quad [7]$$

(Edwards, et al., 2004; Ehrlich, 1975; Emerson and Revsbech, 1994; Little et al., 2004). Dissimilatory metal-reducing prokaryotes are best known for their ability to utilize minerals for their electron acceptors resulting in the solubilization of Fe (Lovley and Phillips, 1988) and Mn (Myers and Nealson, 1988) oxides and any coprecipitated base metals, as well as the formation of magnetite, siderite, chromium hydroxide, and uraninite (Ishibashi et al., 1990; Lovley et al., 1991; Pedersen and Ekendahl, 1990). The most common metal sulfide attributed to biogenic activity is iron sulfide (Tuttle et al., 1969; reaction [8]):

$$Fe^{2+} + H_2S \rightarrow FeS(s) + 2H^+ \quad [8]$$

These dissimilatory processes combined with bacterial surface catalysis are responsible for mineral formation on cell surfaces in these systems.

Although individual bacteria are extremely small, bacteria have played a role in the formation of geologically significant deposits of carbonate, banded iron formations, and phosphorites (Konhauser et al., 2002; Riding, 2000; Youssef, 1965; see **Figure 9**). From a geochemical perspective, the contribution of bacteria to the formation of ancient deposits is often inferred by the enrichment of stable light isotopes by microbial mineral-forming processes (Kakegawa, 2001; Schidlowski, 1988). Mineral signatures then can serve as biomarkers when they are associated with fossils (Cady et al., 2003; Rasmussen, 2000; Southam et al., 2001; Tazaki et al., 1992), when they possess isotopic signatures that point to biochemical (enzymatic) processing of dissolved solutes, or when realistic, abiotic geologic phenomena cannot explain their occurrence (see review in Westall and Southam, 2006).

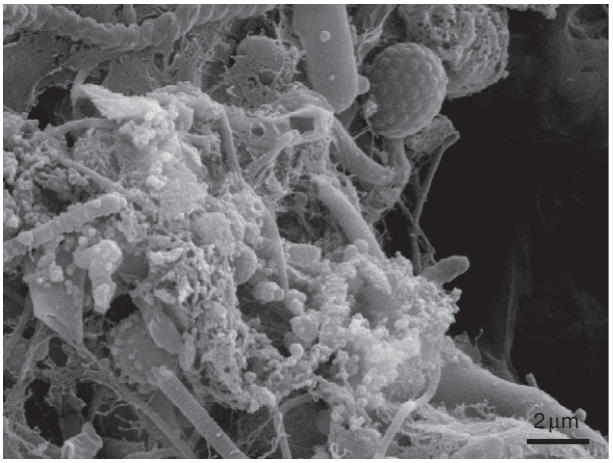

Figure 8 A scanning electron micrograph of a biofilm collected from a borehole flowing from the deep subsurface, 3.1 km below land surface in the Witwatersrand Basin, Republic of South Africa. Note the fine-grained, amorphous iron silicate minerals that have precipitated within the biofilm.

10.14.3.3 Habitable Conditions on Early Earth (and Other Rocky Planets)

As we saw briefly in the Introduction, the early Earth would have presented a very different habitat compared with the modern planet (see reviews in Nisbet and Fowler, 2004; Nisbet and Sleep, 2001). The hotter mantle meant that there was a greater amount of volcanic and hydrothermal activity (perhaps similar

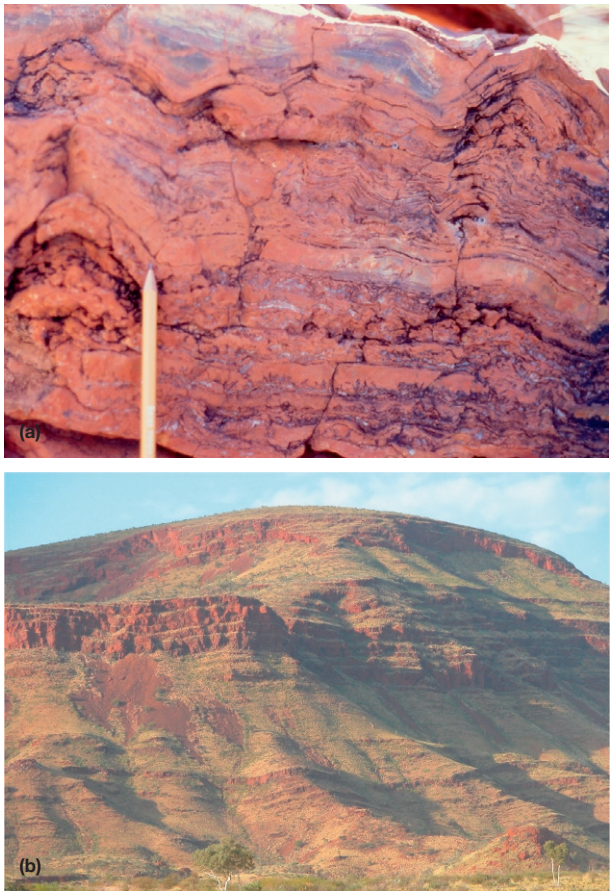

Figure 9 (a) Small, conical stromatolites from the early Archean (>3.46 billion years old) North Pole Dome of the Pilbara (photograph D. Marchesini). (b) A photograph of the Brockman Formation, a banded iron formation found in the Hamersley Range, Pilbara, Western Australia.

to that observed in the central portion of **Figure 2**), as well as faster recycling of the crust (Arndt, 1994). The atmosphere was composed of mostly CO_2, together with CO, NH_3, N_2, and probably a certain amount of CH_4 (the latter possibly at least partly biological; Pavlov et al., 2001; Zahnle et al., 2010). Oxygen levels were low (<0.2% of present atmospheric levels, Kasting, 1993), the oxygen being produced by photolysis of water vapor in the upper atmosphere. Based on the high CO_2 concentrations in the atmosphere (Rye et al., 1995), the oceans were probably slightly acidic, pH 6–7 (Grotzinger and Kasting, 1993). These acidic conditions, combined with the rapid cycling of hydrothermal fluids (Duchač and Hanor, 1987; Hofmann and Bolhar, 2007; Paris et al., 1985), would have resulted in extensive mineral weathering. Higher salinity (de Ronde et al., 1997) and somewhat higher temperatures (≤40 °C according to Hren et al., 2009) were also characteristic of the early to mid-Archean oceans. However, isotopic studies of fluid inclusions in Archean rocks have found that the composition of the oceans has remained somewhat constant over time (Holland, 1984; Kasting et al., 1993). The lack of significant oxygen in the atmosphere meant that UV radiation levels were high, that is, up to 50 times present levels and up to 1000 times in a worst-case scenario (Cockell and Raven, 2004). However, the deleterious effects of UV radiation on the biosphere may have been mitigated by large amounts of dust and aerosols in the atmosphere from volcanic eruptions, meteoritic impacts (Lowe et al., 2003), and possibly water vapor (Lammer et al., 2005) or CH_4 smog (Lovelock, 1988).

The coexistence of reducing and oxidized gases in the prebiotic atmosphere, combined with the input of extraterrestrial organic carbon (e.g., Brown et al., 2000), would have provided abundant untapped chemical energy for early life-forms (Catling and Claire, 2005), for example, methanogens that utilize the redox disequilibrium by combining H_2 and CO_2 to make methane (reaction [4]).

10.14.3.4 The Earliest Traces of Life

We would describe the early life-forms on Earth as being anaerobic, halotolerant, UV-resistant (see Daly et al., 1994), and thermophilic (see Stetter et al., 1990). What is intriguing about the remnants of the oldest life on Earth is (1) the modern-looking aspect of the individual microorganisms, their colonies, and growth as biofilms and mats (**Figure 10**), (2) their diversity, and (3) their wide environmental distribution (see review in Westall and Southam, 2006; Westall, 2011). While stromatolitic structures and shallow water microbial mats of presumably anaerobic photosynthetic origin have been described from the early Archean period (Allwood et al., 2006; Hofmann et al., 1999; Tice and Lowe, 2004; Walsh, 1992; Westall et al., 2006b, 2011), they are orders of magnitude smaller (**Figure 9(a)**) than the aerobic bioconstructions of the late Archean/Proterozoic epochs (**Figure 9(b)**; Awramik and Sprinkle, 1999). Other carbon-rich sediments from this period testify to a relatively abundant input of carbonaceous material from shallower water environments (Tice and Lowe, 2004; Walsh and Lowe, 1999) or from the planktonic photic zone (Javaux et al., 2010; Walsh and Lowe, 1999). However, the main limitation to early Archean productivity appears to be the fact that oxygenic photosynthesis and the corresponding aerobic heterotrophs had not yet developed (Des Marais, 2000).

The advanced level of evolution demonstrated by the remnants of life at 3.5 Ga has implications for the timing of the origin of life. Did the predicted planet-sterilizing impacts (Nisbet and Sleep, 2001; Ryder, 2002; Sleep et al., 1989) during the LHB between 4.0 and 3.85 Ga (Maher and Stevenson, 1988) completely wipe out all traces of life, if it had evolved before, or was life able to survive in protected subsurface ecosystems? Note that an alternative hypothesis proposes that only the topmost 400 m of the oceans would have been evaporated during the worst of the impact events (Ryder, 2002). The occurrence of hyperthermophilic microorganisms in the lowest branches of the evolutionary tree of life (Pace, 1997) is generally considered to imply that early life must have passed through severe (catastrophic) environmental conditions, such as an almost planet-sterilizing impact and that life-forms in protected habitats, such as deep-sea hydrothermal vents, survived, whereas life-forms in the more exposed habitats did not. Whatever the timing necessary for life to appear (Lazcano and Miller, 1996, suggested 10 My), a rocky planet with a hydrosphere can support prokaryote life-forms.

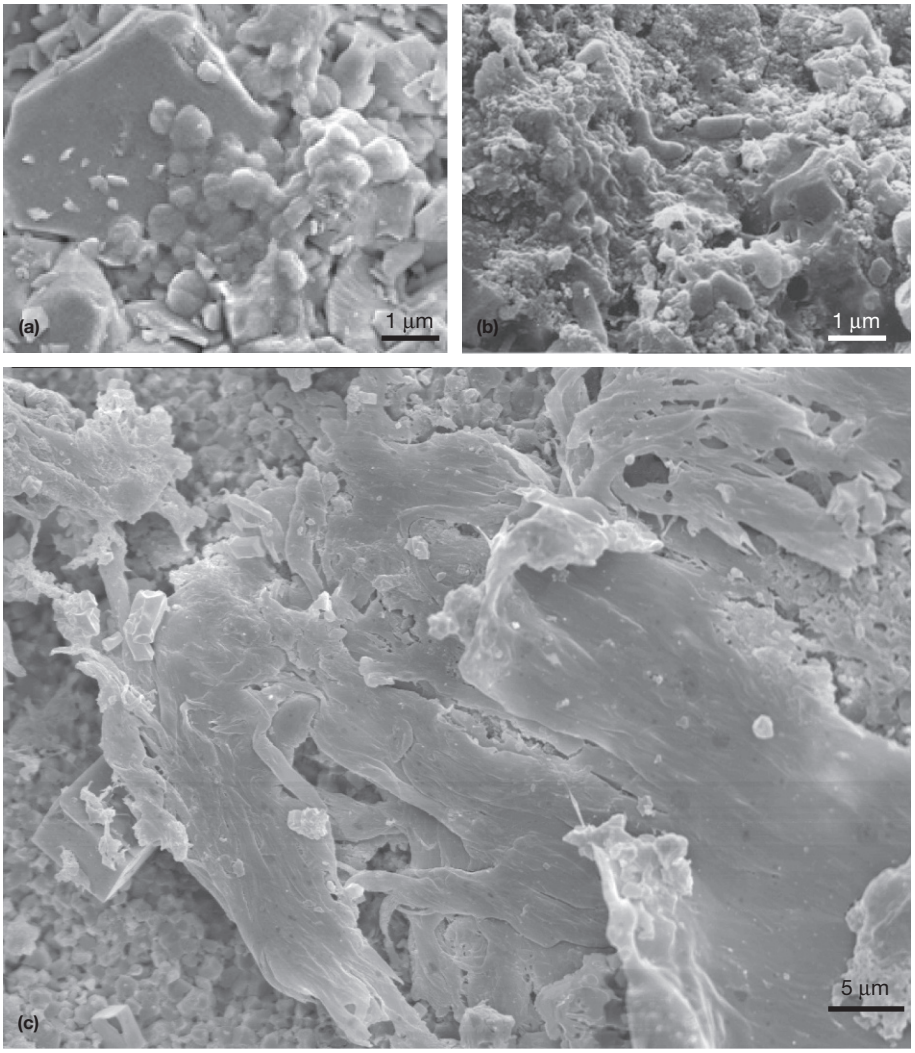

Figure 10 Fossilized early Archean microorganisms (3.47–3.34 billion years) (a) small colony of small coccoid microfossils (arrow) that colonized a marine, subsurface sedimentary habitat (see Westall et al., 2006a); (b) small colony of rod-shaped to vibrioid-shaped microfossils (arrow) that were closely associated with anaerobic, photosynthetic filaments forming a well-developed microbial mat (c) on beach sediments in an evaporitic environment (see Westall et al., 2006b).

10.14.4 Conclusions for Geology, Life, and Habitability Beyond the Earth

The ingredients necessary for life to originate (liquid water in contact with rocks/minerals; abundant organic molecules (exogenous or endogenous); elements such as hydrogen, oxygen, nitrogen, phosphorous, and sulfur; and energy sources (geochemical and sunlight)) were abundant on the early Earth. They were also abundant elsewhere in the early solar system and presumably in the universe. It is therefore legitimate to surmise that life could have arisen independently wherever these initial conditions are stable for the length of time that is necessary for the process. Once started, from a microbiological point of view, these 'primitive' life-forms can exist wherever there are the essential nutrients and potential redox reactions (providing chemical energy) that could support growth. Apart from the classical terrestrial planets in the solar system (Venus and Mars), Europa has also recently excited interest because of the potential for liquid water in contact with a rocky core (Bhattacherjee and Chela-Flores, 2004; Greenberg, 2005), and the presence of water ice on Enceladus is equally stimulating (Brown et al., 2006).

The possibility of extraterrestrial life on Mars has fascinated humans for over a hundred years: Percival Lowell (1910) started the ball rolling with an account of Martian life based on Schiaparelli's (1879) drawing of what he thought were channels (or intersecting straight lines) on the surface of Mars. Although various missions over the last 30 years have discounted these fanciful theories, it is clear that, early in its history, there was a significant inventory of water on the surface of the planet as documented by geomorphological features (e.g., Di Achille and Hynek, 2010; Jaumann et al., 2002) and the presence of minerals produced by aqueous alteration and deposition (e.g., Bibring et al., 2006; Loizeau et al., 2012), albeit probably not sufficient for an ocean covering the northern hemisphere (Clifford and Parker, 2001;

Mouginot et al., 2012), that is, Mars possessed an active hydrosphere during the time when life originated on Earth. As we have seen earlier, microbial life does not require oceans of water in order to function: Once it has got going, it just requires continual access to a very small amount of carbon, nutrients, and energy. Given the access to the basic requirements for an origin of life (liquid water, organics, and rocks/minerals), it is possible that life did arise independently on the red planet (Westall et al., 2013). Indeed, the first results from the Mars Science Laboratory mission with its rover Curiosity in the 3.6-Ga-old Gale crater indicate that there is evidence for habitable conditions in the crater (http://www.nasa.gov/mission_pages/msl/news/msl20130312.html). Therefore, Mars may contain a record of fossilized primitive microorganisms or their associated mineralogical biomarkers, similar to those that are found on Earth. These traces of early Martian life will likely occur in the rocks of the southern hemisphere, which are largely Noachian in age and have apparently undergone aqueous alteration. Of course, boulders or meteorites of southern hemisphere material could be found elsewhere on Mars or even on the moons of Mars, Phobos, and Demos, since Mars, together with the other inner solar system planets, experienced a period of late bombardment between 4.0 and 3.8 billion years ago. It is equally possible that the Noachian-age rocks will contain traces of the prebiotic stage of life and the appearance of the first cells, that is, the critical period of life on Earth's history that is missing on Earth – if we are capable of recognizing these traces (Westall et al., 2013).

If life established itself on Mars during the Noachian age, could it still be present today and, if so, where? The loss of liquid water on Mars' surface and the cessation of any sort of plate tectonic activity (if there ever was any) due to the rapid cooling of the planet limit one of the important criteria for life, that is, a flux of reduced or energetic redox species, although Curiosity did find evidence of the redox couple sulfide and sulfate in Gale crater (Grotzinger et al., 2014; McLennan et al., 2014). As we noted earlier, microorganisms can survive a wide range of extreme conditions, but there are certain combinations that are lethal, and it appears that the combined low water activity, high UV radiation, and the presence of some kind of oxidant species that oxidizes labile organic components (i.e., those that are necessary for life) makes the surface of the planet hostile to any long-term survival. However, Mars is not completely volcanically inactive (Neukum et al., 2004), and there could be hydrothermal activity in its subsurface, as indicated by occasional surface exposure (Malin and Edgett, 2000) and with subsequent implications for life (Farmer, 1996; Schwenzer et al., 2012). Previous identifications of methane on Mars (e.g., Formisano et al, 2004) gave rise to hypotheses of a subsurface origin related to biological activity (Tung et al., 2005) although an alternative hypothesis related hydrothermal melting of CH_4 clathrates was also postulated (Prieto-Ballesteros et al., 2006). However, it now appears that the detections of methane were erroneous (Zahnle et al., 2011). Whether or not methane has been detected, this activity would provide the necessary criteria/conditions for life, at least in the subsurface of Mars, similar to that provided to bacteria in Earth's subsurface (Boston et al., 1992; Wanger et al., 2006).

While we do not know the exact conditions necessary to create life, the basic requirements of a habitable extraterrestrial body (assuming Earth is a representative sample) are fairly well understood. Habitable locations in our solar system today, that is, places where life can be sustained, are not as restrictive as those where life could originate and include Mars' subsurface (Boston et al., 1992), as well as the ocean on Europa (Chyba and Phillips, 2001). It is also intriguing to realize that, in the future as the Sun gets hotter and comes into the red giant phase of its history, these planets and possibly others in the outer solar system will be able to host life, if not see it appear independently. Thus, the possibility of finding traces of extinct or extant life on other planets in the solar system is strong, and the future for life in the solar system is optimistic, even though the habitability of our own planet will slowly decrease starting in another c.1.5 Ga (Franck et al., 2006).

10.15.1 Introduction

10.15.1.1 The Basics

The importance of small bodies – asteroids, comets, and small satellites – to the overall picture of planetary formation and planetary evolution has been recognized for decades (see reviews by, e.g., Bottke et al., 2002b; Festou et al., 2004). Only since the 1990s, however, we learned enough about the small bodies and about solar systems in general to start to make detailed connections. Our advances have come mainly thanks to new opportunities in ground- and space-based telescopic observations of both our own solar system and other systems. Additionally, the multitude of spacecraft that have now visited a variety of small bodies have provided a wealth of detailed context. The 1990s, 2000s, and 2010s have brought incredible insight into the nature of the small bodies.

In this chapter, we will give a review of recent developments in our astronomical understanding of small bodies. To keep

the discussion manageable, note that we focus here mainly on comets and asteroids that are not in orbit around major planets; that is, we are excluding those small satellites that are likely captured comets and asteroids. Such satellites can inform and have informed our understanding of the general comet and asteroid population (see reviews by, e.g., Bell et al., 1993; Jewitt and Haghighipour, 2007; Turrini et al., 2009).

With this restriction, note that when we refer to 'small bodies' in this chapter, we will mean just comets and asteroids. In Section 10.15.1, we will discuss the historical and current definitions of small bodies and motivate their study by describing their scientific importance. In Section 10.15.2, we will describe the bodies' origins, their formation scenarios, their interaction with planets and with each other, and some of their dynamic processes. In Section 10.15.3, we discuss the nature of their surfaces, while in Section 10.15.4, we cover their interiors. Section 10.15.5 treats the composition of small bodies, and we finish in Section 10.15.6 with a summary of some of the big questions in and future directions of small-body research.

10.15.1.2 Definitions

Comets have been noted in recorded history for millennia, and asteroids have been known for over 200 years. For most of their observational history, the two groups of small bodies were thought to be clearly separate. More specifically, observational differences were assumed to translate directly to differences in the fundamental nature of the objects. Asteroids were point-like objects in the sky, mostly physically located between Mars and Jupiter in the asteroid belt (a.k.a. the main asteroid belt or just the main belt). Comets were extended sources – showing comae and tails that are generally much brighter than the solid-body source itself – and were either on parabolic or highly elliptical orbits that took them beyond the planetary region of the solar system or on short-period orbits that barely (if at all) went past Jupiter. Even the names given to the bodies revealed this dichotomy: asteroids were 'minor planets,' basically just smaller, fainter versions of the other planets that were seen to wander across the sky. Comets were entirely different beasts, historically not even recognized as astronomical phenomena (as opposed to atmospheric) until Tycho Brahe's parallax studies in the sixteenth century. Even the physical explanation for why comets looked extended – that is, that they had dust – was not established until the nineteenth century by, for example, Bessel (1836) and Bredichin (1877). The early twentieth century saw further characterization of the composition of the two groups, which further reinforced the apparent differences. Cometary spectra showed emission lines from gas species on top of a continuum spectrum, while those of asteroids sometimes showed broad absorption features in the continuum.

One of the major advances since the early 1990s is the realization that comets and asteroids are in fact not clearly separate classes of objects but instead part of a continuum of composition (e.g., Weissman et al., 1989, 2002). Comets are relatively icy and asteroids relatively rocky, but there are many objects that are now recognized to populate everywhere in between. For example, objects in the trans-Neptunian region – nominally called asteroids because of their lack of activity – are icy and would show cometary activity if they were only closer to the Sun (e.g., Barucci et al., 2002; Prialnik et al., 2008); objects that have orbits that are clearly cometary in nature are seen to be inactive, suggesting that their volatile component is deeply buried or now absent (e.g., Ishiguro et al., 2011); and sustained activity that has been seen to develop from objects in the asteroid belt between Mars and Jupiter appears to be driven by volatiles, indicating that ice must still exist somewhere on such objects that have been in the same thermal environment for billions of years (e.g., Hsieh et al., 2010).

Hence, while the terms 'asteroid' and 'comet' are still commonly used in the small-body community, there is broad recognition that these terms no longer necessarily act as shorthand descriptors for their true physical nature. In this chapter, we will continue to follow common usage when talking about specific objects that are referred to as comets or asteroids, but it is important to recognize that such terms can occasionally be misleading.

For this chapter, we will limit ourselves to a discussion of objects within a range of diameters. At the low end, we will not be talking about dust in and of itself but only dust as it relates to macroscopic comets and asteroids. In this sense, our lower limit to the diameter is about 0.1 m, although in practice, the lower limit is a few meters since almost no small bodies on heliocentric orbits have been observed that are smaller than that. At the upper end, we will limit ourselves to objects that have not pulled themselves into a roughly spherical or spheroidal shape as a result of self-gravity. This is consistent with the IAU definitions of planets and dwarf planets (IAU, 2006); we exclude these bodies from consideration here. We will, however, discuss (4) Vesta as it pertains to asteroid phenomena, though it arguably could be called a dwarf planet and has many terrestrial planet-like characteristics (e.g., Keil, 2002; Zuber et al., 2011).

Finally, a discussion of terminology is in order. Among comets, short- and long-period comets (SPCs and LPCs) are those that have orbital periods less than and longer than 200 years, respectively. SPCs include those of the 'Jupiter-family' (JFCs) and of the 'Halley-type' (HTCs), the former referring to comets whose orbits tend to be strongly influenced by Jupiter, have aphelia near Jupiter's orbit, are mainly in the ecliptic plane, and generally have orbital periods of about 6 years. HTCs are now thought to be dynamically evolved counterparts to the LPCs; they can have any inclination. This terminology is the traditional one; Levison (1996) discussed comet classification and his newer system is in use by some comet scientists. That convention divides the population into 'ecliptic comets' (ECs) and 'nearly isotropic comets' (NICs). ECs include not only the Jupiter-family but also a few other inner-solar system comets that have been decoupled from Jupiter. Furthermore, ECs can include the active 'centaurs,' which are objects orbiting among the outer planets beyond 5 AU and are in transition from the trans-Neptunian region to the inner solar system. NICs include the HTCs and LPCs and so dispense with the arbitrary 200-year boundary.

Among asteroids, most of the over 380,000 numbered asteroids known reside in the asteroid belt between Mars and Jupiter. Asteroids are assigned permanent numbers when their orbits are sufficiently well determined to be identified decades in the future without ambiguity. An additional 260,000 unnumbered asteroids are currently cataloged and may become numbered as new observations are made, and their orbits are better determined. Hundreds more asteroids are discovered in a typical month. Some objects are Mars crossers (MCs), coming closer to the Sun than Mars, and some objects

are Earth crossers, coming closer to the Sun than Earth. Some asteroids cross the orbits of Venus and Mercury as well. A near-Earth asteroid (NEA) is any object with a perihelion distance less than 1.3 AU, and the NEAs are broken down into 'Amors,' 'Apollos,' 'Atens,' and 'Atiras.' Amors are not Earth crossers, staying outside the Earth's orbit; Apollos and Atens do cross the Earth's orbit, with the distinction being whether the orbital semimajor axis is larger or small than 1 AU; Atiras also do not cross the Earth's orbit, staying entirely interior to it. While these definitions are still in use, it is important to note that many of these distinctions are no longer meaningful, as we now know that objects can easily move from one dynamic group to another due to both gravitational perturbations and non-gravitational forces.

A traditional dynamic distinction between comets and asteroids is the Tisserand parameter (T_J). In a solar system consisting of just the Sun, Jupiter on a circular orbit, and the small body (called the 'restricted three-body problem'), this parameter is nearly constant (i.e., an 'integral of the motion' in classical mechanics parlance). In the real solar system, it is still nearly constant and useful since in general asteroids have $T_J > 3$ and comets have $T_J < 3$. This comes from the fact that SPCs tend to be dynamically coupled to Jupiter; the Tisserand parameter can be related to the encounter velocity of a small body with Jupiter. However, there are many asteroids with $T_J < 3$ and several comets with $T_J > 3$, so the distinction is not exact.

Some of the classification distinctions can be seen in Figure 1, which shows a plot of the semimajor axis versus eccentricity of many of the asteroids in the inner solar system. In particular, the curves 'EC,' 'MC,' and 'JC' indicate the curves that mark which asteroids can cross the orbits of Earth, Mars, and Jupiter, respectively. We will return to this

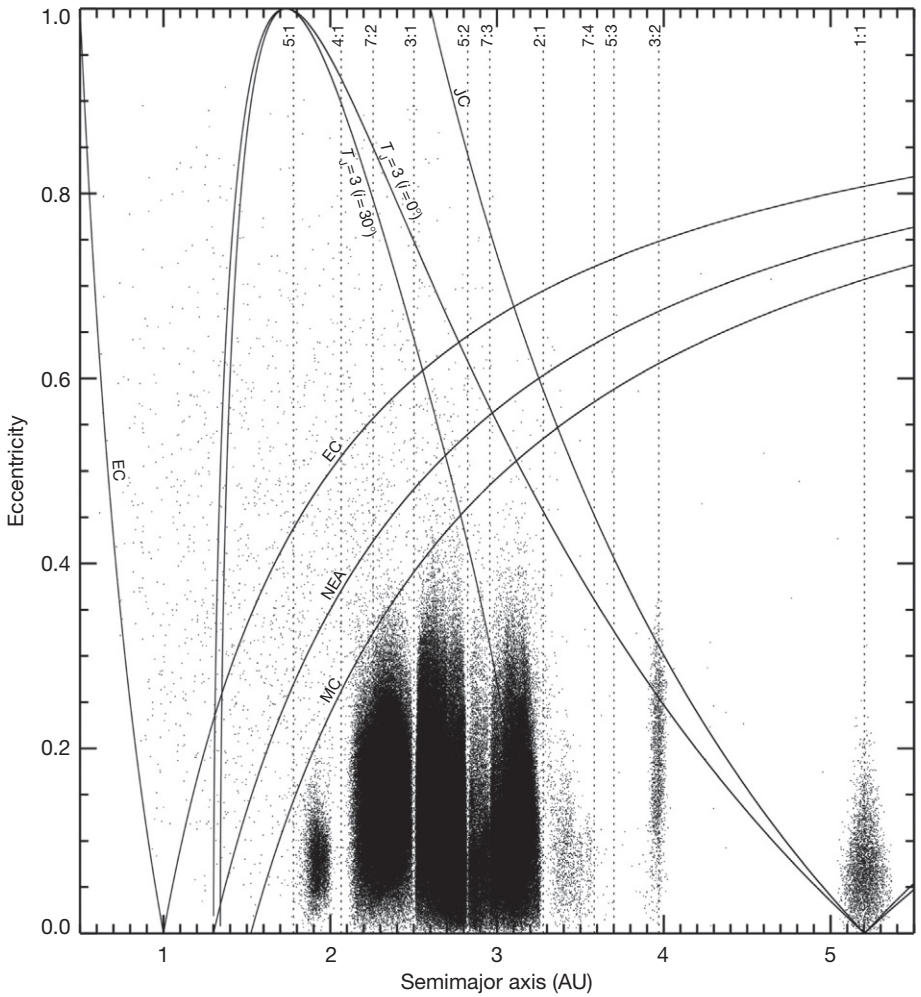

Figure 1 Orbital elements of the over 363,000 numbered asteroids (at time of writing), as represented in *a*–*e* space, where *a* is the semimajor axis in AU and *e* is the orbital eccentricity. Note that 1 AU is currently defined as 149,597,870.7 km exactly and is very nearly identical to the average Sun–Earth distance. There is obvious structure in the asteroid belt, and there are regions of orbital element space that are favored. 'NEA' indicates the locus where perihelion distance *q* is 1.3 AU, the defined boundary for near-Earth objects. 'EC,' 'MC,' and 'JC' indicate the Earth-, Mars-, and Jupiter-crossing boundaries, respectively. The two curves marked '$T_J = 3$' show where the Tisserand parameter is 3.0 for two possible values of the orbital inclination. Vertical dotted lines indicate mean-motion resonances (MMRs) with Jupiter; the resonance is listed at the top of each line. Note that Jupiter's semimajor axis is 5.20 AU; Mars's is 1.52 AU.

figure in later sections when we discuss various dynamic properties of the small bodies.

Note that in this chapter, we will give the complete designation when referring to an asteroid or comet for the first time, but references thereafter will use only the name (unless there is potential cause for confusion).

10.15.1.3 Dynamic Relationships

Some of the subpopulations of the solar system's small bodies are dynamically linked. In particular, the JFCs are linked to several other groups. The 'scattered disk' of the Kuiper Belt – containing objects beyond Neptune on high-eccentricity orbits – is thought to be the original source of these comets, and the objects progress in a dynamic cascade from beyond Neptune to the outer-planet region, essentially being handed off from the control of Neptune, to Uranus, to Saturn, and finally to Jupiter (Duncan et al., 2004). Jupiter-controlled comets have aphelia near 5 AU, and these are the JFCs we see today. As mentioned earlier, many members of the transitional population, the centaurs, have been discovered inhabiting the outer-planet region, and some of the centaurs show cometary activity. The timescale for an object to exist among the giant planets is only a few million years (Horner et al., 2004; Tiscareno and Malhotra, 2003).

JFCs share some of their orbital parameter space with NEAs. Current work suggests that up to a few percent of the NEA population could be JFCs that have simply lost their surface volatiles (e.g., Bottke et al., 2002a; DeMeo and Binzel, 2008; Fernández et al., 2005).

The connection between Jupiter's Trojan asteroids – objects in 1:1 resonance, but on average about 60° ahead or behind Jupiter in orbital longitude – and the JFCs is uncertain. It is possible that there is some leakage from the Trojan swarms to the comet population (Marzari and Scholl, 2002); however, no one has ever reported an observation of a Trojan having a comet-like coma or tail. Nor is it clear what would be an observational difference between a JFC that originated in the Trojan swarm and one that originated in the Kuiper Belt. One possible distinction is that Trojans might be expected to have a lower D/H ratio than objects that formed in the outer solar system, depending on how much compositional radial mixing has occurred; we discuss D/H ratios in more detail in **Section 10.15.5**.

The existence of a link between the asteroid belt and the NEAs is well established, although the details of which dynamic process moves which asteroids are still under debate (e.g., Bottke et al., 2002a).

10.15.1.4 Relevance to Geology

The most obvious geophysical link between Earth and the small bodies is cratering. Many craters are visible around Earth today, and the only reason we do not see more of them is because the Earth's surface is in constant change. Most – though not all! – asteroids have numerous craters, and indeed, most of the larger asteroid surfaces are saturated with craters. The study of the abundant craters on other solar system objects can bring insight into the impact process and how an impact's effects depend on the composition, density, and other bulk parameters of both the impactor and the target body.

Erosive processes that garden and turn over surfaces occur on most, if not all, small bodies. The main difference is that small bodies are airless bodies – none have an atmosphere in the same sense that Mars, Venus, and Earth (or even Mercury and the Moon for that matter) have atmospheres. The only thing that comes close is the gravitationally bound coma that sometimes appears around the largest cometary nuclei (e.g., Meech et al., 1997). But in general, no asteroid that we consider here has an atmosphere, and comets only have exospheres. The building up or tearing down of surface structures comes mainly from external effects (e.g., micrometeorite bombardment and impact cratering), though also perhaps from internal processes in the case of comets.

As will be discussed in later sections, the surfaces and interiors of small bodies can be quite different from those of Earth and the other terrestrial planets. Densities, porosities, compositions, collision histories, and surface processes can all be different from what we know on Earth. Yet all of these properties are crucial for understanding the geophysics of small bodies. Complicating our study of these objects is the fact that detailed geomorphology can only be obtained through the use of spacecraft or radar echoes, meaning that many comets and asteroids simply have not been studied in sufficient detail for there to be a true geophysical analysis. One important point to note is that spacecraft flybys of comets and asteroids have made it abundantly clear that we have not yet seen the full diversity of small bodies close-up.

10.15.1.5 Relevance to Meteorites

We know through laboratory or in situ sample analysis that only a small fraction of meteorites originate from the Moon and Mars; the vast majority are from asteroids. The meteorites thus give us important insights into the composition of the solar nebula from which the planets formed. A comprehensive review of meteorite studies is beyond the scope of this chapter and indeed is the subject of entire volumes (e.g., Lauretta and McSween, 2006). We rely heavily on the studies of meteorites to give us an understanding of the composition of asteroids while at the same time recognizing that the sampling of the asteroid belt may be extremely nonuniform. Attempts to link telescope spectra of asteroids with laboratory measurements of meteorites have shown that there is not a simple one-to-one correspondence and many asteroids do not seem to be represented in the meteorites we have. On the other hand, some links are considered very secure, such as the spectra of howardites, diogenites, and eucrites matching the spectrum of asteroid Vesta; these meteorites are considered to be samples of this asteroid (Binzel and Xu, 1993; Drake, 2001). The identifiable spectrum of Vesta has let us identify collisional fragments of previous impacts in the asteroid belt and among the NEAs (Binzel et al., 2004). However, other connections of specific asteroids to specific meteorites are not so clear.

Several asteroid taxonomies have been suggested to better understand the relationships between different asteroid spectral types, meteorites, and compositions. Tholen and Barucci (1989) gave a thorough review of the most commonly used taxonomic system based on photometry in the visible range

(0.35–1.0 μm). Bus and Binzel (2002) used higher-resolution spectra over a slightly narrower spectral range (0.45–0.95 μm) to extend the Tholen taxonomy to include more specific spectral features. DeMeo et al. (2009) extended the spectral range from visible to near-infrared (0.4–2.5 μm), and this Bus–DeMeo taxonomy is now the most widely used. Three groups of spectral types, S-, C-, and X-complex, encompass the majority of the asteroids. Each complex includes several related taxonomic classes designated by one or two letters; the specific taxonomic class that an asteroid is assigned depends on the details of the spectral shape. **Figure 2** summarizes the spectra of all the taxonomic classes in the Bus–DeMeo system; it shows both the average spectrum of each taxonomic type and some actual asteroid spectra. This figure shows the diversity of asteroid reflectances in visible and near-infrared wavelengths among all the taxonomic types. The S-complex asteroids are primarily pyroxene and olivine, and in some cases metallic iron. Ordinary chondrites (OCs) and other stony but largely undifferentiated meteorites are thought to be samples of S-complex asteroids. The C-complex asteroids are mostly low-albedo, flat featureless spectra except for a broad absorption band at 0.7 μm indicative of oxidized iron (Vilas and Gaffey, 1989) defining the Ch class. Various carbonaceous chondrite meteorites are thought to be samples of these types of asteroids, although the spectral matches are not perfect. The X-complex asteroids have been linked to many different meteorite groups such as aubrites, enstatite chondrites, and achondrites. Links to iron–nickel meteorites are problematic; originally, these were thought to come from the so-called (in the Tholen system) M-type asteroids, but now, it is unclear if any of the large asteroids can be primarily iron–nickel (see, e.g., Shepard et al., 2010, submitted for publication, and references therein for detailed discussion). A few additional taxonomic classes such as A, V, and R are unusual or match specific asteroids. For example, the V types are most likely related to Vesta, as discussed in the succeeding text. Finally, the D-type asteroids have featureless and very red sloped spectra and match the outer belt asteroids and Jupiter Trojans but do not match any meteorites very well, except perhaps Tagish Lake (Hiroi et al., 2001). Interestingly, both of Mars's moons are D-type objects; this is unusual since D types are not so abundant in the inner part of the solar system. For convenience in this chapter, and unless otherwise noted, we will refer to broad spectral groups of asteroids using the Bus–DeMeo taxonomy.

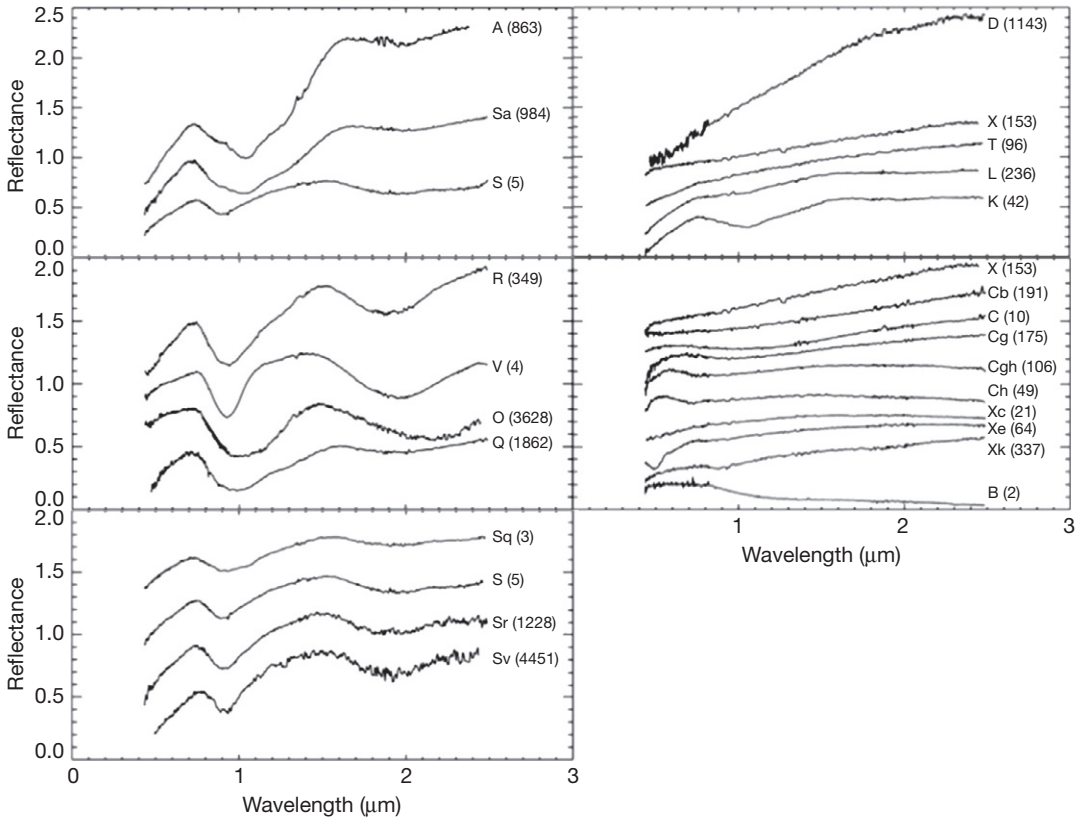

Figure 2 The range of asteroid relative reflectances as seen in the red and near-infrared. There are 26 spectra here, representing the 24 taxonomic classes for the near-infrared devised by DeMeo et al. ('S' and 'X' are shown twice); the taxonomic type is the letter at the right edge of each spectrum. The number after the type is the numbered asteroid that represents the prototype. Note that for clarity, spectra within a panel have been shifted vertically; reflectance is set at unity for a wavelength of 0.55 μm. Asteroids on the left all show the classic two-band ('Band I' and 'Band II') absorption features near 1 and 2 μm due to pyroxene and olivine. These types include the objects in the S-complex (S, Sa, Sq, Sr, and Sv). Asteroids on the right lack these absorptions, including objects in the C-complex (C, Cb, Cg, Cgh, Ch, and B) and X-complex (X, Xc, Xe, and Xk); indeed, many of the asteroids on the right lack distinguishing diagnostic absorption features, making determining their composition problematic. Reprinted from DeMeo FE, Binzel RP, Slivan SM, and Bus SJ (2009) An extension of the Bus asteroid taxonomy into the near-infrared. *Icarus* 202: 160–180, Figures 5–7, 11, and 14, with permission from Elsevier.

The connection between meteorites and comets is very sparse; no meteorite currently in hand is considered to have definitely come from a comet. Cometary meteorites are expected to be rare simply due to high entry speed (Campins and Swindle, 1998), although it is possible that some relatively slow meteor showers may provide meteorites that survive (Brown et al., 2013).

10.15.1.6 Relevance to Astronomy

The asteroids and comets we see today are the survivors of the planetary formation process that proceeded during the start of our solar system. The current dominant hypothesis is that the nebular cloud that formed the Sun also had a protoplanetary disk, from which the first planetesimals, and then planets, formed. The details of what the protoplanetary disk was like and the actual mechanical process that formed the planets are both major questions in astronomy that are the subject of significant research. Thus, the study of comets and asteroids is tied to some of the 'holy grails' of astronomy. The role of comets and asteroids in the history of our solar system's planets has become even more important since the late 1990s and 2000s with the discovery of many other planetary systems in our galaxy.

One of the interesting results from the several hundred exoplanets that have been discovered is the fact that the architecture of our own solar system seems to be relatively unusual (e.g., Borucki et al., 2011; Udry and Santos, 2007). Our planetary system's layout – with small terrestrial planets close to the home star and large gas- and ice-giant planets farther out – has not yet been seen in very many other systems. While observational biases and limitations have made it difficult to ascertain just how many terrestrial planets there are elsewhere, it is clear that there are a great many ways for giant planets to end up being distributed within a planetary system. This reality has motivated dynamicists to investigate possible modes of planetary migration. Some of this migration is influenced by the population of small bodies; essentially, the act of perturbing small bodies may transfer sufficient angular momentum (by the law of conservation) to change a planet's orbit. Thus, the population of small bodies in the protoplanetary disk is a fundamental part of understanding the development of the planets' final layout in the solar system. Furthermore, we are discovering other systems around older stars where clearly there are asteroid or comet belts with masses much larger than those we currently have in our solar system (e.g., Lawler et al., 2009; Lisse et al., 2007). These disks of material are not protoplanetary, since the parent stars are usually hundreds of millions or billions of years old. Two questions stemming from these observations are why some systems have such massive disks and whether our own solar system went through a similar stage in the past.

Another area of relevance that pertains to the solar system itself has to do with water and organic molecules. The existence and distribution of these substances are, of course, crucial things to understand since life on Earth (and so far, life as we know it) requires such compounds to exist. Both comets and asteroids contain water and organics in various forms and concentrations. Current thinking is that it is unlikely that Earth formed with its current water content, since it was likely too hot; most of the Earth's water presumably was brought to it via small-body impacts (e.g., Drake and Campins, 2006; Mottl et al., 2007). The original organic component of Earth was likewise probably miniscule, with small bodies perhaps providing the bulk of the organics (Anders, 1989).

Lastly, small bodies have relevance today since they represent an impact hazard to Earth. The extreme case is the K–Pg mass extinction 65 million years ago, after which a large fraction of the Earth's species became extinct in a geologically short time. Presumably, an important factor in instigating this extinction was the impact of an approximately 10 km wide object striking what is now the Yucatán Peninsula (Alvarez et al., 1980). Many other impacts have happened since that event, causing varying degrees of damage to local and regional ecosystems and in some cases whole biomes. A very recent and well-observed event was the arrival of the ~15 m wide Chelyabinsk bolide in February 2013. That asteroid, which was not known before the encounter, was possibly the largest object to strike the Earth's atmosphere since the 1908 Tunguska event (Brown, 2013). Somewhere out there is the next devastating small body that will eventually collide with us; the questions are how big is it, and is it coming in a few years, centuries, millennia, or longer? Unlike the dinosaurs, we can actually attempt to answer this question and try to guard against catastrophe.

10.15.2 Origins

10.15.2.1 Basics

The traditional, fundamental compositional distinction between comets and asteroids is the ice content. The zeroth-order explanation for that distinction involves the existence of a 'snow line,' a distance from the forming Sun within the protoplanetary disk beyond which water could condense. While the term 'snow line' conjures up the idea of a sharp boundary in the protoplanetary disk, it appears (as mentioned in **Section 10.15.1**) that the reality is more complicated, with the disk having a trend of ice abundance that varied with time rather than a sharp falloff (see, e.g., the review by Encrenaz, 2008). The most widely accepted idea is that the comets and asteroids we see today are the remnants of the planetesimals that formed by accretion within the protoplanetary disk.

The specifics of the accretion process still provoke a major ongoing research effort, most strikingly epitomized by the so-called meter barrier. While numerical modeling has been able to reproduce the accretion of solid-phase rock, metal, and ice grains into conglomerates up to submeter scales with the correct timescales, simulating the creation of larger bodies has been difficult. The main problem is that, in many simulations, a two-body collision between meter-size objects seems to result in a destructive collision rather than an accretion. One possibility is that the interaction between the meter-size boulders and turbulent gas in the disk can sufficiently affect the nature of the collisions so that kilometer-scale bodies can actually be created (e.g., Chiang and Youdin, 2010; Johansen et al., 2007).

There is evidence for a protoplanetary disk within which species aside from ice exhibited trends with distance from the Sun. The distribution of spectroscopic asteroid types is not randomly mixed, but instead follows a trend with heliocentric distance, which has been interpreted as a remnant of the solar nebula. This phenomenon has been known for decades (e.g.,

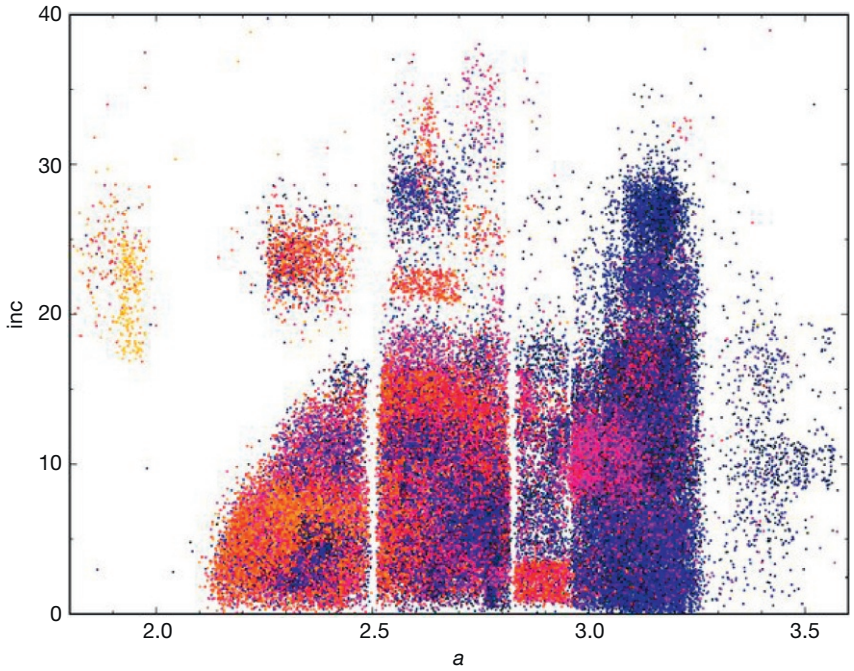

Figure 3 Scatter plot of main-belt asteroids in *a*–*i* space (where *i* is the orbital inclination) showing the albedos of the asteroids as derived by observations with the WISE spacecraft. The color coding of the points gives the albedo, with black and gray as the lowest albedos (0.05 and below), increasing to blue, purple, pink, red, and orange, with yellow showing the highest albedos (above 0.35). There is a clear trend of albedo with distance from the Sun; the trend exists for composition as well. Reproduced from Masiero JR, Mainzer AK, Grav T, et al. (2011) Main belt asteroids with WISE/NEOWISE. I. Preliminary albedos and diameters. *Astrophysical Journal* 741: 68, Figure 12, ©AAS, with permission.

Gradie et al., 1989), but a recent demonstration of the situation is shown in **Figure 3**. Thousands of asteroids observed by the WISE spacecraft (Masiero et al., 2011) show that asteroid albedos (and similarly, taxonomic types and compositions) are not uniformly distributed in the asteroid belt; more primitive (lower albedo) objects dominate farther out, while more processed (higher albedo) objects dominate closer in. The correlation of spectral types with distance motivates the idea that the asteroid belt can be used to better understand the conditions in the solar nebula and the material that formed the terrestrial planets. However, discoveries of extrasolar planets and other planetary systems have greatly broadened our notions of what is 'normal' and 'typical.' Also, increasing computation capabilities have allowed ever more realistic and detailed models of accretion and are now challenging long-held ideas of what we thought we knew about solar system formation. The asteroid belt and Kuiper Belt are important keys to constraining and testing these models.

The mass of the asteroids in the asteroid belt between Mars and Jupiter is about 6×10^{-4} times the mass of Earth, extremely depleted compared to a protoplanetary disk extending smoothly from 1 to 5 AU and likely originally containing many Earth masses of material (e.g., Morbidelli et al., 2012). The formation of Jupiter was long thought to be responsible for disrupting the formation of a planet in this region and for scattering material around the solar system. The asteroids remaining in the asteroid belt have dynamic signatures from Jupiter's gravitational effect, such as the Kirkwood gaps – evident as the gaps in semimajor axis as seen in **Figure 1**. These gaps are created by mean-motion resonances (MMRs) with Jupiter, where the orbital period of the asteroid is a small-integer ratio of Jupiter's; they are denoted at the top of **Figure 1**. An MMR tends to enhance perturbations from Jupiter and so helps kick the asteroid out of that region of orbital element space. The belt's inner edge is controlled partially by Mars. This is also seen in **Figure 1**; most of the asteroids now in the asteroid belt do not cross the MC line. The belt is also sculpted by the ν_6 resonance – a secular resonance arising from when the asteroid's longitude of perihelion has a precession frequency matching that of Saturn (see, e.g., Froeschlé and Morbidelli, 1994). This resonance is most noticeable in a plot of inclination versus semimajor axis, as in **Figure 3**; the reason the asteroids look confined to low inclinations is because the ν_6 resonance tends to kick out any asteroid with an inclination that is too high. The equivalent resonance with Jupiter, ν_5, operates at higher inclinations, so in this case, Saturn's influence is stronger than Jupiter's.

10.15.2.2 Recent Models

Recent modeling efforts to reconcile formation timescales of the outer planets have led to consideration of large-scale migration of the giant planets. The so-called Nice model (Gomes et al., 2005; Morbidelli, 2010; Morbidelli et al., 2005; Tsiganis et al., 2005) – named after the city in France where many of the model's originators work – has come to be broadly accepted, although the details are still debated. Indeed, the model, while explaining many observed orbital properties of small bodies in our solar system, has only made limited observational

predictions and could not account for the small mass of Mars (compared with Earth and Venus).

The basic premise of the model is that the outer planets (Jupiter, Saturn, Uranus, and Neptune) started out in orbits much closer to the Sun than they are now. There was also a disk of material – forerunners to today's comets – that was the remnant of the protoplanetary disk from which the four planets formed. Scattering of these small bodies (as mentioned in Section 10.15.1) caused the planets to migrate in semimajor axis, eccentricity, and inclination. Approximately 800–900 million years after the planets formed, Saturn and Jupiter happened to fall into a 2:1 MMR. This had a profound effect on the layout of the solar system, strongly perturbing the remaining small bodies in the outer solar system, as well as Uranus and Neptune themselves. There is even a possibility that Uranus and Neptune switched order; this falls out of some simulations and would nicely explain the long-standing mystery of why Neptune is more massive than the next planet closer in to the Sun. An example of the effects of the model is shown in Figure 4; small bodies in the vicinity are very rapidly scattered. The model can explain such other observables as the inclination distribution of the Jovian Trojan asteroids and the basic structure of the Kuiper Belt and would be the cause of the Late Heavy Bombardment seen in the lunar cratering record, about 3.9 billion years ago.

More recently, Walsh et al. (2011) had added an early, inward migration of Jupiter to 1.0 AU, which finally allows Mars to form with its small mass. However, this requires a complete reworking of our interpretations of the asteroid belt. The 'Grand Tack,' as this model has been called, is still being refined, but like the Nice model, it explains some long-standing mysteries in an appealing way. It too may be overturned, but at present, it provides a useful framework for understanding the asteroids that is substantially different from before. Morbidelli et al. (2012) gave a comprehensive review of the formation of the terrestrial planets, from nebular dust to present-day bodies. The asteroids are an important constraint, as the asteroid belt as seen today is not consistent with early Jupiter migration in the gas disk (Walsh et al., 2012) or the later outer-planet migration (jumping Jupiter) scenarios.

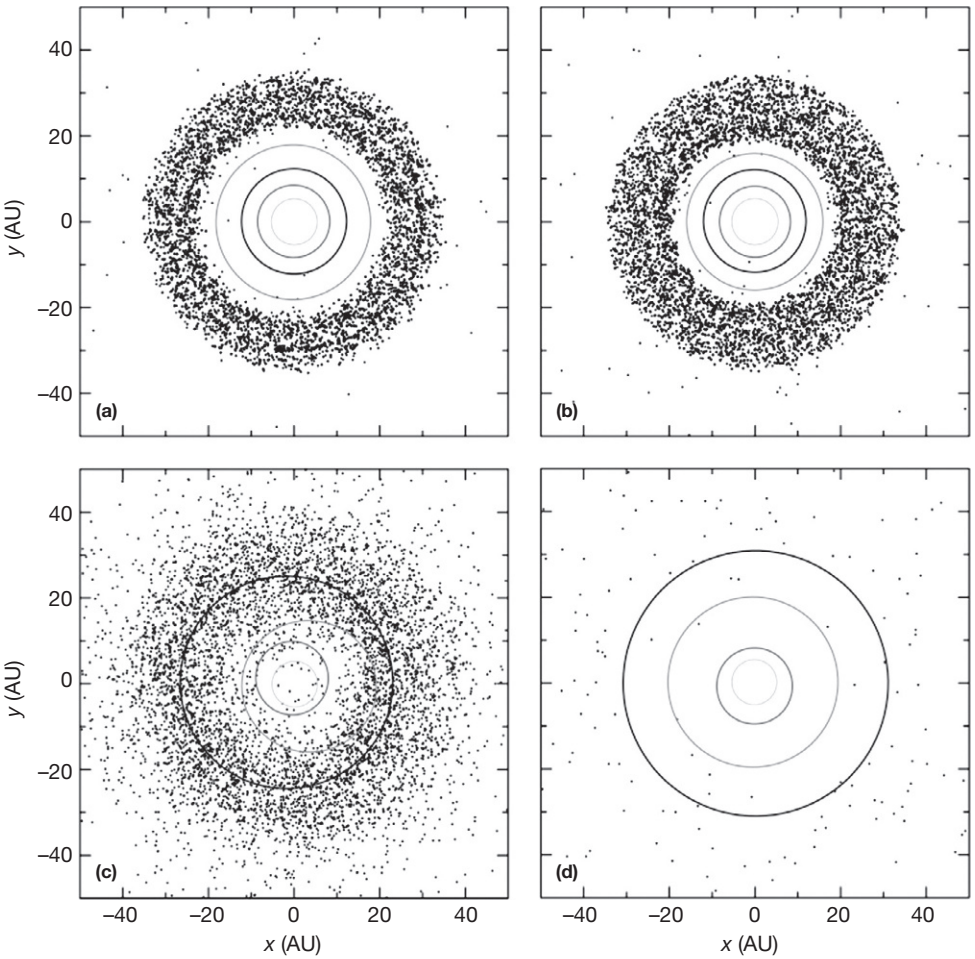

Figure 4 An example simulation of the Nice model. The four panels show the development of the four outer planets plus thousands of massless test particles through the use of a numerical simulation. Panel (a) represents the solar system 200 million years after the formation of the planets; panel (b), 879 million years; panel (c), 880 million years; and panel (d), 1080 million years. Jupiter and Saturn enter the 2:1 MMR at 880 million years, and the disk of test particles is quickly disrupted. Reprinted from Gomes R, Levison HF, Tsiganis K, and Morbidelli A (2005) Origin of the cataclysmic Late Heavy Bombardment period of the terrestrial planets. *Nature* 435: 466–469, Figure 2, with permission from Macmillan Publishers Ltd.

Finding dynamic models that can match the current inclination and eccentricity distribution of the largest asteroids is surprisingly difficult and serves as a sensitive measure of the dynamic evolution of the solar system.

Morbidelli et al. (2012) and references therein described how the original material in the asteroid belt would have been disrupted by inward migration of Jupiter, leaving only the inner asteroid belt intact and scattering some of these objects outward behind it as it moves. After Saturn moved into resonance with Jupiter, both began to migrate outward, and some of the scattered objects were scattered back into the asteroid belt region, along with many additional volatile-rich objects (C-type asteroids) that may have formed closer to 5 AU. This scenario solves the problem of having both high- and low-temperature materials side by side in the asteroid belt. However, it means that the compositional gradient with heliocentric distance is not primordial and allows a larger amount of radial mixing than is usually considered probable. The problem of linking meteorites to their asteroid parent bodies also becomes nearly impossible, since the current position of the asteroids may not be at all related to where those bodies formed. However, the observations that asteroid families, collisional fragments of once intact parent bodies, are nearly all spectrally uniform, while many meteorites clearly show that differentiation has occurred, is no longer an impossible situation. Differentiated objects can form closer to the Sun and be emplaced in the asteroid belt by Jupiter during migration. Undifferentiated objects form farther out and are scattered inward by Jupiter. Both can now exist side by side, but neither is representative of material that condensed at 2–4 AU. We may have little hope to identify primordial material, if this accretion model is correct.

The topic of the origin of the Kuiper Belt, which is likely the original source of the JFCs we see today, is discussed in detail in **Chapter 10.19**. Briefly, the orbital distribution of today's belt can be a useful constraint on the historical dynamic effects that sculpted it. For example, the slow outward migration of the outermost planet may have swept up some objects into MMRs; Pluto, residing in Neptune's 3:2 resonance, is the most famous example. But the belt also holds a 'scattered disk' of objects that were presumably scattered by Neptune into highly eccentric orbits. There is also a 'hot' classical disk that maintains relatively low eccentricity but is dynamically 'hot' in the sense of having higher inclination. In contrast, the 'cold' classical disk has lower-inclination objects. There seems to be some difference in origin of these various populations since there is some difference in their surface properties – namely, color (e.g., Romanishin et al., 2010; Sheppard, 2012), which is for the most part the only measurable property available for the vast majority of known Kuiper Belt objects. As mentioned earlier, the Nice model would suggest that Saturn's 2:1 MMR crossing disrupted the primordial Kuiper Belt, and it would imply that we may have a difficult time disentangling primordial and evolutionary effects.

10.15.2.3 Size Distributions

The size distribution of the asteroids has been measured to increasingly smaller sizes, but is still not linked to the dust distribution with any confidence. Models and observations have finally come together and agree that below about 10 km in diameter, all main-belt asteroids are collisional fragments (e.g., Bottke et al., 2005). Asteroids bigger than 30–50 km are likely to be fractured from multiple collisions but have lifetimes of 4.5 Gy or more and could be survivors of the formation of the planets. However, if the source regions for the present-day asteroid belt are as broad as 1—6 AU or more, these limits may change. There is some observational evidence for waviness in the cumulative size distribution – that is, for a distribution that follows a power law but with a bump at certain sizes (e.g., O'Brien and Greenberg, 2005). The cumulative size distribution as shown in the review by Bottke et al. (2005) is shown in **Figure 5**. This waviness could be interpreted as being controlled by the strength–size relationship of the asteroids. However, the existence of the waviness, and its location in the size distribution, is still under debate (e.g., Gladman et al., 2009).

The current size distribution of comets is, compared with the asteroids, poorly known. Work on the JFCs has been done by several teams (e.g., Fernández et al., 2013; Meech et al., 2004) and suggests that there is currently a lack of sub-kilometer-size comets. Some recent estimates of the distribution are shown in **Figure 6**. Note that there is no expectation that the current observed distribution of comet sizes reveals the primordial distribution; the collisional environment in the Kuiper Belt is likely too violent (Farinella and Davis, 1996). The observational situation is even worse for LPCs. Using the current size distribution of comets to work backward and tease out the original size distribution is a very long-term project that will require having a much better understanding of collisions, of cometary mass loss, and of fragmentation.

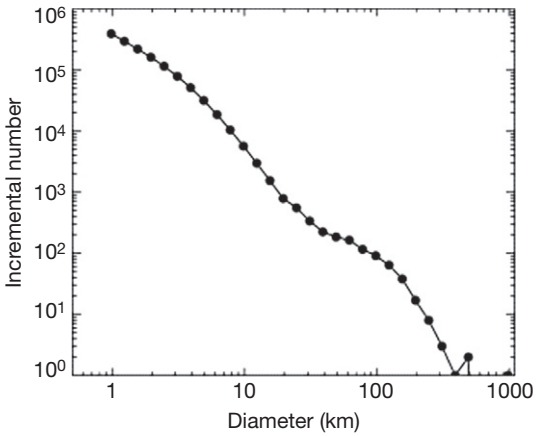

Figure 5 Main-belt asteroid size-frequency distribution, as shown in Figure 1 from the work of Bottke et al., 2005. This distribution is computed from the absolute magnitude H distribution, transformed into diameter bins assuming an average geometric albedo p_v of 0.092. For the fainter objects, those with $H > 12$ (i.e., a diameter less than 18 km for the average albedo), the data are from the Sloan Digital Sky Survey. For the brighter objects, with $H < 12$, the observational census is virtually complete and so the data are from the list of known asteroids. Reprinted from Bottke WF, Jr., Durda DD, Nesvorný D, et al. (2005) The fossilized size distribution of the main asteroid belt. *Icarus* 175: 111–140, with permission from Elsevier.

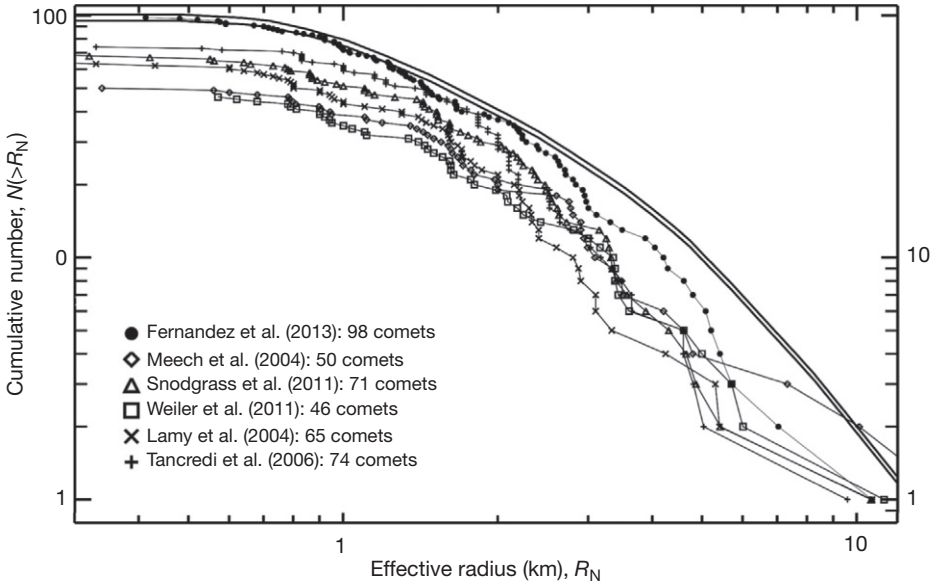

Figure 6 Cumulative size distributions of the Jupiter-family comets as reported by various workers. The legend indicates how many JFCs were used in each result. All results used primarily visible-wavelength measurements of nuclei, except for Fernández et al., who used exclusively infrared measurements. There is broad agreement in the distributions. The double-solid lines indicate the intrinsic distribution model by Meech et al. (2004) that best reproduces their observed distribution; this model requires that there be a lack of sub-kilometer JFCs to account for the small number of such comets that have been discovered. Adapted from Fernández YR, Kelley MS, Lamy PL, et al. (2013) Thermal properties, sizes, and size distribution of Jupiter-family cometary nuclei. *Icarus* 226: 1138–1170, with permission from Elsevier.

10.15.3 Surfaces

10.15.3.1 Background

Twelve asteroids and five comets have been imaged at close range by spacecraft through flybys and/or rendezvous, returning a huge number of disk-resolved images of these small bodies. Table 1 lists all small-body encounters within 10^6 km. Some views of these flyby targets are shown in Figures 7–10.

These planetary exploration missions have fundamentally changed solar system small bodies from astronomical objects to geologic objects. Our knowledge about the surface morphology and cratering characteristics has been greatly expanded as a result of those planetary missions. We will discuss the surface morphology of comets and asteroids separately; both kinds of objects are affected by cratering, but cometary surfaces are also changed on much shorter timescales by outgassing and erosion due to sublimation.

10.15.3.2 Surface Morphology on Asteroids

The first ever spacecraft flyby of an asteroid was in 1991, when the Galileo spacecraft visited (951) Gaspra while en route to Jupiter (Belton et al., 1992; Veverka et al., 1994). This flyby marks the start of observational studies of asteroid geomorphology. Since then, 11 more asteroids have been visited through either flybys or rendezvous missions (Table 1). Among those asteroids, (9969) Braille, (5535) Annefrank, and (132524) APL were observed at relatively low resolutions that do not allow for detailed studies of their surface morphology. The remaining asteroids represent a considerable sample of the general morphological properties of asteroids, from a small size of about half a kilometer in the maximum dimension for (25143) Itokawa (Demura et al., 2006) to the second largest of all main-belt asteroids, Vesta (Jaumann et al., 2012), and from near-Earth population – (433) Eros and Itokawa – to main-belt asteroids.

Despite their small sizes and therefore much weaker surface gravities compared with planets, asteroids display a large variety of surface features, including craters, boulders, lineaments (grooves, troughs, and ridges), rough and smooth terrains, regolith, and landslides. Being geologically inactive, the surfaces of asteroids are usually dominated by impact craters. The surface features reflect the mechanical responses of the target asteroids to various impact energies under various geometric settings and therefore reveal their physical properties. We summarize the major geologic features found on asteroids in this section, compare different asteroids, and discuss the implications to asteroids' evolutionary history and properties.

10.15.3.2.1 Craters

The dominant geomorphological features on the surfaces of almost all larger asteroids are craters, most of which are of impact origin, although this is not entirely certain for the small asteroid Itokawa due to the different morphology of the 'circular depressions' (Hirata et al., 2009). After formation, craters on asteroids are subject to size-dependent degradation and removal processes, such as regolith movement, slope failure, and micrometeorite bombardment. Three collective properties of crater populations on asteroids are the most important and widely studied. First, the spatial density is a critical indicator of surface age since the last resurfacing (e.g., Chapman, 2002; Ivanov et al., 2002). Second, the size-frequency distribution (SFD) is related to the SFD of impactors via cratering scaling laws (e.g., Holsapple et al., 2002, for a review; Holsapple and Housen, 2007; Melosh, 1989). The gravity and strength of asteroid material affect the scaling law, along

Under 'Type,' 'HTC' refers to Halley-type comet; 'JFC,' Jupiter-family comet; 'MBA,' main-belt asteroid; 'NEA,' near-Earth asteroid. The letter before 'MBA' and 'NEA' refers to the taxonomic type; the types are discussed in **Sections 10.15.1.5** and **10.15.3.3**. Note that flybys of comets 21P/Giacobini–Zinner and 26P/Grigg–Skjellerup returned no imaging, hence we have put a '?' in the dimension column.

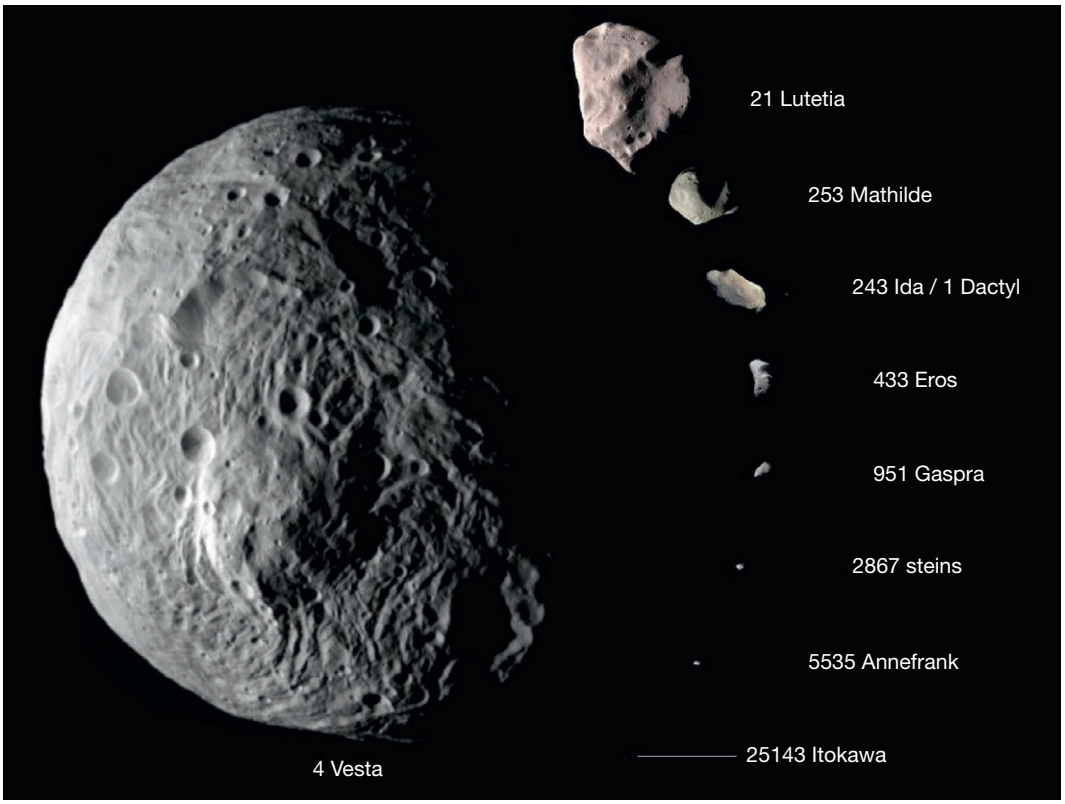

Figure 7 Montage of many of the asteroids that have had close spacecraft flybys, shown to scale. Note that the diameter of the largest object, Vesta, in this view is about 560 km, while that of the smallest object, Itokawa, is under 1 km. Courtesy NASA/JPL-Caltech/JAXA/ESA (Photojournal image PIA14316).

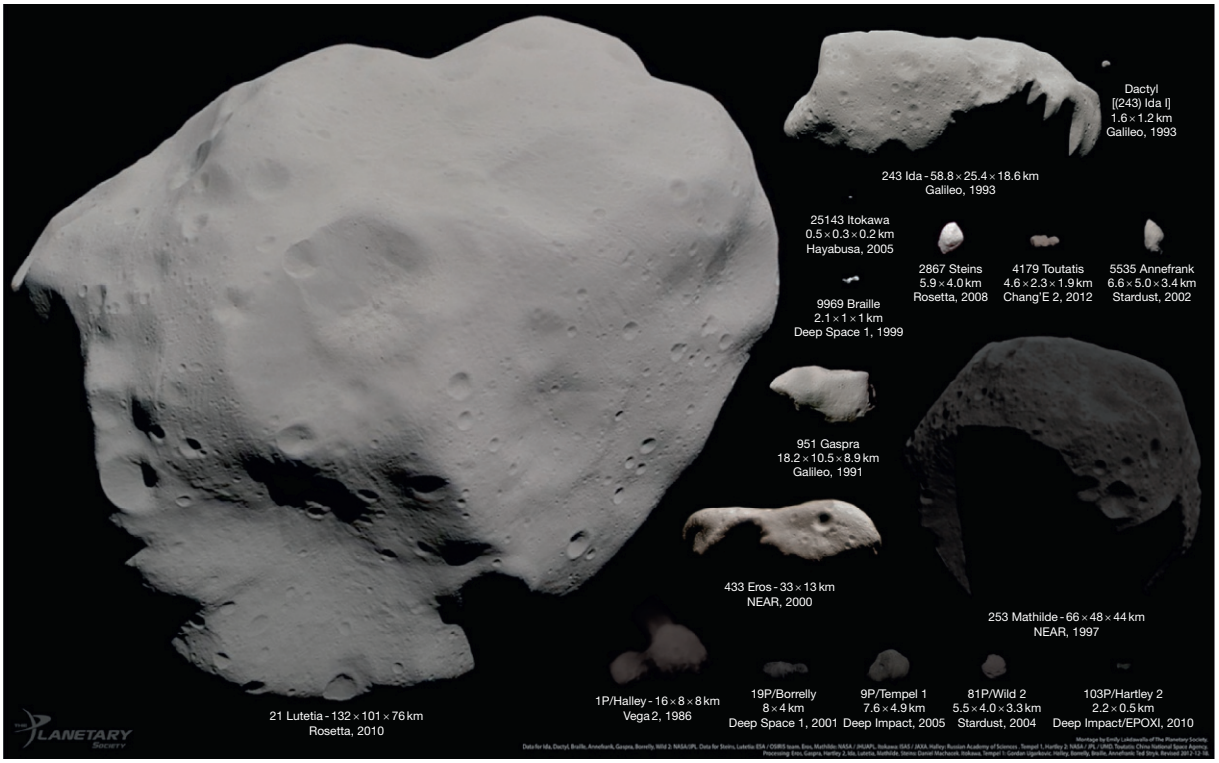

Figure 8 More complete montage of all small bodies that have had spacecraft flybys, except for Vesta, shown to scale. Each asteroid is as close to true color and albedo as possible. Note that the diameter of the largest object here, Lutetia, is about 100 km. Montage by Emily Lakdawalla. Data from NASA/JPL/JHUAPL/UMD/JAXA/ESA/OSIRIS team/Russian Academy of Sciences/China National Space Agency. Processed by Emily Lakdawalla, Daniel Machacek, Ted Stryk, Gordan Ugarkovic. with porosity. Third, the depth-to-diameter ratio (d/D) is affected by many factors including impact energy, target strength, and the degradation processes and trend (e.g., Carr et al., 1994; Melosh, 1989; Sullivan et al., 1996) and is also an indicator of regolith depth (e.g., Vincent et al., 2012a,b). The d/D on small bodies, however, is not well measured due to the uncertainties in reconstructing 3-D topography.

The cumulative SFD of craters on asteroids generally follows a power law with an index between −2 and −4, which is consistent with the SFD of main-belt asteroids from both observations (Jedicke et al., 2002) and theoretical modeling (e.g., Bottke et al., 2005; see **Figure 5**). This particular range of the power-law index is the expected result of asteroid collisional evolution (Davis et al., 2002). Starting from an asteroid population model, relative velocity, and the assumption of scaling laws, one can fit the SFD and density of craters on an asteroid or a region to derive its crater retention age, which is the time since the most recent resurfacing event (e.g., O'Brien and Greenberg, 2005; O'Brien et al., 2006). While generally this approach matches the crater size frequency on asteroids and allows us to derive these relative ages satisfactorily on, for example, (243) Ida, Dactyl (Ida's moon), parts of (21) Lutetia, and parts of Vesta (Chapman et al., 1996a; Davis et al., 1996; Marchi et al., 2012a,b), most asteroids show obvious deviations from the models at various crater sizes.

Gaspra (**Figure 9**) has few, if any, large craters but is peppered with fresh, small craters of several tens to hundreds of meters that are saturated, that is, in an equilibrium state (Carr et al., 1994; Chapman et al., 1996b). The number of craters on an object is said to reach equilibrium when for every new crater that forms, another is lost or covered up, so that the total number cannot increase. On Gaspra, the lack of large craters is inconsistent with the abundance of smaller craters. This property is so far unique to Gaspra. Gaspra possesses a few flat facets, which might be the remnants of large impact craters of sizes approaching the size of the asteroid itself (Greenberg et al., 1994; Thomas et al., 1994). The lack of large craters on Gaspra indicates a young age of ~250 My (Chapman et al., 1996b). However, Greenberg et al. (1994) and Chapman (1997) argued that the surface of Gaspra could be either much older or younger, if one assumes rubble pile structure (nearly strengthless) or monolithic structure (strong), respectively.

Unlike Gaspra, Eros (**Figure 10**) shows an extreme paucity of small craters of <100 m, while large craters >200 m are in an equilibrium state, similar to that of Ida (Chapman et al., 2002; Veverka et al., 2000). Richardson et al. (2004) and Michel et al. (2009) showed that the most likely reason for the paucity of small craters on Eros is seismic shaking erasure. The possibility that small impactors are preferentially removed by a size-dependent mechanism – that is, by the Yarkovsky effect, a thermal radiation force that causes objects to undergo semimajor axis drift due to asymmetrical radiation (Bottke et al., 2006) – has been considered but rejected (O'Brien, 2009).

Itokawa (**Figure 10**) and (2867) Šteins also show obvious depletion of small craters (Besse et al., 2012), probably also due to seismic shaking. The YORP (Yarkovsky–O'Keefe–Radzievskii–Paddack) effect (Bottke et al., 2006) – analogous to the Yarkovsky effect except it changes the asteroid's spin state due to that asymmetrical radiation of thermal emission – might be responsible for regolith movement on Šteins (Marchi et al., 2010a), effectively 'reshaping' the asteroid in that sense. Alternatively, for Itokawa, the high abundance of boulders on its surface could have protected it from forming small craters, with impactors simply fragmenting the boulders rather than creating craters (Michel et al., 2009).

The most striking features on (253) Mathilde (**Figure 9**) are several large craters with sizes comparable with the size of the asteroid itself (Cheng and Barnouin-Jha, 1999). The number of those large craters exceeds the saturation density, suggesting to several authors that Mathilde may be composed of weakly bonded, porous, crushable material that absorbs impact shock efficiently without disrupting preexisting large craters (Asphaug, 1999; Housen et al., 1999). The population of small craters on Mathilde also saturates its surface, consistent with an old surface of perhaps several billion years (Davis, 1999), although the estimate varies depending on the internal strength.

Vesta and Lutetia are both large and each shows a complicated cratering record on their surfaces. Vesta is ~560 km in diameter (Jaumann et al., 2012) and is large enough to trap

sufficient radiogenic heat during its accretion to lead to the differentiation of its interior. Vesta is thus a differentiated protoplanet (e.g., Keil, 2002; Russell et al., 2012). On the other hand, the internal structure of Lutetia (~100 km across) is uncertain, but it is unlikely to be differentiated, so it represents an ancient planetesimal (e.g., Coradini et al., 2011; Sierks et al., 2011). The cratering morphology on both asteroids includes all crater preservation states and different crater densities from region to region, suggesting very different crater retention ages from hundreds of My to >3.6 Gy (Marchi et al., 2012a,b; Massironi et al., 2012; Schenk et al., 2012; Thomas et al., 2012). On the oldest terrain on Lutetia, a region called Achaia, the SFD shows a distinct flexure point at 4–7 km diameter, attributed to the presence of a stratified surface with fractured material overlying a more competent interior (Marchi et al., 2012a), similar to the case for Mercury (Marchi et al., 2011). The full analysis of cratering properties on Vesta from Dawn data is still ongoing as of the writing of this chapter. Readers are referred to, for example, Yingst et al. (submitted for publication) and Williams et al. (in press) for the geology of Vesta.

The degradation states of craters can be gauged with the depth-to-diameter ratio (d/D), and the ratio can be also an indicator of the depth of regolith. Typically, the crater d/D on these asteroids is between 0.12 and 0.15 (Gaspra, Ida, and Eros) (Carr et al., 1994; Sullivan et al., 1996; Veverka et al., 2000), although for large asteroids Mathilde, Lutetia, and Vesta, this value could have a large range of <0.1 to >0.2 (Jaumann et al., 2012; Veverka et al., 1999; Vincent et al., 2012a,b). The small asteroid Šteins also has a large range of d/D of 0.04–0.25 (Besse et al., 2012). The smallest asteroid Itokawa has much shallower craters with d/D of 0.08 on average and a relatively narrow range of ±0.03, possibly due to the small size of the asteroid, the small number of craters with which to make the analysis in the first place, the incomplete formation of raised rims, and/or the infilling of crater by pebbles (Hirata et al., 2009; Michel et al., 2009). In contrast, the Moon, Mars, and Phobos typically have a depth-to-diameter ratio of about 0.2 (Shingareva et al., 2008). The wide range of d/D values among all these bodies indicates that crater creation and degradation depend on the detailed properties of the targets themselves. A comprehensive understanding of the variety of depth-to-diameter ratios – and of asteroid cratering in general – is a project for the future; the study of cratering on asteroids is complicated by both observational and modeling limitations. The most obvious factors include the identification of secondary craters (formed by reimpact of ejecta), the existence of extremely degraded craters underlying new craters, and the often irregular shapes of asteroids with complicated local topography. Crater chronology is almost always limited by our knowledge of the impactor populations, the mechanical properties of the surface (affecting scaling laws), and the removal process. The result is that surface ages are often strongly model-dependent.

10.15.3.2.2 Boulders

The visiting spacecraft imaged boulders on the surfaces of Eros, Lutetia, Vesta, and especially Itokawa. The surface of Itokawa is in fact dominated by boulders rather than craters (Barnouin-Jha et al., 2008; Fujiwara et al., 2006; Michikami et al., 2008). This is dramatically shown in **Figure 10**. The boulders on Vesta have not yet been thoroughly studied as of the writing of this chapter. Therefore, we will focus on the other three asteroids to discuss boulders. The shape of boulders on Eros and Itokawa is consistent with laboratory impact experiments (Michikami et al., 2010). The SFDs of boulders on all of them, as well as on Phobos, follow a power-law index of nearly −3 within a few meters to 80 m (Michikami et al., 2008; Thomas et al., 2000; 2001), a steep slope of power index of −6 for <10 cm size on Eros near its landing size (Thomas et al., 2001), and steep slopes of indexes −5 for boulders >80 m for both Eros and Lutetia (Küppers et al., 2012; Thomas et al., 2001).

The origin of boulders is generally associated with impact breaking of the target material. Since boulders are subject to destruction by the bombardment of small impactors, the existence of a large number of boulders usually suggests relatively young ages of the associated impact craters. For example, Geissler et al. (1996) noted that the distribution of large blocks on Ida is consistent with ejecta from the impact that created Azzurra crater; Thomas et al. (2001) studied the spatial distribution of boulders and their characteristics on Eros and established the formation of Shoemaker crater as the probable source of most of its boulders; a similar study for Lutetia by Küppers et al. (2012) also showed that most boulders on Lutetia were generated by the formation of the central crater in the youngest region, Baetica. The boulders on Itokawa, however, show a global distribution. There are no large craters on this small asteroid, and the total volume of boulders accounts for ~25% of the total excavated volume of craters, much higher than that on Eros (<1%) and on the Moon (~5%) (Cintala et al., 1982; Thomas et al., 2001). These arguments led Fujiwara et al. (2006) and Michikami et al. (2008) to conclude that the bulk of boulders on Itokawa most likely originated from the disruption of the parent body and re-accumulated on the surface of Itokawa during its formation.

10.15.3.2.3 Lineaments

Lineaments were first seen quite prominently on the global scale on Eros (Thomas and Prockter, 2010). The term includes grooves, troughs, and ridges, and they can be local or global in scale. Examples of lineaments are shown in **Figures 11–13**. All the asteroids that are resolved at sufficiently high resolution – except for Itokawa, which is a rubble pile – show either local or global lineaments on their surfaces. They seem to be caused by propagation of stress or tension and indicate to some extent a coherent interior. Local-scale lineaments appear to be associated with strong impacts that formed large craters. Global-scale lineaments could be associated with either the global response to seismic waves during large impacts or the stress environment of being broken up from the parent bodies (Buczkowski et al., 2008; 2012; Prockter et al., 2002; Sullivan et al., 1996; Thomas et al., 1994, 2002, 2012; Veverka et al., 1994). However, an intriguing alternate hypothesis for the Eros lineaments was given by Greenberg (2008), who suggested instead that the lineaments are near a vein of stronger rock (perhaps created by partial melt) that was more resistant to impact erosion. Grooves seen in the regolith are probably expressions of fracture within a more coherent substrate (Thomas et al., 1979) and may provide additional clues about the interior structure.

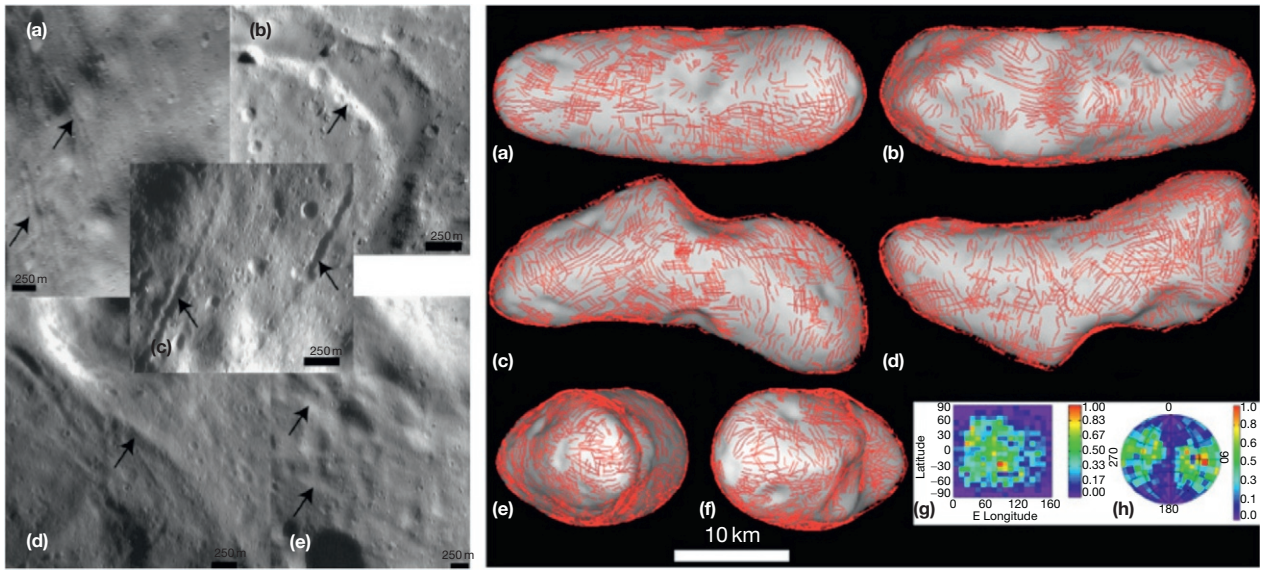

Figure 11 Lineaments on Eros. The left panel demonstrates various lineament morphologies, with the arrows indicating the relevant features, as follows: top left, grooves; top right, flat-floored troughs; bottom left, ridges; bottom right, shallow troughs; center, pit chains. The right panel shows the extensive network of 2141 lineaments (red marks) identified by software. Eros is shown in six orientations. The maps at bottom right (in two different projections) show the distribution of the poles of all the lineaments; the lineaments seem to be randomly distributed. Reprinted from Buczkowski DL, Barnouin-Jha OS, and Prockter LM (2008) 433 Eros lineaments: Global mapping and analysis. *Icarus* 193: 39–52, Figures 4 and 5, with permission from Elsevier.

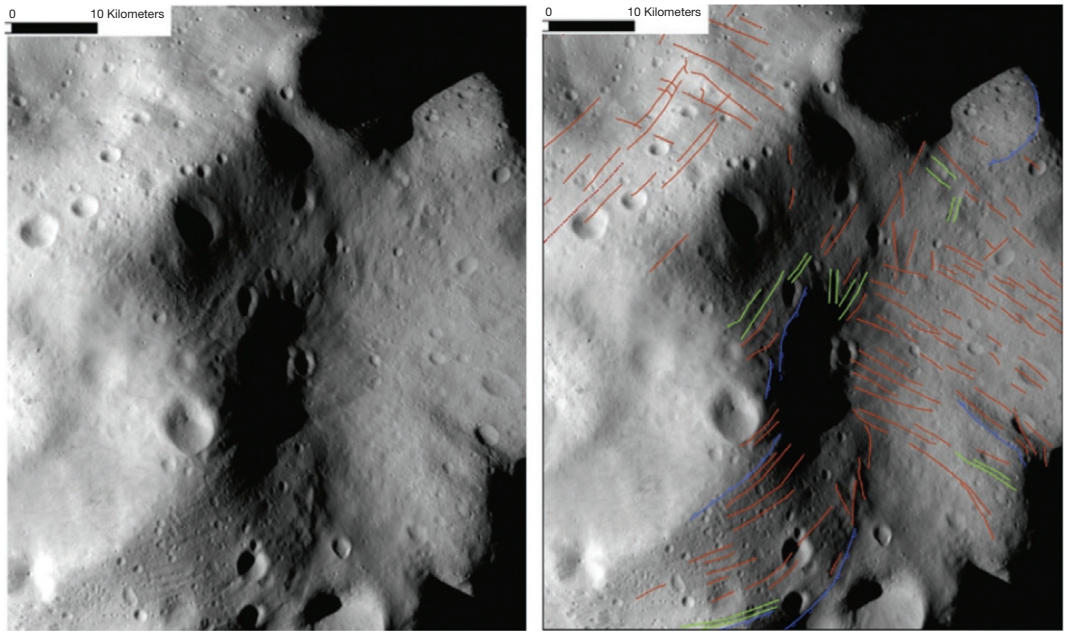

Figure 12 Lineaments on the surface of asteroid Lutetia. Note the scale bar at top. Reprinted from Massironi M, Marchi S, Pajola M, et al. (2012) Geological map and stratigraphy of asteroid 21 Lutetia. *Planetary and Space Sciences* 66: 125–136, panels (a) and (b) of Figure 6, with permission from Elsevier, with the actual image from Rosetta on the left, and the lineaments marked with colored lines on the right.

The most interesting lineament systems exist on Eros, Lutetia, and Vesta. Buczkowski et al. (2008) mapped >2000 lineaments on Eros ranging up to tens of km in length (Figure 11). They found that, except for the lineaments that are radial or circumferential to ~10 craters and obviously associated with those impacts, the majority of lineaments belong to three sets: parallel to meridian, encircling one end of Eros, and toward the other end. While interpreting the first set as due to impacts on the long side of the body, they proposed that the second and third sets could be due to the stress environment in its parent body. Nevertheless, the large number of lineaments on Eros on a global scale is not consistent with a rubble pile internal structure.

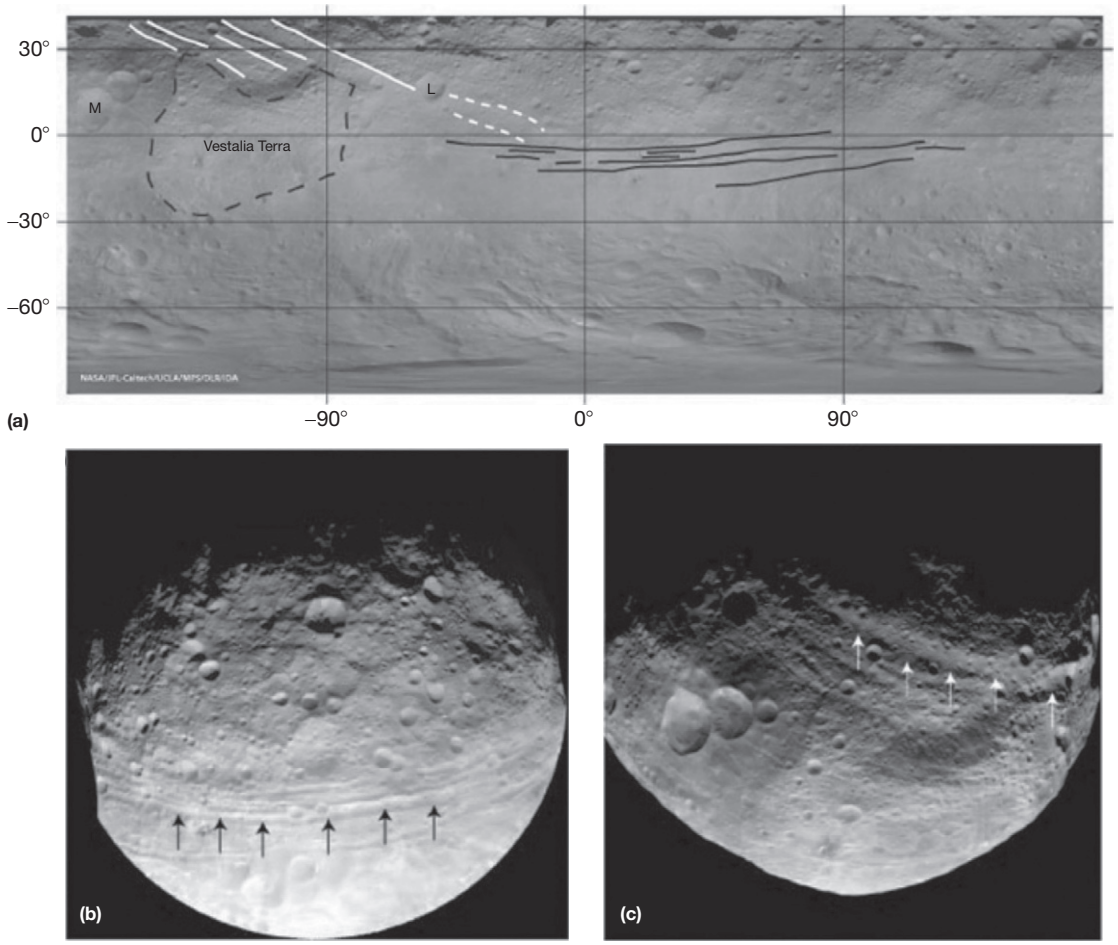

Figure 13 Lineaments on Vesta. The top panel is a cylindrical-projection map of Vesta; various systems of troughs are marked in black solid, white solid, and white dashed lines. The bottom left panel shows the equatorial troughs (the black solid lines in the top panel), while the bottom right panel shows the northern troughs (the while solid lines in the top panel). Both images are from the Dawn spacecraft. Reprinted from Buczkowski DL, Wyrick DY, Iyer KA, et al. (2012) Large-scale troughs on Vesta: A signature of planetary tectonics. *Geophysical Research Letters* 39: L18205, Figure 1, with permission from John Wiley and Sons.

Lutetia shows an extremely complicated system of lineaments on the full globe except for the geologically youngest region near the north pole (Thomas et al., 2012), and not as systematically distributed and organized as on Eros. An example of the lineament system is shown in **Figure 12**.

While the full analysis of lineament systems on Vesta is still ongoing, the most striking features are two sets of long linear structures near the equator and on the northern hemisphere that almost encircle the whole body (**Figure 13**) (Jaumann et al., 2012). Buczkowski et al. (2012) categorized these linear structures as grabens. These grabens appear to be coplanar with the respective poles coincident to the centers of two large basins near the south pole, Rheasilvia and Veneneia. They concluded that the properties of the grabens are consistent with impact-induced, global-scale deformation of a fully differentiated body, completely distinct from the responses of small, undifferentiated asteroids to impacts.

10.15.3.2.4 Smooth deposits

Both NEAs visited by spacecraft, Eros and Itokawa, display apparently smooth regions, termed 'ponds' on Eros (Abe et al., 2006; Barnouin-Jha et al., 2008; Cheng et al., 2001; Robinson et al., 2001). The smooth areas on both asteroids are located in gravitationally low areas, indicative of movements of regolith with centimeter- to millimeter-scale particles. Cheng et al. (2002) proposed that the ponded deposits on Eros are consistent with fluidlike motion of dry regolith, possibly induced by seismic agitation from impacts, the same process that is responsible for preferentially removing small craters on both of these objects (Michel et al., 2009; Richardson et al., 2004).

10.15.3.2.5 Regolith

Regolith (defined as loose, fragmental debris, regardless of origin) was not originally predicted before the Galileo encounter with Gaspra because of the low gravity (e.g., Housen et al., 1979a,b), although other early work, including that of Veverka et al. (1986), indicated that regolith would accumulate on small objects. The surfaces of asteroids are now known to possess a substantial amount of regolith derived from impacts, and this regolith demonstrates considerable mobility. The depth of regolith is generally inferred from crater morphology and ejecta, distribution of smooth deposits, the morphology of

geologic features such as boulders and lineaments, and spectrophotometric variations of the surface. In general, meters to hundred of meters thick regolith are inferred on asteroids, depending on the size of the objects (Barnouin-Jha et al., 2008; Besse et al., 2012; Carr et al., 1994; Chapman et al., 1996a,b; Prockter et al., 2002; Sullivan et al., 1996; Vincent et al., 2012a,b). The regolith on Vesta displays global variations from tens of meters to >1 km (Denevi et al., 2012; Jaumann et al., 2012) due to the complicated impact history.

Movement of regolith is evident from the localized smooth areas (as discussed in the previous section) and by mass wasting due to slope failure, as commonly seen on steep slopes of crater walls (e.g., Jaumann et al., 2012; Krohn et al., in press; Miyamoto et al., 2007; Thomas et al., 2012). The mobility and evolution of regolith are generally inferred from both geomorphological evidence and the optical maturity of regolith (i.e., from space weathering; see next section). For NEAs, the causes of mass movement are generally considered to be (a) seismic shaking induced by impact, (b) YORP spin-up, and (c) tidal disturbance from close encounters with planets. In binary asteroids, tidal effects of one body on the other can similarly move regolith around.

10.15.3.3 Space Weathering

Our knowledge about the mineralogy of asteroids is dominated by remote sensing observations of the spectral reflectance properties of asteroidal surfaces, supplemented by laboratory experiments of meteorite samples. It has long been recognized that the optical properties of silicate rocks are subject to change due to exposure in the space environment, caused by solar wind irradiation and micrometeoroid sputtering (Hapke, 1973). For the case of the Moon, the exposure causes the surface to darken, the spectral slope to redden, and the mineral absorption bands to weaken. Such optical phenomena and the associated processes are broadly termed 'space weathering.' The space weathering process on the Moon is well understood (see, e.g., Hapke, 2001; Pieters et al., 2000, for comprehensive reviews). Laboratory measurements and experiments of lunar samples showed clear evidence that vaporization of silicate minerals and redeposition of nanophase iron ($npFe^0$) coat the surface of regolith particles (cf. Hapke, 2001). Because the sizes of metallic Fe particles are smaller than visible wavelengths, they strongly absorb incident light, and their absorption coefficient decreases as the wavelength increases, resulting in darkening and reddening of the regolith particles, and masking out mineral absorption bands (cf. Hapke, 2001). However, this process cannot be easily extended to asteroids in general (Gaffey, 2010). Chapman (2004) presented an excellent historical review on this topic. Our understanding of space weathering on asteroids has been severely limited by both the lack of direct samples and the limited high spatial resolution spectroscopic data. Because mineralogical identification on asteroids almost entirely relies on the spectral reflectance properties of asteroidal surfaces, understanding the space weathering processes is an important aspect of asteroid science. As we shall see in this section, the surfaces of asteroids display different manifestations of space weathering from that on the Moon. For the convenience of our discussion, we refer to the space weathering process on the Moon and its associated optical effects as 'lunar-type.'

Space weathering on asteroids was first proposed to explain the spectral difference between the most abundant samples in our meteorite collections, the OCs, and the most abundant type of main-belt asteroids, S types (cf. **Section 10.15.1.5**). Presumably, the S types were the sources of OCs, yet the spectral differences remained problematic. Under the assumption that no mechanical or mixing process should change the mafic band centers and their relative strength, Gaffey et al. (1993) studied the mineralogy of S-type asteroids and found that the spectra of a particular subclass (known as 'S(IV)') imply mineralogy similar to the known OCs, therefore providing a generic link between S types and OCs. However, the S-type asteroids show much weaker absorption bands and much redder spectral slopes than do OCs. On the other hand, in the NEA population, a small class of asteroids, labeled the Q types, with sizes of a few km, show similar spectral characteristics to those of OCs (Binzel et al., 2002; McFadden et al., 1984). This relationship is a good reality check because the OC meteorites were NEAs before falling to Earth, so one would expect that there would be a closer spectral match. Binzel et al. (1996, 2002) showed that nonprimitive NEAs show a continuous spread in their spectra from OC-like to S-like, implying a process that is continuously operating on the surfaces of one class and changing their optical properties to the other. Both observational (Binzel et al., 2010) and dynamic (Nesvorný et al., 2010) evidence suggested that tidal encounters to within ~5 planet radii of Earth and Venus could reset the weathered surfaces on small S-type asteroids, by exposing a relatively fresh unweathered surface and changing them to Q types.

To put it another way, S-type main-belt asteroids have highly weathered surfaces because they have been exposed to the space environment for ostensibly tens of millions to billions of years. Q-type surfaces, that is, those with little or no weathering, on the other hand would appear in the NEA population because NEAs are collisional fragments and relatively recent escapees from the asteroid belt; thus, their surfaces have only been exposed for millions of years or perhaps much less.

Recent observations of small S-type asteroids in the main belt that are of comparable size with NEAs also show spectral variation, which is logical because these objects have fresher surfaces and may be on their way to becoming NEAs. Some of these small objects have spectra that match the OCs (Mothé-Diniz et al., 2010). Further studies of the colors of many S-type dynamic families in the main belt have shown that their red spectral slopes are clearly correlated with dynamic ages since breaking up, consistent with continuous weathering process on S-type asteroids (Nesvorný et al., 2005).

Recent asteroid missions have both confirmed the existence of space weathering on asteroids and raised more questions. The Galileo spacecraft flybys of two S-type main-belt asteroids Gaspra and Ida showed that the surfaces of Gaspra and Ida both have large variations in colors and at least a factor of two variation in the strength of mafic bands. While the overall spectra of Gaspra and Ida are typical of S-type asteroids, small, fresh craters and ejecta appear to be bluer, and the ridges with steep slopes tend to be bluer than other areas (Belton et al., 1992, 1994; Geissler et al., 1996; Sullivan et al., 1996).

Close examination of the spectral trend on Ida revealed that the geomorphologically freshest units have spectral intermediate between OCs and the S-type asteroids (Chapman, 1996). However, because the albedo variation on Ida is small, the space weathering process does not seem to have darkened the surface of Ida as much as it has of the Moon.

The clearest evidence of space weathering on Eros was identified in the large crater named Psyche, where brighter materials are exposed on the wall and darker materials are deposited at the bottom (Clark et al., 2001). The albedo variation from wall to bottom is a factor of several. The color of the bright crater wall is slightly bluer than that of the dark crater floor, consistent with, but much subtler than, lunar-type space weathering (Izenberg et al., 2003; Murchie et al., 2002). Therefore, the wall of Psyche crater was recently exposed due to mass wasting of the original regolith on the slope and is much less space-weathered than the crater floor. However, there are a number of inconsistencies in terms of space weathering on Eros. First, the color and spectral variations on Eros are remarkably uniform to within 2% (Izenberg et al., 2003; McFadden et al., 2001). The lack of color contrast between the supposedly fresh crater wall and the weathered crater floor certainly suggests different weathering processes on Eros than on Gaspra, Ida, and the Moon; this is represented schematically in **Figure 14** (Gaffey, 2010). Second, the downslope movement of Psyche crater wall material had to be driven by, for example, other impacts after the formation of the slope. However, Psyche crater appears to be the youngest on Eros; none of the small craters on Eros appear fresh, that is, brighter and bluer than average surface. Cheng et al. (2002) considered that the shaking of Eros, probably induced by tidal forces during close approach with terrestrial planets, could induce mass wasting on slopes and the formation of ponds. In addition, ejecta blocks on Eros, mostly excavated by the impact that formed Shoemaker crater, show similar albedo and spectra to other areas on Eros, a relation that also indicates relatively mature surfaces.

The Hayabusa mission to Itokawa provided evidence of space weathering on this small (550 m) NEA from both spectroscopic observations and the first samples directly returned from known sites on an S-type asteroid. Hiroi et al. (2006) showed that a dark region on Itokawa has a spectrum clearly consistent with significant space weathering with accumulated $npFe^0$ (nanophase metallic iron) with about 0.03–0.07 vol.%. Ishiguro et al. (2007) analyzed the spectral data of the whole surface of the asteroid to map the space weathering maturity on Itokawa and found that fresh materials are generally observed in regions of steep slopes and craters, whereas mature materials are ubiquitously distributed. Laboratory measurements of the Itokawa samples showed surface modifications on the rims of some particles, with sulfur-bearing Fe-rich nanoparticles, interpreted as a consequence of alteration by vapor deposition (Noguchi et al., 2011, 2014).

The presence of $npFe^0$ is one consequence of space weathering that appears to be the same on both the Moon and asteroids. In addition to the evidence of $npFe^0$ found in Itokawa regolith samples (Noguchi et al., 2011, 2014), nanosize metallic particles are also found in some OC meteorites (Longobardo et al., 2011; Moretti et al., 2005, 2006) and in the howardite (i.e., likely Vesta fragment) Kapoeta meteorite (Noble et al., 2010). Furthermore, extensive laboratory experiments of space weathering have been conducted to simulate the effects of micrometeoroid impacts through laser impulses and solar wind bombardment through plasma irradiation (e.g., Brunetto and Strazzulla, 2005; Brunetto et al., 2006; 2007; Dukes et al., 1999; Hapke, 1973, 2001; Loeffler et al., 2008, 2009; Marchi et al., 2005; Noble et al., 2007; Strazzulla et al., 2005; Yamada et al., 1999). The most significant result from these experiments has been the reproduction of the lunar space weathering effects by generating $npFe^0$ coating on mineral grains (Keller and McKay, 1993). The timescale of space weathering due to micrometeoroid impacts has been estimated to be of order 10^8 years (Sasaki et al., 2001).

For non-S-type asteroids, such as the more primitive objects in the C-complex, the effect of space weathering is not obvious. This lack of spectral detection might be because the dark, opaque, carbonaceous materials (which are thought to be the dominant composition of low-albedo asteroids like those in the C-complex) may obscure the effects of space weathering. Or alternatively, a low abundance of Fe might suppress the formation of $npFe^0$ and slow down the process of lunar-type space weathering.

Finally, we point out the puzzling case of Vesta, which resides on the opposite end of the traditional space weathering problem, that is, Vesta shows a lack of weathering, even though it is expected. McCord et al. (1970) found an exact match between the spectrum of Vesta and the spectra of the most abundant achondrite meteorite samples, the howardite–eucrite–diogenite (HED), leading to the conclusion that Vesta is the source of HEDs. Compelling evidence from almost every aspect confirms the HED–Vesta connection. Early evidence includes the identification of small (few km) spectrally similar

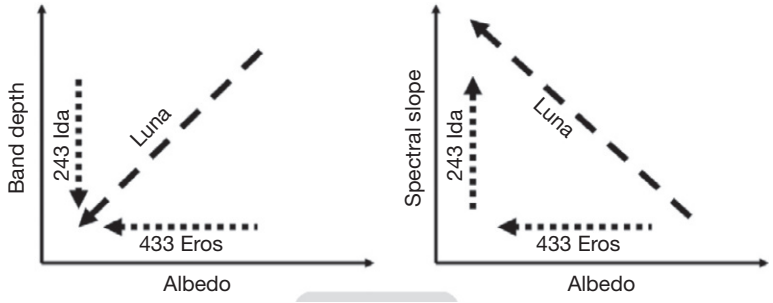

Figure 14 Comparison of space weathering across asteroids and the Moon. There are many manifestations of 'space weathering,' and the trends of albedo versus depth of an absorption band versus spectral slope can be different depending on the properties of the surface under study. Reprinted from Gaffey MJ (2010) Space weathering and the interpretation of asteroid reflectance spectra. *Icarus* 209: 564–574, Figure 4, with permission from Elsevier.

asteroids (now known as taxonomic type V) that provide a dynamic pathway to transport meteorites from the asteroid belt to Earth (Binzel and Xu, 1993) and the existence of a large basin near Vesta's south pole (Thomas et al., 1997a,b). Recent observations by the Dawn mission confirmed the mineralogical connection between Vesta, HEDs, and V-type asteroids (Ammannito et al., 2013; De Sanctis et al., 2012, 2013) and confirmed a highly impacted surface with two large, overlapping basins near the south pole, with the youngest one perhaps just ~1 Gy old (Marchi et al., 2012b; Schenk et al., 2012). However, laboratory studies suggest that ion irradiation on HEDs darkens and reddens the samples rapidly, corresponding to a space weathering timescale of 10^5–10^6 years (Fulvio et al., 2012). The lack of space weathering on Vesta itself is thus a mystery (see summary by Pieters et al., 2006). To explain it, Vernazza et al. (2006) postulated that Vesta has a magnetic field that can shield it from solar wind irradiation. The discovery of magnetism in the Millbillillie eucrite (Fu and Weiss, 2011) seems to support this idea. But magnetic shielding does not completely protect the whole surface of Vesta from weathering, and Dawn should have identified local weathered areas with high-resolution imaging and spectroscopy. Alternatively, the whole surface of Vesta could have been recently resurfaced by a major impact. However, the age of the largest impact basin on Vesta is much older than the timescale generally accepted for space weathering, as mentioned in the preceding text. On the other hand, the comparisons of red slopes among V-type asteroids and HEDs support the existence of space weathering on V-type asteroids, although the reddening trend with solar wind exposure age is difficult to interpret (Marchi et al., 2010b). Pending the solution of whether the traditional view of space weathering on the Moon and S-type asteroids occurs on Vesta, Pieters et al. (2012) proposed an alternative view of the space weathering based on Dawn observations, in which a physical process on the surface such as regolith mixing, rather than chemical alteration, dominates the space weathering. Still, the most significant question for Vesta is that we do not know how to fit the lack of traditional space weathering into the whole paradigm of such processes on the Moon, Eros, and Ida.

10.15.3.4 Surface Morphology on Cometary Nuclei

The encounters with comet 1P/Halley by ESA's Giotto spacecraft (Reinhard, 1986) and the Soviet Union's Vega spacecraft (Sagdeev et al., 1986) marked the first close-up imaging of solar system small bodies. During the close encounter, the Halley Multicolor Camera (HMC) on board the Giotto spacecraft centered on the brightest part of the inner coma, showing the silhouette of a large, solid, and irregularly shaped nucleus and jet-like dust activity that was much brighter than the nucleus (Keller et al., 1986). Due to the bright jets in the foreground of the nucleus, it was difficult to see the surface morphology of this cometary nucleus from these images. Nevertheless, the solid nature of cometary nuclei as icy conglomerates as proposed by Whipple (1950) was directly proved correct. And for the first time, the albedo of a cometary nucleus was directly measured to be ~4%.

Since the P/Halley flybys, there have been five additional cometary missions returning disk-resolved images of four more cometary nuclei (**Table 1**). A montage (not to scale) of the comets is shown in **Figure 15**. The imaging data from those cometary missions have formed the foundation of our current understanding of the surface morphology of cometary nuclei. While the comets have a variety of overall morphologies, there are many common features, including pits and pitted terrains, smooth areas, icy patches, and numerous small, bright, or dark spots.

Comets have numerous (nearly) circular depressions with or without raised rims on their surfaces, generally termed 'pits' due to their completely different morphology from impact craters on asteroidal surfaces. Pits are observed on all four cometary nuclei with various sizes and morphologies (**Figure 15**; Britt et al., 2004; Brownlee et al., 2004; Thomas et al., 2007, 2013a,b). The associated pitted terrains usually occupy a large fraction of a comet's surface, except in some regions where there are smooth terrains. The cumulative size distributions of pits on comets 9P/Tempel 1 and 81P/Wild 2 have slopes between −1.7 and −2.1 (Thomas et al., 2013a), significantly different from the size distribution of typical impact craters on the Moon or asteroids (between −2 and −4). Therefore, pits on comets either do not all originate from impacts or have been modified after formation. The pits on comet P/Tempel 1 are up to a few hundred meters in diameter and up to 25 m in depth, mostly without flat floors. Those on P/Wild 2 have larger sizes up to ~1.5 km, mostly with flat floors and some with central peaks. The most distinctive feature on comet P/Wild 2 is the nearly vertical walls of the pits, sometimes with overhangs. While some pits with raised rims on some comets could have impact origins (such as the two circular depressions bracketing the Deep Impact (DI) mission impact site on comet P/Tempel 1), most of them are probably cryovolcanic collapse features associated with cometary activity (Belton and Melosh, 2009; Belton et al., 2008). Belton et al. (2013) ascribed >90% of the pits to cometary outburst activity.

The apparently smooth areas on comets P/Tempel 1 (Thomas et al., 2007, 2013a) and 103P/Hartley 2 (Thomas et al., 2013b) are probably one of the most intriguing features observed; such areas are visible in **Figure 15**. These terrains have smooth texture up to 30 m scale but most likely also at a 5 m scale, with slightly lower reflectance than the surrounding terrains, and they are usually laterally confined. They occupy topographic lows with slopes up to a few degrees, suggestive of flows. The 'mesas' on comet 19P/Borrelly as termed by Britt et al. (2004) appear to be similar to the smooth areas on comets P/Tempel 1 and P/Hartley 2. Belton and Melosh (2009) proposed a fluidized multiphase transportation of dust resulting from the sublimation of material with higher volatility than water, such as CO or CO_2, from beneath the surface as the origin of the smooth areas on comet P/Tempel 1. No such smooth area was observed on comet P/Wild 2. Belton (2010) used the smooth areas to hypothesize an evolutionary sequence of the four comets, where the surface of comet P/Wild 2 represents the early stage in the sequence and has not developed smooth areas that are large enough to be visible, while the surface of comet P/Hartley 2 represents the latest stage with the largest fraction of surface covered by smooth areas.

From the Deep Impact flyby spacecraft images of comet P/Tempel 1, Sunshine et al. (2006) for the first time unambiguously discovered water ice deposits on the surface of a cometary

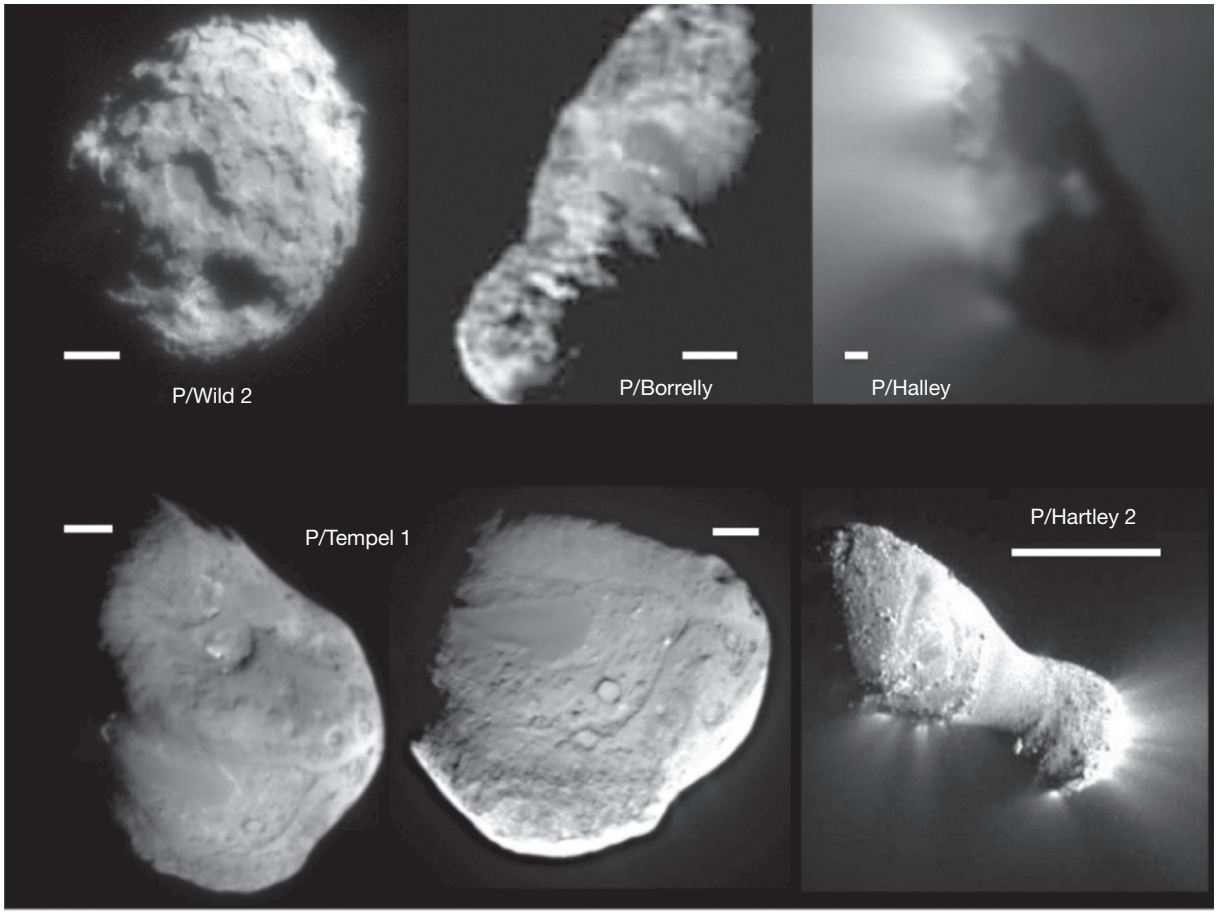

Figure 15 Montage of the five comets that have had spacecraft encounters (with imaging). P/Tempel 1 has been visited twice. P/Halley was visited four times (see **Table 1**) but for clarity we only show a Giotto picture. White horizontal bar in each panel represents 1 km. Note the variety of surface morphologies. Image sources: P/Wild 2 is courtesy NASA/JPL-Caltech (Photojournal image PIA05571); P/Borrelly is courtesy NASA/JPL (Photojournal image PIA03500); P/Tempel 1 (left image) is courtesy NASA/JPL/UMD (Photojournal PIA02142); P/Tempel 1 (right image) is courtesy NASA/JPL-Caltech/Cornell (Photojournal image PIA13860); P/Hartley 2 is courtesy NASA/JPL-Caltech/UMD (Photojournal image PIA13570); P/Halley is from the Giotto archive of data in the NASA Planetary Data System (Keller et al., 1992).

nucleus. Similar water ice concentration was again observed on comet P/Hartley 2 (Sunshine et al., 2011). The icy patches cover less than 1% of the total surface areas of comets and only contain about 3–6% water ice, with typical particle sizes of ~30 μm, much larger than those in ejecta observed by Deep Impact (~1 μm) (Sunshine et al., 2007) and in comet P/Hartley 2's coma (Protopapa et al., 2014). Temperature measurements and thermal modeling suggest that the water ice deposits are thermally decoupled from the refractory dust on the surface (Groussin et al., 2007, 2013). The locations of the identified ice deposits on comets P/Tempel 1 and P/Hartley 2 are both near the morning terminators, suggesting that they are probably condensation of water vapor in diurnal cycles as opposed to ice exposed from the interior (which would have much smaller particle sizes, too; Sunshine et al., 2007). It is quite possible that the reason for water ice being definitively discovered on only two cometary nuclei is that only the Deep Impact spacecraft, among those having visited comets, is equipped with a spectrometer capable of detecting water ice. Therefore, it is reasonable to speculate that water ice patches are likely common on cometary nuclei.

In addition to the large-scale features discussed earlier, there are numerous bright and dark spots on all well-imaged cometary nuclei (**Figure 16**). Some of them appear to be albedo features, such as some bright spots on comets P/Wild 2 and P/Tempel 1. The spots could be water ice concentrated in areas due to topography, but it is not possible to determine their origins conclusively because of the limited resolution or the unavailability of spectroscopic data. On the other hand, some dark spots could be either small-scale albedo features or small, deep pits or holes (Nelson et al., 2004).

Cometary surfaces are under constant change due to outgassing activity. The second flyby of comet P/Tempel 1 by the NExT mission in 2011 just one perihelion passage after the Deep Impact flyby in 2005 showed clear change in surface morphology (**Figure 17**; Thomas et al., 2013a), although no obvious change in photometry was identified (Li et al., 2013). The most significant change observed was the retreat of the scarp bounding the smooth area near the south pole by at least 50 m. In addition, at least two crudely triangular areas evident in 2005 disappeared by 2011, representing a backwasting along at least 1000 m of the boundary. It is estimated that

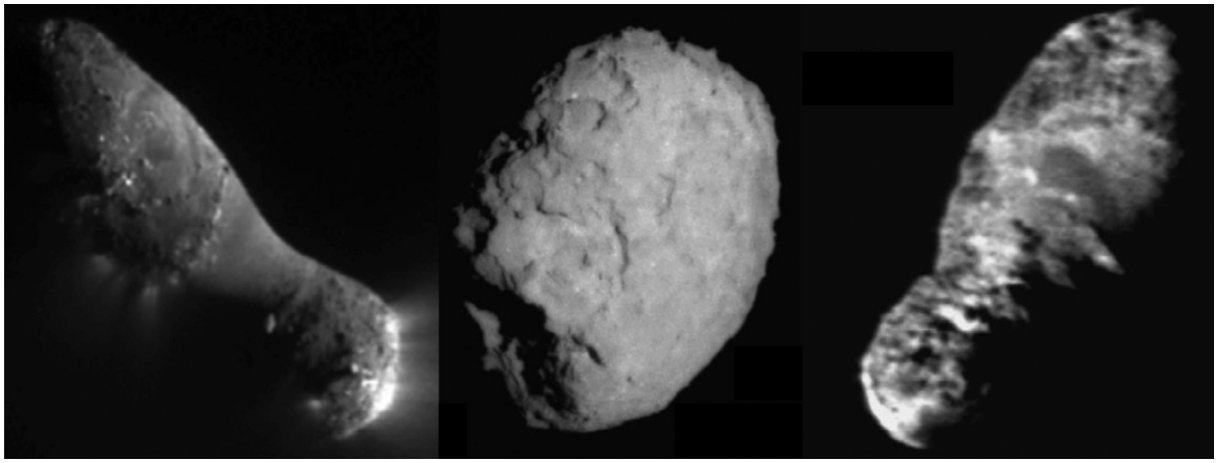

Figure 16 Examples of the bright and dark spots seen on cometary surfaces. Images are of P/Hartley 2, P/Wild 2, and P/Borrelly, from left to right. The P/Hartley 2 and P/Borrelly images are the same as those seen in **Figure 15**, but with better contrast to enhance the features. P/Wild 2 image is from the Stardust archive of data in the NASA Planetary Data System (Newburn and Farnham, 2008). Some of the bright spots could be footpoints to jets. The dark spots could be low-albedo features or actual pits.

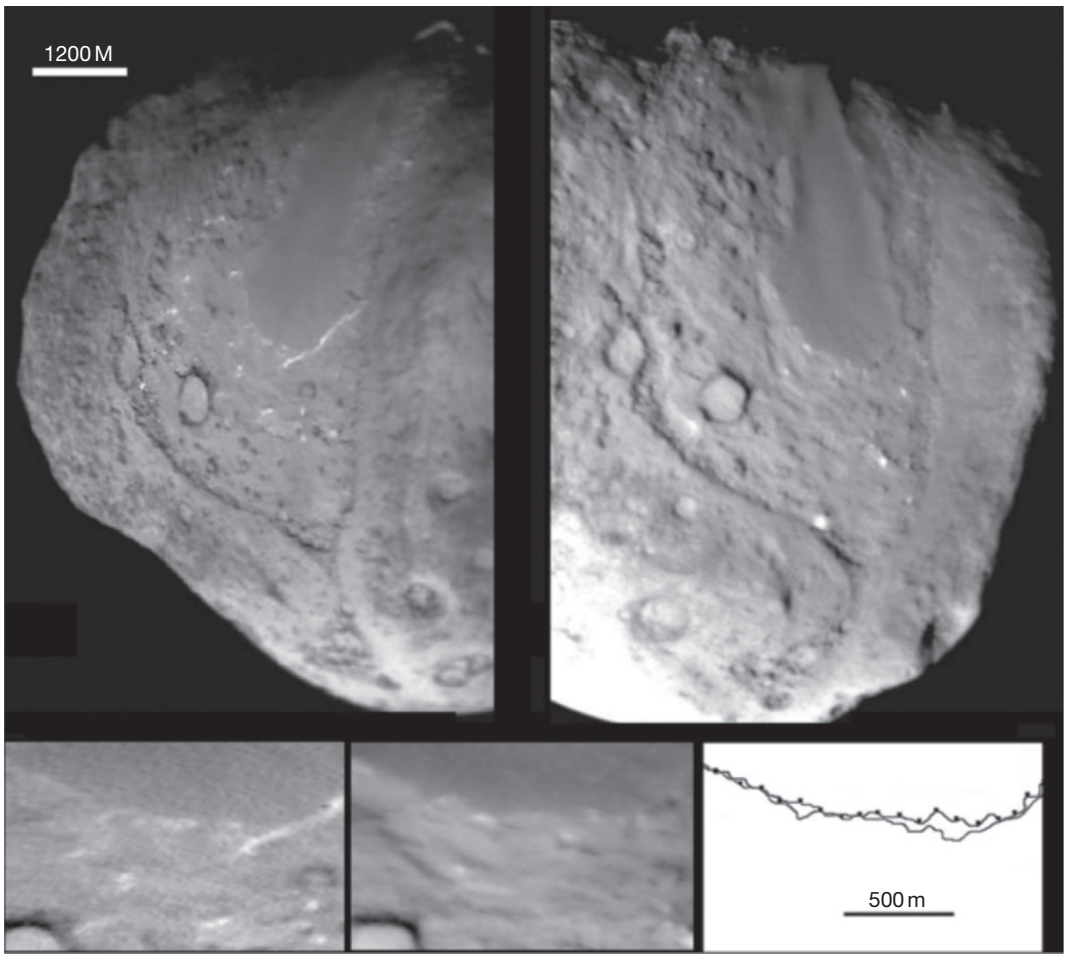

Figure 17 Changes in the surface of comet P/Tempel 1 from one orbit to the next. The left image is from the Deep Impact flyby in 2005, and the right image is from the Stardust flyby in 2011. Various bright and dark spots have appeared and/or disappeared in the intervening 6 years. The edge of the scarp has clearly changed, losing up to 50 m of extent in some locations. This change is shown in the bottom three panels, with the right panel showing the traces of the scarp. Reprinted from Thomas P, A'Hearn M, Belton MJS, et al. (2013) The nucleus of Comet 9P/Tempel 1: Shape and geology from two flybys. *Icarus* 222: 453–466, Figure 9, with permission from Elsevier.

the total volume loss was about $2–4 \times 10^5$ m^3, corresponding to $8–16 \times 10^7$ kg, assuming an average density of 0.47 kg/ m^{-3} (Richardson et al., 2007). It has also been noted that there is concentrated jet activity originating near the scarps (Farnham et al., 2013). In addition to the boundary of the smooth features, several small bright albedo spots (<30 m) in the region have changed in contrast and extent. However, due to their small sizes, the changing viewing geometry, and the different imaging instruments, it remains uncertain whether these are real changes or are due to the effect of different illumination and viewing geometries or instrument effects. Interestingly, no obvious ejecta blanket produced by the DI impact could be identified on the surface of comet P/Tempel 1 (Schultz et al., 2013).

The high-resolution images of comets P/Borrelly, P/Wild 2, and P/Tempel 1 reveal another common feature, that is, ubiquitous surface layering that possibly extends into the interior. Based on these layers, Belton et al. (2007) hypothesized a 'talps' model or 'layered pile' model to describe the internal structure of JFCs. In this model, the nucleus interiors are composed of layers of different thicknesses, sizes, and possibly compositions that were accumulated during the primordial accretion phase of comets through low-speed collisions between cometesimals. This hypothesis presents a completely different internal structure from the classic rubble pile model for asteroids (cf. Richardson, 2002, and references therein). While the evolution of asteroids mostly occurred in the inner solar system and was dominated by intensive collisions after their formation, leading to their rubble pile nature, the evolution of comets probably took a completely different path. JFCs we see today were frozen for ~4 Gy in the Kuiper Belt, that is, where they are thought to have formed, before being gravitationally perturbed into the inner solar system (e.g., Duncan and Levison, 1997; Duncan et al., 2004; Morbidelli and Brown, 2004). Comets in JFC orbits are active for only 7% of the orbit (Duncan et al., 2004). Therefore, the evolution of JFCs is first dominated by the collisional environment in the Kuiper Belt and then on their surfaces by volatile sublimation during repeated perihelion passages. If talps are primordial in JFCs, then their preservation seems to indicate a much more benign collisional history than the asteroids have undergone. Future cometary missions, especially the CONSERT experiment on ESA's Rosetta mission that will use ground-penetrating radar to study the internal structure of comet 67P/Churyumov–Gerasimenko (Schulz, 2009), should provide definitive tests on the talps model.

10.15.4 Structure, Interior, and Spin

10.15.4.1 Structure of Asteroids

From the discovery of the largest asteroid, (1) Ceres, in 1801 by Piazzi (Foderà Serio et al., 2002) until the 1990s, asteroids were largely unresolved point sources. Reflected light can reveal surface composition and perhaps some level of structure through the thermal properties, but the interiors of asteroids were largely inaccessible to study. As described in the previous section, spacecraft missions can reveal exquisite detail of a body's surface structure and in some cases interior by means of gravity measurements. However, the number of missions will by necessity be limited, so studies of the population must rely largely on ground-based remote sensing.

Ground-based radar does reveal the shapes and surface details of NEAs at few-meter resolution and has led to some surprising discoveries about their structure. Ostro (1989) summarized the early efforts to study the shapes and outer contours of NEAs. The two planetary radar facilities, Arecibo Observatory and Goldstone Deep Space Network, are complementary in their capabilities and ability to study solid solar system bodies, primarily NEAs (Ostro et al., 2002 and references therein). Starting in 1998, the increased sensitivity of the Arecibo planetary radar system, along with the huge increase in the discovery rate of NEAs, has begun to reveal their detailed shapes. Some were the expected collisional fragments, with irregular facets, craters, and ridges. However, some were surprisingly spheroidal, even at sizes of only a few hundred meters. The self-gravity of such small bodies is not nearly enough to overcome the strength of the rock, so these must be strengthless rubble piles. However, other objects in the same size range were seen to be elongated, or rapidly rotating, which required a coherent rock. The diversity of NEAs is remarkable and indicates a variety of formation mechanisms (Nolan et al., 2005; Ostro et al., 2002).

Radar imaging is accomplished by sending a monochromatic signal to the asteroid and receiving the signal, which reflects from the solid surface. Because the precise timing and characteristics of the transmitted signal sent are known, the return signal reveals much about the body, depending only upon knowing the time and speed of light. We can use the time sampling and rotational velocity information to reconstruct an image of the asteroid, with some projection effects, and ambiguity in that several points on the asteroid surface may have identical distance and apparent velocity and thus map to the same location in the radar image (see Magri et al., 2007; Ostro, 1993, for more details).

The resolution of a radar image depends on the signal-to-noise ratio (SNR) of the signal reflected from the asteroid. The power of the transmitter, size of the telescope, and gain contribute to the SNR, but the dominant factor is usually distance from Earth. The SNR depends on the inverse fourth power of the distance, so NEAs dominate the sample of high-resolution images. About 300 objects have been imaged as of 2014, with about 50 of those at the highest resolution available at Arecibo, 7.5 m per pixel. Before 2011, the highest resolution at Goldstone was 19 m per pixel, but currently, for very close approaches to Earth, images from GSSR can reach 3.75 m per pixel as in asteroid 2005 YU_{55}. Examples of some radar images are shown in **Figure 18**. As described earlier, NEAs are collisional fragments of larger objects that are then perturbed into planet-crossing orbits (e.g., Bottke et al., 2002a). While some NEAs do indeed look like irregular collisional shards, many others do not. About 25% of the NEAs between 200 and 800 m are spheroidal, and another 10–15% are two spheroidal lobes joined together. Elongated objects, with axial ratios of 2:1 or more, comprise about 10% of the sample, while binary systems are another 15% of NEAs less than 10 km in diameter (Taylor et al., 2012). An asteroid less than 10 km can only be spherical from its own gravity if it is strengthless, although surface features such as craters and ridges can be supported by friction in the surface material. Surface features seen in radar images must

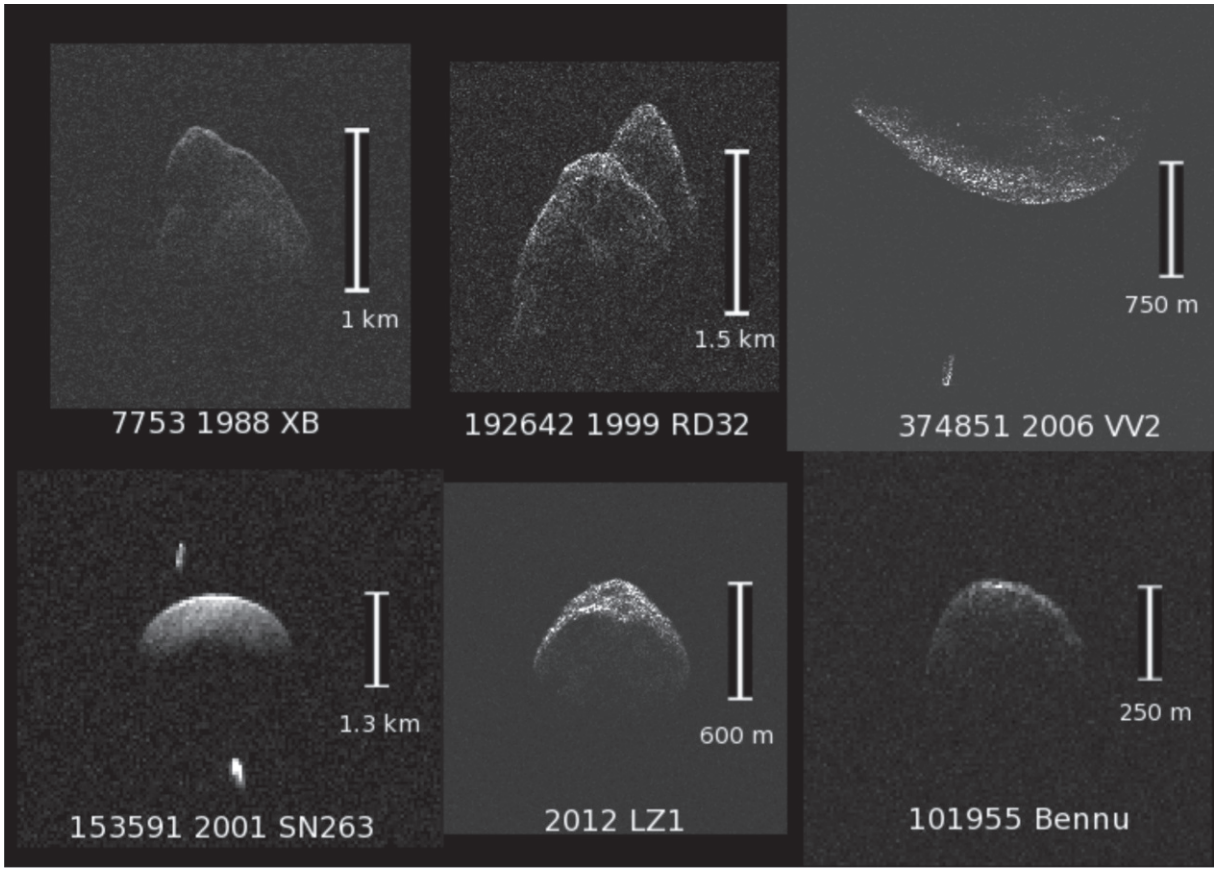

Figure 18 Arecibo radar images of a variety of asteroids can reveal surface features as small as 7.5 m. Scale bars show the approximate size in the vertical direction. In each of these images, the distance from Earth increases from top to bottom (except for 2006 VV2, where it is the opposite), and Doppler frequency or object rotation velocity in the line of sight increases from left to right. These are not spatial images, but for a rigid body, they map into a spatial image, and surface features can be interpreted readily with some projection effects.

be interpreted with caution, because the image is not a spatial image, but it does map into a spatial image. A radar image is really distance from the observer in one dimension, and rotational velocity in the other dimension, or distance from the rotation axis. By convention, radar images always appear as if the object is viewed from the north pole, illuminated from 90° phase angle. From a single image, the location of a feature on the surface cannot be determined uniquely. However, a series of images over several days can be used to derive a shape model (e.g., Magri et al., 2011; Nolan et al., 2012; Ostro et al., 2005). More limited datasets can be used to identify surface textures and features that often reveal internal structure.

The sample of objects shown in **Figure 18** includes some notable objects. Asteroid (153951) 2001 SN_{263} is the first triple asteroid system discovered among the NEAs, where the outer satellite is larger (below the primary in this image) orbiting in about 6.2 days and the smaller inner one (above the primary) orbits in about 16.5 h. The OSIRIS-REx mission will visit asteroid (101955) Bennu (formerly 1999 RQ_{36}), a 550 m spheroidal asteroid, which although rotating relatively quickly (4.2 h) does not appear to have a satellite larger than 10 m at the present time. Both (374851) 2006 VV_2 and Bennu have one or more boulders on the surface larger than 10 m, perhaps similar to those seen on Itokawa and Eros. The population of NEAs is varied in size and shape, composition, and rotation, suggesting a variety of possible outcomes for the same formation conditions.

10.15.4.2 Spin of Asteroids

The rotation rate of an object can put constraints on its internal structure. Optical light-curve observations of asteroids and comets have been carried out by both amateur and professional astronomers for many decades and provide an extensive database with which to study the population of asteroids. The most reliable data from the asteroid light-curve database compiled by Warner et al. (2009) – and which is frequently updated at http://www.minorplanet.info – are plotted in **Figure 19** for main-belt asteroids, with H magnitude on the x-axis and rotation frequency (rotations per day) on the y-axis. The H magnitude is the brightness of an asteroid at 1 AU from both Earth and Sun, and at zero phase angle, so is a proxy for the asteroid diameter. The plot shows that for about $H < 20$, a rotation frequency of 10, or about 2.4 h rotation period, is a limiting value for all asteroids. This corresponds roughly to the fastest rate at which a strengthless rubble pile structure can spin without flying apart (e.g., Pravec and Harris, 2000). Smaller asteroids ($H > 20$) can break this spin barrier and can rotate as

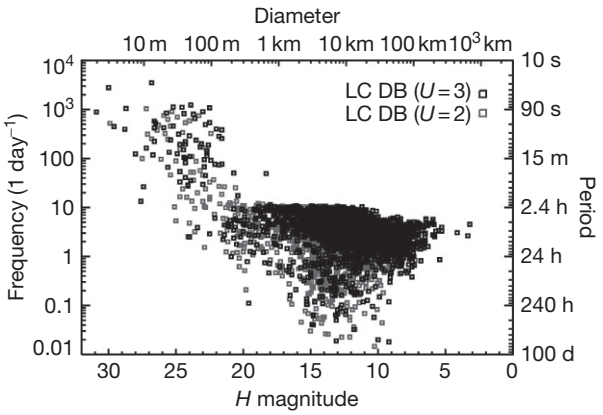

Figure 19 Distribution of the rotation rates of asteroids. Rotation rates are given as frequencies (left axis) and periods (right axis). The rates are shown as a function of diameter (top axis), which is estimated from the absolute magnitude (*H*; bottom axis) using an assumed geometric albedo of 0.20 (cf. **Figure 5**). Plotted here are the higher-quality observations ('*U*' parameter of 2 or 3) taken from the asteroid light-curve database (Warner et al., 2009), based on many nights of observation for each asteroid to determine the rotation rate from changes in the brightness of the object as it rotates. Note the sharp cut in the distribution at a rotation period near 2.4 h. This rate seems to be a limit for asteroids larger than *H* magnitude of about 21, which has been interpreted as being the fastest that a strengthless, rubble pile body can spin without breaking apart. Figure is courtesy Patrick Taylor.

rapidly as 30 s. This certainly requires some tensile strength, although some internal fractures and porosity can still be present. The spin limit depends on the material density, so it is slightly slower for icy bodies. No asteroids appear to be both small and rotating slowly, although these are difficult to measure using ground-based optical telescopes. Radar measurements should see small objects rotating slowly if they exist, but the distribution from radar observations matches the light-curve distribution very closely, despite having very different observational biases.

10.15.4.3 Binaries

The discovery of the first binary NEA, (185851) 2000 DP_{107}, in 2000 (Margot et al., 2002) opened up a new window on studying interior structure of asteroids. Radar images allow the sizes of both components to be observed so the mass of the primary body can be derived from the orbit. Searches for binary asteroids had been inconclusive prior to this time, even leading to theoretical arguments as to why binaries did not exist and would not be stable (e.g., Gehrels et al., 1987). Light-curve measurements suggested binary systems existed for decades, but the possibility of two-lobed or contact binary objects could not be ruled out for most of the cases. Clear evidence of occultations and eclipses in asteroid light curves had not been confirmed prior to the discovery of 2000 DP_{107}. However, after the first radar detection of an NEA binary system, showing the clear separation of the components, the light-curve evidence was then considered much more convincing.

As of 2014, two-thirds of the approximately 50 known NEA binary systems have been discovered using radar, still the most powerful means of identifying binary systems. Light-curve detection continues to be an important contributor and is now showing binary systems are equally common in the main-belt population in the few kilometer-size range (Pravec et al., 2006). Yet another technique that works quite well for binary discovery in the main belt is direct imaging through the use of telescopes that have adaptive optics. Normally, the atmosphere distorts the wave fronts from an astronomical source that are collected by a telescope; turbulence in the atmosphere leads to the light coming through many cells of air that each have slightly different indices of refraction. When the telescope tries to bring all the light to a focus, the resulting image is blurry, usually far blurrier than would be expected from just considering the diffraction limit of the telescope's optics. For example, a 10 m telescope at a good astronomical site, without the aid of adaptive optics, might normally achieve images with ~0.5 arcsecond resolution, whereas the diffraction limit (Rayleigh criterion) at visible wavelengths for such a telescope is about 0.01 arcsecond. 'Adaptive optics' is the term for the technological feat of having a deformable mirror in the optical path (after the secondary mirror) that deblurs the light by changing the light's reflection just enough to cancel out the effects of the turbulent cells of air. The mirror is deformed and re-deformed many times per second. An example of the incredibly good resolution that can be achieved through adaptive optics is shown in **Figure 20**, where one can clearly see a triple asteroid system, (216) Kleopatra (Descamps et al., 2011).

Following the discovery of binary 2000 DP_{107}, several formation theories were put forth. Tidal effects due to planetary encounters, collisional debris, disruption by collisions and reformation as a binary, and rotational fission all seemed viable possibilities (Merline et al., 2002). However, after several more binary systems were observed, and their common features compared, it was clear that some of these formation theories could be ruled out. All NEA binary systems have a fast rotating primary body, usually close to 2.5 h, near the theoretical spin barrier for a rubble pile structure (see **Figure 19**). The angular momentum of the system was well above the stability threshold, suggesting that spin-up and fission had occurred. The size of the secondary is remarkably consistent, between one-third and one-fifth of the primary diameter, and the orbit falls within 3–5 primary radii away. Many of the satellites are in synchronous rotation, and most are in very circular orbits, suggesting substantial tidal evolution. However, a few systems are not in synchronous rotation, and some satellites have orbital eccentricities of up to 0.15; one system, (153958) 2002 AM_{31}, has eccentricity near 0.45 (Taylor et al., 2013).

Ostro et al. (2006) and Scheeres et al. (2006) discussed the shape and orbital dynamics of the binary asteroid, (66391) 1999 KW_4, in exquisite detail from radar observations. The elongated shape of the satellite demonstrated libration, and material shifting on the surface due to the extremely low gravity explains the smooth central band of the primary. Many other asteroids have now been shown to have this same basic shape, not all of them binary systems, which suggests either that a satellite may have formed and was subsequently lost or that this shape can be the result of spin-up alone and does not require the presence of a satellite to form initially. Future spacecraft missions to such objects may help answer this question.

The diversity of binaries among asteroid taxonomic types suggests that mechanical structure, and not composition, is the

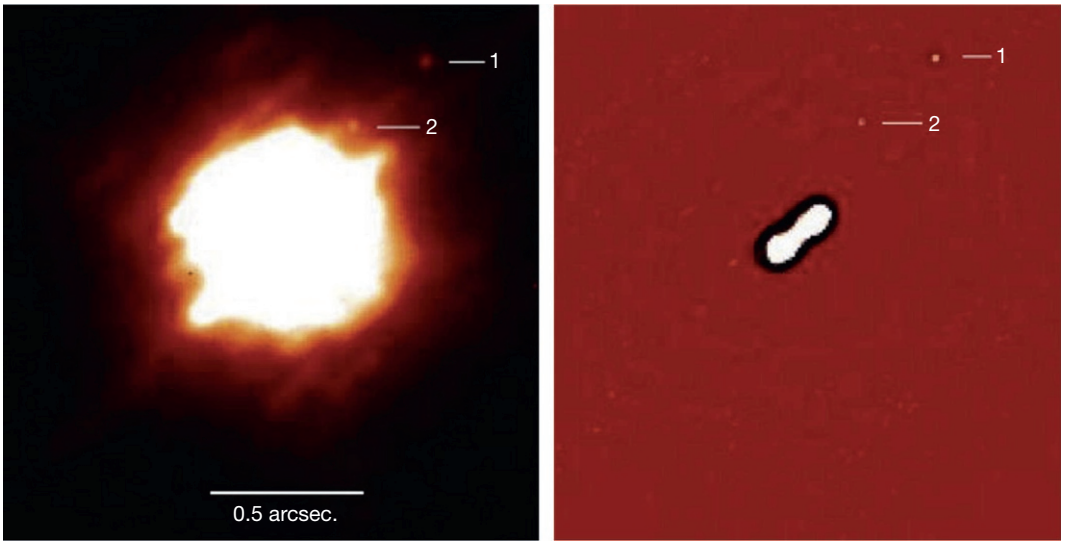

Figure 20 Adaptive optics image of asteroid Kleopatra as taken by Descamps et al. (2011) with the Keck II telescope atop Mauna Kea, Hawaii. The panel on the left shows the original image, which has been heavily stretched to show the effects of diffraction. The panel on the right shows the image after some deconvolution and filtering and has a resolution of about 0.035 arcsecond. The elongated nature of the asteroid is evident, and Kleopatra's two moons are also clearly revealed. Note that the effective resolution in the right panel rivals the resolution obtained by, for example, the Hubble Space Telescope. Reprinted from Descamps P, Marchis F, Berthier J, et al. (2011) Triplicity and physical characteristics of Asteroid (216) Kleopatra. *Icarus* 211: 1022–1033, Figure 1, with permission from Elsevier.

most important factor in forming binaries. Binary systems are found, for example, among S-complex objects, X-complex objects, and V types (e.g., 2006 VV_2). In particular, some binaries share characteristics that point to formation by spin-up due to the YORP effect, in particular some V types and Xe types, especially those Xe types that are part of the Hungaria family (the high inclination, low semimajor axis, and high-albedo group seen in the upper left of **Figure 3**). Note that Xe types used to be known as E types in the Tholen system and may have enstatite surfaces.

The densities of NEA binaries, 1.0–2.0 g cm^{-3}, imply porosity of 30–50% if the grain density is 2.5–3.2 g cm^{-3} for ordinary or carbonaceous meteorites assumed to be the parent body analogs for at least some of the S-complex and X-complex objects. Britt and Consolmagno (2003) measured porosities of meteorites and found that cracks and fissures on all scales give moderate porosities (20–30%) for seemingly solid samples. Asteroid porosities of 50% or even more are not inconsistent with many meteorite samples we have. A thorough compilation of asteroid porosities is given by Carry (2012) and shown in **Figure 21**.

The first asteroid shape model resulting from radar observations, that of (4769) Castalia (formerly 1989 PB), is a two-lobed structure, reminiscent of a molar tooth (Hudson and Ostro, 1994). Many more asteroids have since been seen to have this same basic shape, not only NEAs but also comet nuclei (Harmon et al., 2010, 2011; Magri et al., 2011). Unlike near-Earth binary systems, these contact binaries tend to be slowly rotating and have nearly equal mass lobes (Benner et al., 2008). Jacobson and Scheeres (2011) suggested that when an object splits into nearly equal mass lobes, a stable binary system is difficult or impossible to form. The equal mass systems, (69230) Hermes (Margot et al., 2003) and (90) Antiope, are rare in the near-Earth and main-belt zones. In the Kuiper Belt, binary systems of nearly equal mass are more common, but the discovery biases are quite different from those in the other regions, as are the size ranges observable. The conditions that would lead to the formation of a contact binary rather than a rapidly rotating binary with mass ratio 1:3 or more may not really be fundamentally different, but may instead be a stochastic process.

10.15.4.4 Cometary Properties

Comets lag far behind asteroids in terms of our understanding of ensemble properties of structure and rotation. There are fewer available targets for study by radar, and rotational studies at visible wavelengths can be complicated by the fact that often, the coma is much brighter than the nucleus. Radar delay-Doppler imaging of the sort that appears in **Figure 18** has only been obtained on four comets: P/2005 JQ_5 (Catalina) (Harmon et al., 2006), 73P/Schwassmann–Wachmann 3 (Howell et al., 2007), 8P/Tuttle (Harmon et al., 2010), and P/Hartley 2 (Harmon et al., 2011). This last comet is shown in **Figure 22**, and one can compare the radar image of P/Hartley 2 to those shown in **Figures 15** and **16**.

In addition to the delay-Doppler imaging, basic radar spectra have been obtained from 11 other comets total (Harmon et al., 2004, 2011), yielding constraints on nuclear sizes and on rotation rates. In some cases, the radar echoes contain a wide (in velocity space) skirt of flux. Since the wavelength of the radar is cm scale, this skirt is thought to show echoes from very large grains (>2 cm diameter) in the near-nucleus coma. Typical cometary activity can only lift (through the drag force) grains up to cm size; larger grains are usually too heavy and do not reach escape velocity (Grün and Jessberger, 1990), although in the context of fragmentation, larger grains can be liberated (e.g., Howell et al., 2007). In any case, the radar echo

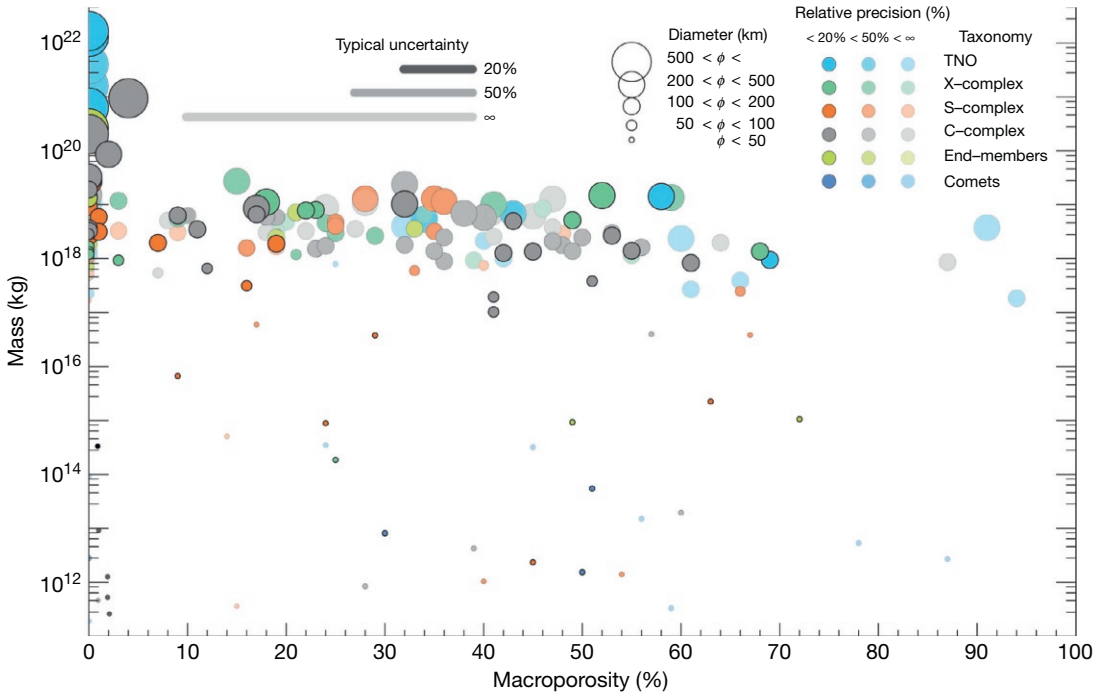

Figure 21 Scatter plot of macroporosities and masses of various small bodies as compiled by Carry (2012). Shading of each circle indicates the approximate uncertainty of the porosity measurement; Carry (2012) quantized the uncertainty as 20%, 50%, and 'infinity' (i.e., very large). Most of these results are from the 1990s and later; it is only since then that we have come to realize that many small bodies have large porosity. Reprinted from Carry B (2012) Density of asteroids. *Planetary and Space Sciences* 73: 98–118, Figure 8, with permission from Elsevier.

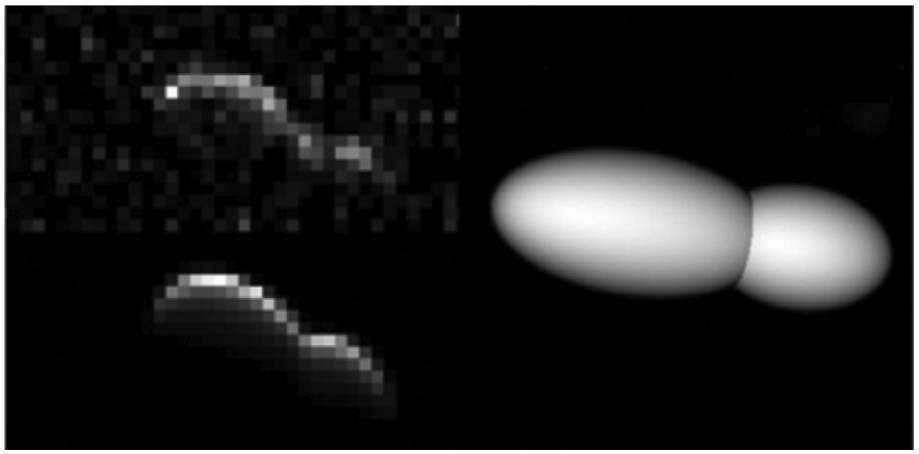

Figure 22 Radar echoes from and shape modeling of comet P/Hartley 2. One of the delay-Doppler images of the nucleus is shown at top left, along with a simulated image from a shape model of two joined ellipsoids at bottom left. That shape model itself for the nucleus is shown at right. The long axis of the nucleus is about 2.3 km. Compare the model to the spacecraft imaging shown in **Figures 15** and **16**. Radar observations prior to the flyby of the comet by the Deep Impact spacecraft helped to refine the position of the comet nucleus and were critical to the success of the mission. The radar image sequence also helped to refine the rotation state. This is an excellent example of how ground-based observations provide important context for spacecraft missions. Reproduced from Harmon JK, Nolan MC, Howell ES, Giorgini JD, and Taylor PA (2011) Radar observations of comet 103P/Hartley 2. *Astrophysical Journal Letters* 734: L2, Figure 2(b), ©AAS, with permission.

skirt is showing us the large end of the comet's dust coma and can provide an important constraint on the total mass loss.

A review of cometary rotation is provided by Samarasinha et al. (2004), and from 2004 to 2014, there have been only a few new rotation periods found for comets. The existence of excited (nonprincipal axis) rotation states has been noted in a few comets (e.g., comet P/Halley; Belton et al., 1991), but it is not always easy to confirm such spin states. One important advance since the mid-2000s however has been the discovery that several comets change their rotation periods significantly on orbital timescales. This phenomenon was first confirmed for 10P/Tempel 2 (Knight et al., 2012; Mueller and Ferrin,

1996), although it might have been seen in other comets earlier (e.g., Schleicher et al., 1991). Recently, changes in the rotation period have been noticed in comets 2P/Encke, P/Tempel 1, and P/Hartley 2 (Chesley et al., 2013; Meech et al., 2011; Mueller et al., 2008; Samarasinha et al., 2011). The change is on the order of 0.1–1%. For P/Encke; the change is a few minutes per orbit; for P/Tempel 1 and P/Hartley 2, it is on the order of 1 h per orbit. The primary driver is a net torque exerted on the nucleus by the reaction force of its outgassing. The physical importance of understanding such short-term changes in the rotational state is that one can then try to understand how long it takes for the excited rotation state to damp out, an effect that depends on the bulk solidity of the nucleus itself – that is, how much different pieces of the low-density nucleus rub up against each other. In other words, studies of cometary rotation states provide a clever way to try to understand the physical nature of cometary interiors.

The rapid changes that a comet can make to its own rotation period mean that in general, a comet has no memory of its primordial spin state. An intriguing study – but likely only feasible far in the future – would be to look at the distribution of rotation states among LPCs that are each on their first trip in from the Oort cloud and before they actually turn on. In other words, how are the LPCs spinning before they feel any torques from their own outgassing? Such observations would likely give us a window into a more primordial spin state distribution or at least certainly a glimpse of what very long-term, evolutionary dynamic processes might affect the comets while they are in the Oort cloud, tens of thousands of AU from the Sun. The difficulty is that there are virtually no LPCs discovered that are new in the Oort sense that are inactive; such objects are simply too faint to detect with current technology.

Even such fundamental quantities as the mass and the density of a cometary nucleus have been exceedingly difficult to constrain. Spacecraft have in general been too far from each comet under study to have their trajectories gravitationally deflected. The ejecta cloud produced by the impactor experiment with the Deep Impact mission suggested that the density of comet P/Tempel 1 is very low, about 400 kg m^{-3} (Richardson et al., 2007) although the quoted range is 200–1000 kg m^{-3}. The shape of comet P/Hartley 2's nucleus, like two ellipsoidal lobes, suggests that it might be showing an equipotential surface; if that is the case, Thomas et al. (2013b) derived a density of 200–400 kg m^{-3}. Before these missions, the most common way to estimate a comet's mass was through the use of its nongravitational parameters, that is, by making use of the changes to a comet's orbit caused by the reaction force of its own outgassing. Not only does outgassing change the spin state (as discussed earlier), but also the orbit then deviates from a purely gravitational solution (Marsden et al., 1973). Some recent estimates have been made for P/Wild 2 (upper limit of about 600–800 kg m^{-3}; Davidsson and Gutiérrez, 2006) and P/Borrelly (100–300 kg m^{-3}; Davidsson and Gutiérrez, 2004). Other estimates using the fact that the density must be sufficient to keep a comet from splitting apart due to its rotation are in the range of about 200–500 kg m^{-3} (Davidsson, 2001). While it is wise to keep in mind that some of these analyses are model-dependent, the results are consistent with the idea that cometary nuclei are underdense and very porous bodies.

10.15.5 Composition

10.15.5.1 Basic Premises

It is commonly assumed that because the comets we see today have spent most of their lifetimes in an environment too cold for most geochemical processes to occur and are too small to differentiate or retain heat of formation, that to first order the gas that comes off pristine comets will tell us about the compositional and chemical environment of the young solar system's protoplanetary disk. The situation is more complex for asteroids, which may have suffered more processing due to internal heat and in some cases differentiation, but some primordial information can still be inferred.

As discussed earlier, the comets we see today are vestiges of the icy planetesimals that were formed during the era of planetary formation. When such a planetesimal was created, while the primary component was water, many icy species (CO, CO_2, CH_3OH, CH_2O, etc.) were incorporated into its body. The relative amounts of these species were a direct sample of the chemical and thermal properties of the protoplanetary disk at that time and at that location (or perhaps the locations sampled by the planetesimal if scattering occurred while it was accreting).

Since the volatile content of asteroids in general does not outgas, but is locked in the minerals, it is much more difficult to ascertain compared with comets. Except in the case of sample return, asteroid composition is determined either by analysis of meteorites (which may have lost some of their volatiles during atmospheric entry or due to weathering after reaching the ground) or by modeling the compositional diagnostics in the reflectance and emission spectra of the surfaces. These multicomponent fits are highly dependent on the typical grain size of the regolith on the surface, making it difficult to distinguish between, for example, adsorbed water in layer phyllosilicates, OH groups on hydrated silicates, and actual water on clay grains. Basically, most remote sensing observations – even by a spacecraft that might be considered to be in situ – are only sensitive to the topmost microns of an object's surface, leaving most of the bulk of the object itself unsampled. Radio and radar observations can penetrate deeper – several wavelengths, so roughly a few decimeters – but there are fairly restrictive detectability limits in that wavelength regime.

As mentioned in Section 10.15.1, some asteroids have been observed to have outbursts of dust, showing something like a cometary coma and tail. While some of these objects have merely suffered a collision and thrown off dust as debris from an impulsive impact, several objects have been observed to have sustained dust production over weeks or months. Presumably, such activity is driven by water (although this has yet to have observational confirmation), and rather than the sharp classifications of icy comets and rocky asteroids, it seems likely there is a spectrum of compositions between the two endpoints. The active objects with asteroid-like orbits have been dubbed the 'main-belt comets.' The prototype MBC, with not only the comet designation 133P/Elst–Pizarro but also the asteroid designation (7968), is shown in Figure 23. Dynamic modeling of the long tail shows that the cause of the ejection of dust from the object could not have been impulsive; it must have lasted for months and therefore is likely to be water sublimation-driven. Furthermore, P/Elst–Pizarro has shown activity consistently now at

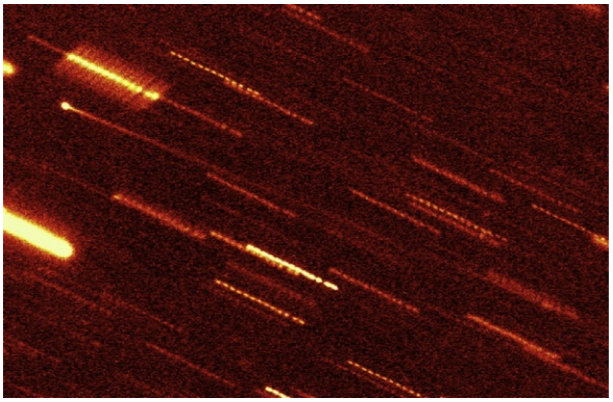

Figure 23 Image of comet 133P/Elst–Pizarro, a.k.a. Asteroid (7968) or the first 'main-belt comet,' as observed by Hsieh et al. (2004). The comet is the continuous object with the bright spot (the comet's head) in the upper left and the long tail extending down toward lower right. Other dotted sequences of spots in the image are background stars; note that the comet's tail is in a different orientation from the star trails. The comet's tail extends several arcminutes and is continuous, giving strong evidence that the object was continuously active for months on end and thus being driven by cometary activity. While about ten objects in the asteroid belt have shown extended emission from dust, about seven (including P/Elst–Pizarro) show evidence for comet-like activity; the others were likely the result of impulsive events such as from an impact event. The persistence of ice to drive such activity has significant implications for our understanding of small-body evolution. Reproduced from Hsieh HH, Jewitt DC, and Fernández YR (2004) The strange case of 133P/Elst-Pizarro: A comet among the asteroids. *Astronomical Journal* 127: 2997–3017, Figure 4, ©AAS, with permission.

nearly the same orbital longitudes for four orbits (Hsieh et al., 2013). There are currently less than ten known MBCs, but surveys are ongoing and it is expected more will be discovered. Statistical analysis of asteroid populations has suggested there may be on the order of a few hundred to a few thousand MBCs (Bertini, 2011; Gilbert and Wiegert, 2010; Hsieh, 2009). The existence of these objects has already transformed the way we think about the formation of planetesimals and mixing in the early solar system (see, e.g., Bertini, 2011). As we move from the discovery phase to the determination of composition of these objects, they should prove to be a valuable tool in constraining protoplanetary chemistry.

10.15.5.2 Volatiles

As discussed in Section 10.15.1, the primary difference between comets and asteroids is that the composition of comets is dominated by volatiles, while asteroids are dominated by rock-forming minerals but should have volatiles in increasing proportion with distance from the Sun. As comets approach the Sun, their volatiles begin to sublimate, likely from the outer 1–2 m (Prialnik et al., 2004). This produces a coma that is usually bright enough to make it difficult to discern the nucleus itself from Earth-based observations. Thus, frequently, the nucleus's properties are inferred from studies of the coma. From observations of gas in cometary comae, we can examine the distribution, composition, and rate of gas production from the nucleus. Modeling of these properties can yield, for example, the rotational state of the nucleus and lower limits on its size (e.g., Samarasinha et al., 2011; Schleicher and Woodney, 2003). Some gases sublimate directly from the nucleus (parent) and others are produced in the coma (daughter), either by chemical reactions or, more commonly, by photodissociation of the original molecules. As water is the most abundant volatile, all other volatiles in comets are typically measured by abundance relative to water or its direct photofragment OH.

The various volatile species found in comets have a wide variety of sublimation temperatures, which means they have the ability to begin outgassing at a variety of heliocentric distances. CO is the most volatile with a sublimation temperature of 25 K, though the somewhat more abundant CO_2 with its sublimation temperature of 80 K and ability to begin outgassing around 13 AU is believed to be the likely driver of most distant comet activity (Meech and Svoren, 2004). Water gradually takes over as the primary driver of cometary activity as heliocentric distance decreases. This variation in onset sublimation temperature leads to variations in abundance with heliocentric distance for some species (**Figure 24**; Biver et al., 1997, 2002). This is not the only reason abundances can vary with heliocentric distance, for instance, the variation in the HNC/HCN ratio has been shown to be due to chemistry in the coma (Irvine et al., 1998; Rodgers and Charnley, 1998).

Chemical abundances of volatiles vary from comet to comet, but when a large number of comets are observed, statistically significant groupings appear; thus, much work from the 1980s to the 2010s has gone into developing and understanding compositionally based taxonomies. The first of these was done with daughter fragments OH, NH, CN, C_3, and C_2 as these are readily observed in the optical, often with smaller aperture telescopes (~1–2 m), owing to their electronic transitions at visible wavelengths. A'Hearn et al. (1995) observed 85 comets, discovering that a significant fraction of JFCs (those originating in the Kuiper Belt) were depleted in carbon-chain molecules – C_2 and C_3 – relative to comets originating in the Oort cloud. This is shown in **Figure 25**, which is taken from the work by A'Hearn et al. As of 2013, this work has been extended to 101 comets, and principal component analysis continues to show that the carbon-chain depletion is not associated with evolution, but is primordial in nature (D. Schleicher, private communication). Additional optical surveys have been done spectroscopically. Those done by Fink (2009) and Langland-Shula and Smith (2011) also divide their comets into taxonomies and agree with the A'Hearn et al. results where they overlap on carbon-chain depletion.

To determine composition, one would ideally observe the species that sublimate directly from the surface – that is, the parent species – rather than the chemical fragments. Most of these species, however, only have spectroscopic transitions in the infrared (vibrational and rovibrational) and radio (rotational). Some important species – most significantly, CO_2 – have transitions that occur at wavelengths where the atmosphere is effectively opaque. Such species can only be observed from space. Emissions from many parent species at radio wavelengths tend to be faint enough that they can only be observed in the brightest comets. Despite these challenges, the database of observed comets at these wavelengths continues to grow and taxonomies of parent species are beginning to emerge. **Figure 26** from the work of Mumma and Charnley (2011) shows all of the species thus far observed. Radio surveys

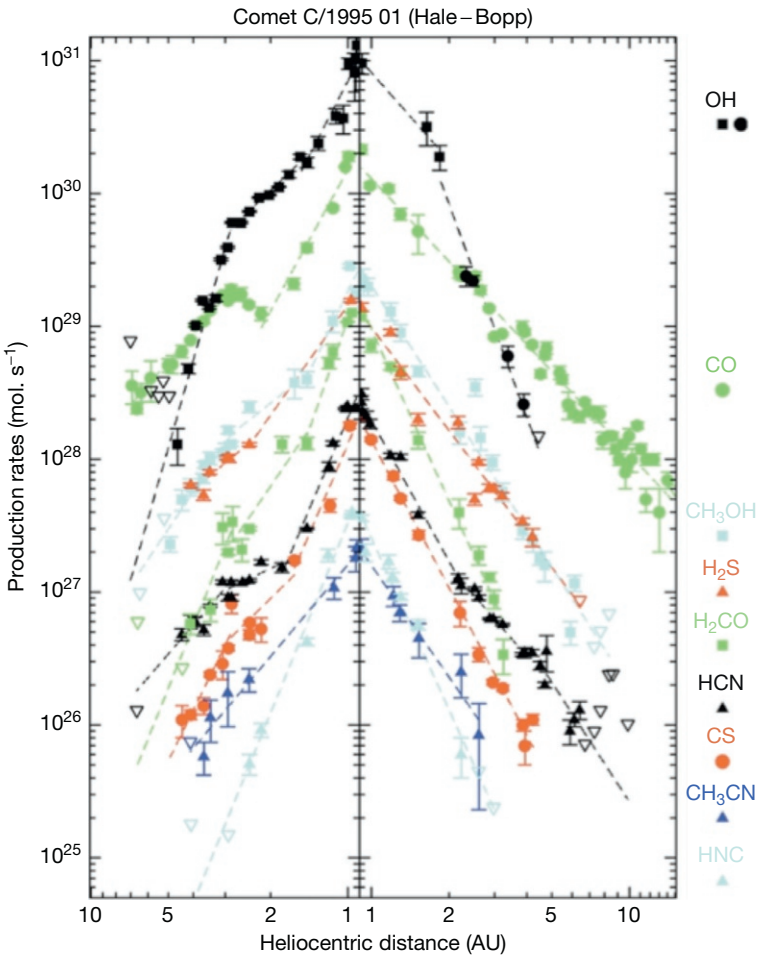

Figure 24 The so-called Christmas tree diagram, that is, the production rates from comet C/1995 O1 (Hale–Bopp) as observed using radio telescopes over the course of several years in the late 1990s and early 2000s. This was the first time that comet scientists were able to follow the production rates of so many species for such a long time interval, monitoring how their relative abundances changed as the thermal wave from the Sun penetrated to the interior and as various ices sublimated. Reproduced from the work by Biver N, Bockelée-Morvan D, Colom P, et al. (2002) The 1995–2002 long-term monitoring of comet C/1995 O1 (HALE BOPP) at radio wavelength. *Earth Moon and Planets* 90: 5–14, Figure 5, with kind permission from Springer Science and Business Media.

of 14 different species, 10 of them primary, in more than 40 comets have revealed no significant groupings related to dynamic origin (Biver et al., 2002; Crovisier et al., 2009).

The late 2000s and early 2010s have seen a burst of detections of CO_2, in over 40 comets, thanks to spacecraft observations, both *in situ* and remote (e.g., Combes et al., 1988; Crovisier et al., 1997; Feaga et al., 2007; Ootsubo et al., 2010; Reach et al., 2013). The abundance of CO_2 relative to water varies from ~3% to 30% when measured within 2.5 AU of the Sun (i.e., where water-driven outgassing is most vigorous), and no abundance variation based on primordial origin is observed (Mumma and Charnley, 2011).

Many of the organic species shown in **Figure 26** are seen, as mentioned, at infrared wavelengths through the use of high-resolution, cross-dispersed echelle spectrometers. Such instruments can observe the vibrational transitions of many species at once. This has the advantage of there being no uncertainties in relative abundances due to rotational variation. In the infrared, water, the species to which all others are compared, can also be measured directly. Species included so far in surveys are H_2O, CO, HCN, CH_3OH, H_2CO, CH_4, C_2H_2, C_2H_6, OCS, and NH_3 (Bockelée-Morvan et al, 2004; DiSanti and Mumma, 2008; Mumma et al, 2003). These surveys, which have included 26 comets so far, find three groupings based on organic abundances: organic-normal, organic-enriched, and organic-depleted. Interestingly, unlike the optical photofragment-based surveys mentioned earlier, there is no clear relation between composition and origin, since comets of both Kuiper Belt and Oort cloud origin occur in all groups. Work to increase the sample size and improve statistics is ongoing (Mumma and Charnley, 2011).

The isotopic ratios of a number of elements in comets are of interest because they are considered signatures of the environment in which the Sun formed. The D/H ratio is one of the most sought after due to the question of how much comets contributed to the Earth's water. The six Oort cloud comets measured before 2010 all had D/H ratios much higher than Standard Mean Ocean Water (SMOW). The first measurement of a Kuiper Belt comet was made by the Herschel space telescope, and P/Hartley 2 was observed to have the same

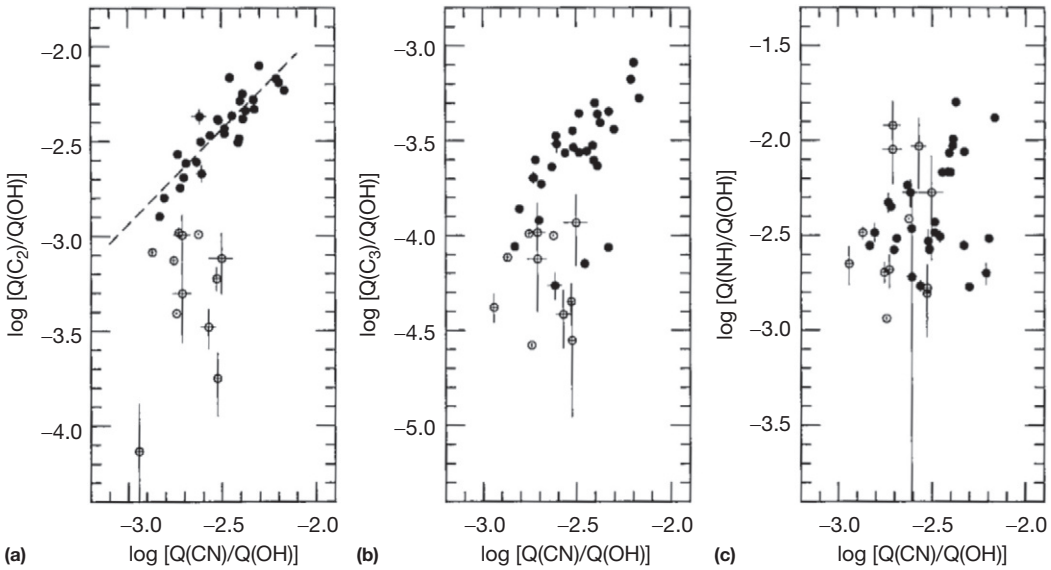

Figure 25 Correlations between relative abundances of daughter species in the comae of comets. $Q(X)$ refers to the production rate of species X. The strong depletion of C_2 and C_3 in some comets – denoted by the open circles – indicates a significant heterogeneity in the comet population. For the 'typical' comets (filled circles), the abundance of C_2 and CN (relative to water) is about the same (left panel), with the abundance of C_3 about a factor of 10 lower (middle panel). The dichotomy of abundance ratios does not extend however to NH (right panel). Reprinted from A'Hearn MF, Millis RL, Schleicher DG, Osip DJ, and Birch PV (1995) The ensemble properties of comets: Results from narrowband photometry of 85 comets, 1976–1992. *Icarus* 118: 223–270, Figure 10, with permission from Elsevier.

D/H ratio as SMOW to within the errors (Hartogh et al., 2011). This detection was followed by an upper limit for another JFC, 45P/Honda–Mrkos–Pajdušáková, which was consistent with the low D/H observed in P/Hartley 2 (Lis et al., 2013). The enigma of these observations is that the deuterium in comets originating in the Kuiper Belt was expected to be enriched relative to that of the isotropic comet population (Kavelaars et al., 2011). If the protosolar nebula began with enriched D/H similar to dense molecular clouds ($\sim 1 \times 10^{-3}$, Butner et al., 2007), and the reactions that reduce that ratio in the protoplanetary disk decrease with distance due to decreasing temperature, density, and turbulent mixing with distance (e.g., Aikawa and Herbst, 2001; Drouart et al., 1999; Mousis et al., 2000), then it would be expected that the D/H ratio would increase with increasing distance. While this led Hartogh et al. (2011) to conclude that it was possible that either these models could be incorrect or P/Hartley 2 could be an escaped Trojan (since Trojans possibly formed closer to the Sun where D/H ratios would be more depleted), the discovery of a second depleted JFC makes it even more important to measure the D/H ratio in a greater sampling of this population to determine whether this is a real taxonomic difference and also whether this can constrain our models of solar system formation. Additionally, this question has significant implications for the delivery of water to the inner solar system. A thorough review of D/H observations and challenges can be found in work by Mumma and Charnley (2011).

Since studies of comet composition make use of the coma and not the actual cometary nucleus itself, it is reasonable to wonder if the composition of the coma really can tell us the composition of the nucleus. More specifically, how do we know that the layer in the nucleus from which the coma gases originate is truly indicative of the interior composition? How much heterogeneity is there?

An important clue was provided by the Deep Impact spacecraft's visit to comet P/Tempel 1. The mission used an impactor to excavate a crater, yielding an opportunity to compare the composition of typical outgassing from surface layers with that of freshly excavated deeper layers as much as 20 m below the surface (Richardson et al., 2007). Measurements from both the ground and the spacecraft showed to within the uncertainties no change in abundance in most chemical species between the typical near surface outgassing and the ejecta plume from the excavated crater. Parent species CO_2 (Feaga et al, 2007), CO (Feldman et al., 2006), and HCN (DiSanti et al, 2007), as well as daughter fragments (photodissociation products of the larger parent molecules) NH, CN, C_3, CH, NH_2, and C_2 (Cochran et al, 2007), all retained the same relative abundance to water. So at the 0–20 m depth level, the degree of heterogeneity in comets – at least in comet P/Tempel 1 – seems to be low.

The topic of heterogeneity came to the forefront again after the spectacular data returned by the Deep Impact spacecraft as it flew by P/Hartley 2. Heterogeneity is demonstrated in **Figure 27**, which shows various images of the comet as constructed from the extensive infrared spectroscopy that was obtained. By looking at specific wavelengths in the spatially resolved spectra, spectral maps could be created. This particular figure is from the work of A'Hearn et al. (2011). The maps show that the sublimation of water was predominantly coming from the central region of the nucleus, as seen in the bottom left panel labeled 'H_2O vapor.' However, the reflected sunlight off the dust (top left) and the emission from organic species (middle right) are almost entirely spatially uncorrelated with

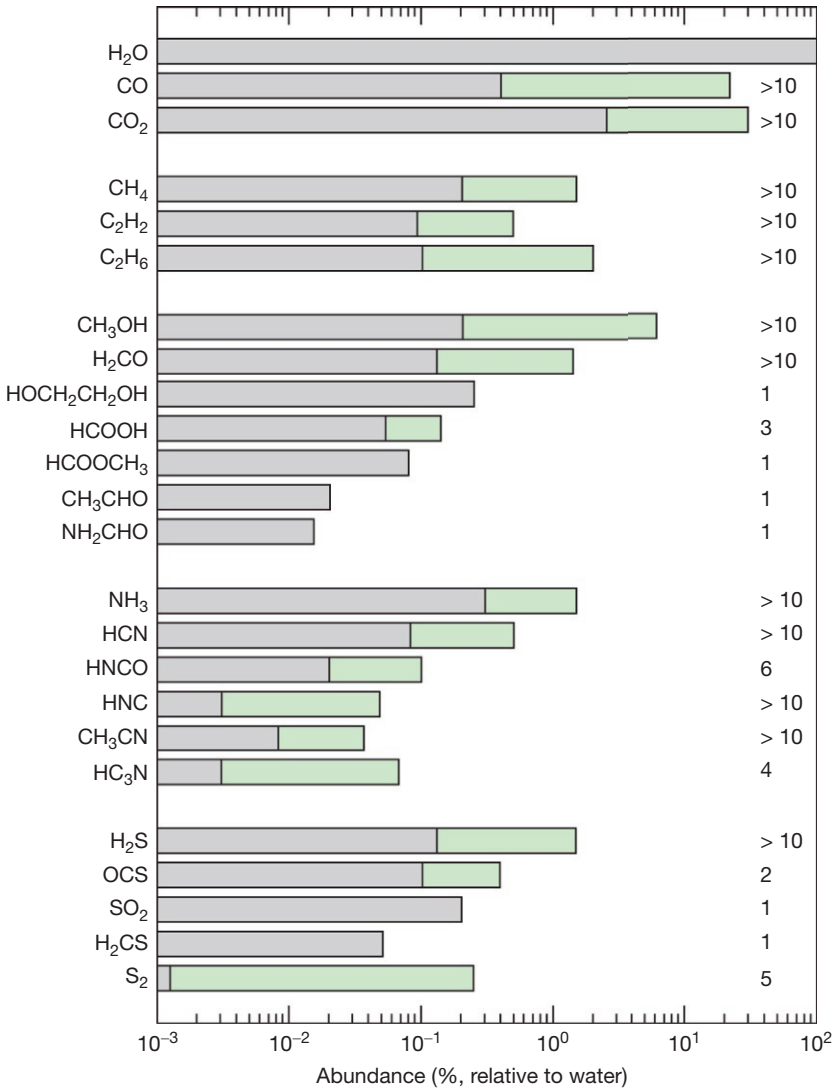

Figure 26 Relative production rates of various volatile species in comets. All abundances are scaled to water, which is set at 100%. The red segment shows the range among all measured comets; the numeral at the right edge gives how many comets in which the production rate of that species has been measured. After water, carbon dioxide, carbon monoxide, and methanol are the next most abundant species. Note the large variation in diatomic sulfur. Reprinted from Mumma MJ and Charnley SB (2011) The chemical composition of comets—emerging taxonomies and natal heritage. *Annual Review of Astronomy and Astrophysics* 49: 471–524, Figure 4, with permission from Annual Reviews.

the water vapor. Instead, they are strongly correlated with the CO_2 emission as seen in the top right panel, indicating that CO_2 at one end of the comet is driving much of P/Hartley 2's activity. Indeed, the CO_2 is even pulling off chunks of water ice (bottom right panel) into the coma.

However, the heterogeneity question is not yet fully understood, since there is good evidence that some comets are homogeneous perhaps all the way through – in particular comet P/Schwassmann–Wachmann 3, which was observed extensively in 2006 after it had broken into several large pieces during the previous two apparitions in 1995 and 2001. The gas and dust compositions in the comae of the comet's fragments were basically identical (Dello Russo et al., 2007; Sitko et al., 2011). There was no indication that the two main pieces of the comet (fragments B and C) had radically different makeup. Both comets P/Schwassmann–Wachmann 3 and P/Hartley 2 are JFCs, but the lack of heterogeneity in P/Schwassmann–Wachmann 3 suggests that the two comets could not have been formed from material that had experienced the same amount of mixing in the protoplanetary disk. Of course, there are few comets with detailed enough measurements to make a claim about heterogeneity, so this topic requires more data before broad generalizations can be justified.

The volatile content of MBCs is a new development that has taken on added importance with the claim of water ice on the surface of asteroids (24) Themis and (65) Cybele (Campins et al., 2010; Licandro et al., 2011; Rivkin and Emery, 2010). While it was certainly true that the primitive bodies in the outer main belt were thought to have appreciable water content, the observational results provide confirmation. Note however that the existence of water-bearing minerals on asteroids – as evinced by the 3 μm absorption band – has been known since the late

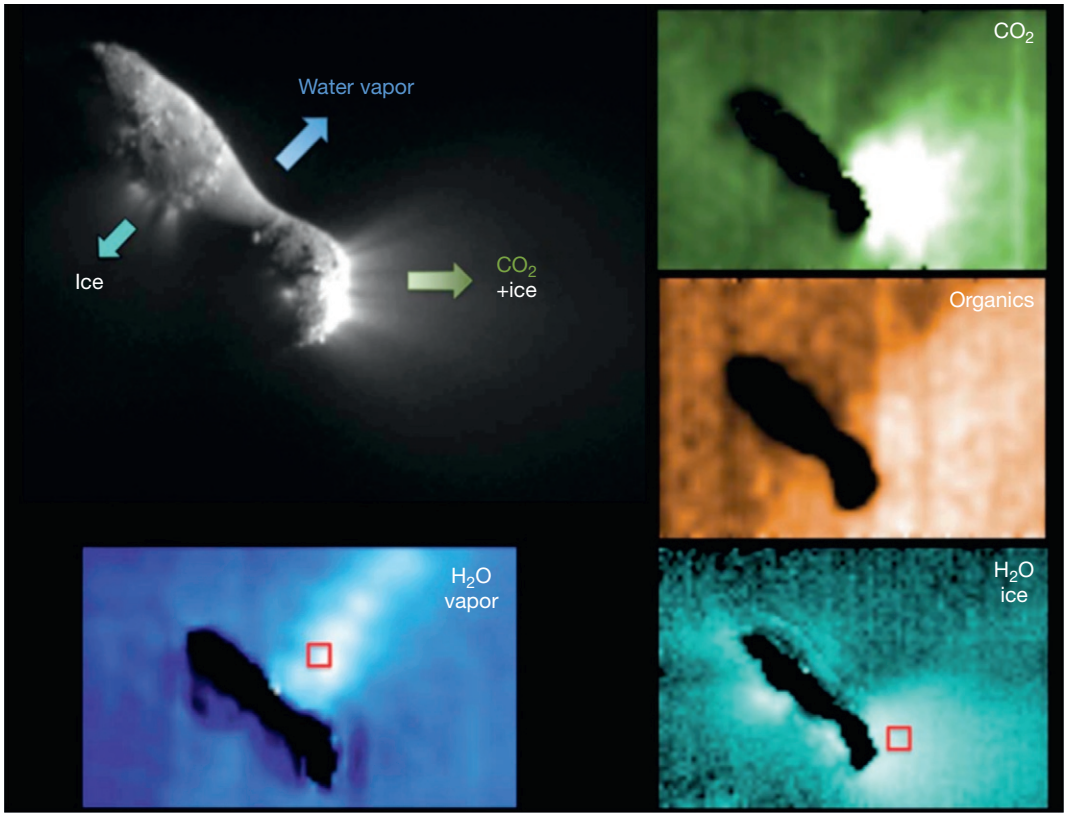

Figure 27 Heterogeneity in the nucleus of comet P/Hartley 2 as imaged by the EPOXI mission. The flyby of this comet revealed for the first time the significant role of carbon dioxide in driving cometary activity in a Jupiter-family comet in the inner solar system. Top left panel: Context image of the comet in visible-light continuum. Bottom left panel: Water vapor map, showing that most of the water is sublimating from the center of the comet's nucleus. Top right panel: CO_2 vapor map, showing that most of the carbon dioxide is sublimating from one of the ends of the nucleus. Middle right and bottom right panels: Maps of organic emission (C–H stretching bonds) and water ice absorption, which clearly show the vastly stronger correlation with the CO_2-driven activity rather than the water-driven activity. The long axis of the nucleus is about 2.3 km. Reproduced from A'Hearn MF, Belton MJS, Delamere WA, et al. (2011) EPOXI at Comet Hartley 2. *Science* 332: 1396, Figure 5, with permission from AAAS.

1970s, when it was first seen on Ceres by Lebofsky (1978). Interestingly, there is evidence of transient or variable OH coming from Ceres, first reported by A'Hearn and Feldman (1992) using IUE and then later by Küppers et al. (2014) using Herschel. In particular, the Herschel observations have shown evidence of OH while Ceres is near perihelion, and the amount is seen to vary with Ceres's rotation, suggesting specific source regions on the surface. Detection of water and/or ice in the outer part of the asteroid belt has also motivated some theoretical work on understanding how volatiles – in particular, water ice – can survive in the asteroid belt for billions of years (e.g., Schorghofer, 2008). The key seems to be having low thermal inertia so that diurnal and annual heat pulses from sunlight simply cannot make it down deep into the interior of the bodies. Thus, the natal water ice can survive for long periods of time and is available when, for example, an impactor strikes the body, clearing away the topmost layers and exposing the underlying ice to space and to the telescopes of astronomers.

The longevity of water ice and the poor thermal coupling between volatiles and rocks are also exemplified by the findings of the Deep Impact spacecraft on both comets P/Tempel 1 and P/Hartley 2, where surface ice was seen to cover a small percentage of each nucleus's surface in locations where ostensibly the local temperature of the rock was well above the water ice sublimation temperature (Groussin et al., 2013; Sunshine et al., 2006). While this ice is likely not primordial, but probably a recondensation of settled water that was formerly in the gas phase, it is remarkable that cold ice could so clearly be seen surrounded by much hotter rock. Furthermore, the fact that CO_2 was so abundant in as small a comet as P/Hartley 2 – one might have expected such a highly volatile species to have been completely baked out of the comet – lends further credence to the idea of cometary ice being decoupled from cometary silicates, probably helped by high porosity.

Much of the water content of the asteroids is studied through its existence within hydrated minerals, largely phyllosilicates. Studying the hydration is important for understanding what was going on in the young solar system such that liquid water could actually be in the physical presence of some of these minerals. In particular, the absorption band near 3 μm has been studied extensively in many asteroids, as mentioned earlier, going back over 30 years (e.g., Lebofsky, 1980). The aqueous alteration of minerals is seen in many primitive asteroids, but it is important to note that not all of them have it (e.g., Barucci et al., 1998; Rivkin, 2012; Rivkin et al., 2002). Interestingly, some of the asteroids that show evidence of hydration – for example, the so-called M types (under the Tholen taxonomy) – were once thought to be largely metallic

asteroids and to have been heated to quite high temperatures. The presence of hydrated minerals and the lack of FeO seem to contradict this scenario. Radar observations do not support most of the M types having significant iron metal, at least near the surface (Shepard et al., 2010, submitted for publication). However, iron–nickel meteorites must come from somewhere, and the parent bodies of these are still under debate (e.g., Emery and Lim, 2011). In the Bus–DeMeo taxonomy, the former M types now fall within the X-complex, distributed among several taxa, and are apparently a compositionally heterogeneous group.

10.15.5.3 Mineralogy

As stated in **Section 10.15.1.5**, **Figure 2** has a sampling of the spectral diversity among the asteroids. Note that the figure is not exhaustive; the overall slope of an asteroid's spectrum can change depending on how much weathering it has suffered, so in some cases, a single type of asteroid can actually encompass a range of spectral slopes.

In any case, the figure demonstrates that many asteroids have absorption features that are diagnostic of the surface composition; the most prominent and commonly seen ones are the deep features near 1.0 and 2.0 μm, commonly referred to as 'Band I' and 'Band II,' respectively. Both absorption bands are due to pyroxene, while olivine also contributes to Band I. The band centers and band areas can be used to place some constraints on the mineral abundances of Ca and Fe in the pyroxenes, of clino- versus orthopyroxene, and of olivine (e.g., Gaffey et al., 2002). However, it is important to note that the mixing of various different particle sizes and compositions can lead to nonunique interpretations of observed spectra.

Another frequently seen absorption feature occurs near 0.7 μm, which seems to arise in asteroids with phyllosilicates on the surface (Vilas, 1994). The oxidized iron within the hydrated mineral undergoes a charge transfer from doubly to triply ionized (i.e., Fe^{2+} to Fe^{3+}). As might be expected, the existence of this feature is correlated with an absorption feature near 3 μm that is also indicative of hydrated minerals (e.g., Rivkin, 2012; Rivkin et al., 2002); the visible-wavelength feature however is much easier to observe.

Direct sampling of asteroid mineralogy has now become possible with the success of the Hayabusa mission, which returned samples from the surface of Itokawa. In particular, one major result was that the strongly suspected link between S-type asteroids and OCs was confirmed (Nakamura et al., 2011). Furthermore, the isotopic oxygen abundance suggests that Itokawa itself is one of the sources of the OCs (Yurimoto et al., 2011).

Comet mineralogy has largely been studied through the dust grains that are dragged into space by the sublimating gas. An excellent recent review has been given by Kelley and Wooden (2009). Typical grain sizes are on the order of 1 μm, which is small enough that emission features from silicates appear in the 10 μm region, a wavelength regime amenable to ground-based spectroscopy. One of the most intriguing results from the study of many comets is the existence of crystalline silicates. Such crystallinity is in contrast to interstellar silicates, which may start out crystalline but are amorphized on million-year timescales (e.g., Kemper et al., 2004). Thus, crystalline silicates within the comets must have been heated to crystallize before being incorporated into the comet. We discuss this further in **Section 10.15.6.3**.

The silicates themselves are most commonly olivines and pyroxenes, as evinced by the shape of the 10 μm silicate feature. The shape also can be used to derive the degree of crystallinity and also the relative amounts of Mg and Fe. Many comets seem to have Mg-rich olivines and pyroxenes, or at least roughly equal amounts of Mg and Fe. This is not universal, however, and among the comets in which it has been studied, there appears to be diversity in the Mg-to-Fe silicate abundance. (Pyroxenes with some fraction of calcium (e.g., diopside and hedenbergite) are not commonly seen in comets although there are some claimed detections, including in the Deep Impact ejecta.) This high average Mg-to-Fe ratio is interesting since in asteroids and meteorites, it is more common to see the Fe-rich silicates. This dichotomy is presumably related to the compositional gradients in the protoplanetary disk. The cometary silicate composition is also somewhat dependent on dynamic class, perhaps again revealing something about formation regions of these objects.

The existence of hydrated minerals in comets, as claimed in the Deep Impact ejecta, would have significant implications for cometary formation, since presumably, the hydration could only come from liquid water, that is, water heated out of the solid phase. Yet we know that comets must have retained most of their water ice and indeed even the more volatile and highly abundant species like CO and CO_2.

Our understanding of the mineralogy of comets was helped greatly by the success of the Stardust mission, which brought dust grains from comet P/Wild 2 back to Earth. A summary of Stardust's major results in this regard has been provided by Bradley et al. (2009), and implications of the results have been reviewed by Wooden (2008). One major result from the enabled laboratory studies is that the high degree of crystallinity in the silicates – mentioned in the previous text as a result of telescopic observations – was confirmed. This was a direct laboratory measurement and so a nice corroboration of the telescopic data. Such materials must have been heated and then brought out past the snow line, potentially many AU away, in order to be incorporated into the icy comets.

The result is even more significant since it appears that the fraction within the Stardust sample of so-called 'presolar' grains – grains that condensed in the interstellar medium or around other stars before finding their way into our own protoplanetary disk – is lower than what was expected based on what is seen in primitive meteorites (Stadermann et al., 2008). At face value, this implies that the rocky component of comets is quite heavily derived from material that was in the inner solar system and flowing outward. However, there is some evidence that presolar grains were preferentially destroyed by the collection process (Floss et al., 2013), which may complicate the interpretation.

Yet another interesting aspect to the Stardust sample is the low abundance of chondrules and phyllosilicates (Nakamura et al., 2008; Zolensky et al., 2006). With the disk evidently cycling material outward to the comet-formation region fairly efficiently, one might expect that collisions among young asteroidal bodies in the inner solar system could deliver chondrules and aqueously altered materials to the region where comets

could incorporate them. Chondrules and phyllosilicates are after all common, judging by the meteorite record and by asteroid spectroscopy. However, the P/Wild 2 grains contain few of either, suggesting that the parent bodies to today's cometary nuclei are 'preaccretionary,' that is, formed before the epoch of chondrule formation (Wooden, 2008). While the details of the thermodynamics, transport, and chemistry in the protoplanetary disk are important for getting the right answer, the result can place constraints on disk evolution models.

10.15.6 Big Questions and the Future

In this last section, we summarize some of the significant problems with regard to small bodies that we think are the most pressing. We also provide some discussion of how such problems could be addressed. The study of small bodies has been recognized by the Planetary Science Decadal Survey (Committee on the Planetary Science Decadal Survey 2011) as a way to address some of the questions of the highest overarching importance in the field. What the small bodies lack in mass relative to other parts of the solar system, they make up for in importance to understanding solar system history and evolution.

There are several general points that are useful to keep in mind regarding observations of small bodies. (1) Discovery far outpaces characterization. There are over 600 000 known asteroids, almost 500 JFCs, and a few thousand known Halley-type and LPCs. It is far easier to discover such objects than to study them and discover their compositional, structural, and physical properties. (2) Many small bodies have no or only very weak spectroscopic features that can be used for compositional diagnostics. To put it another way, the jump from reflectance and thermal emission properties and taxonomy to composition and mineralogy is often not straightforward, nor unique. (3) Observations rarely sample an object deeper than a few microns; many datasets obtained on small bodies really are only addressing the topmost microscopic layer. This is especially unfortunate because it is that layer that is the most processed. Seeing deeper down into an object is very useful but often very difficult to do unambiguously. (4) While we know that the small-body populations are a diverse group, we have only begun to understand the full variety of comet and asteroid properties. In other words, we know we are ignorant, but we are not yet quite sure just how ignorant! (5) The meteorite collection is indeed vast, but a significant barrier to advancing our understanding of small bodies is the relative lack of samples with known context. At the moment, we only have samples from Itokawa and from P/Wild 2.

10.15.6.1 Where Is the Water?

As discussed earlier, we know that water makes up a significant fraction of the mass of a comet, but its contribution to the masses of the asteroids is much more uncertain. An important clue is the fact that CI and CM meteorites can be up to 15% water by weight (Salisbury et al., 1991). The water content of asteroids is a vital question since it is important to know what kind of objects actually provided Earth with its water. Part of this investigation requires studying how much of the water is bound up in hydration of minerals. This is a fundamental chemistry problem and needs to be addressed if we are to understand how much water there actually was available in the protoplanetary disk. Recent discoveries of water, or at least OH, in somewhat nonintuitive locations such as the poles of Mercury and the surface of the Moon suggest that it is crucial to know the details of the thermal environment in order to understand where water can survive.

Observationally, one approach that could vastly improve the state of the art is to have a large spectroscopic census of the 3 μm region in many asteroids. This wavelength region contains a broad absorption feature due to overlapping vibrational overtones of water and OH. The spectrum of each object should have high enough signal-to-noise to be able to use the shape of the absorption feature to distinguish between water itself and water that is bound in a hydrated mineral. Such a census would let us find surface water abundance as a function of taxonomic type and heliocentric distance and thus give us some connection between water and the birth location of the object. To some extent, this project is already underway, but spectroscopy at these wavelengths is not trivial, requiring dry air with low precipitable water above the telescope. Preliminary results suggest that the distribution of hydrated asteroids is not related to asteroid size or orbital location in a simple way (e.g., Rivkin et al., 2002).

10.15.6.2 Where Are the Organics?

As with water, the key to understanding the organics is in spectroscopic studies of the 3.2–3.6 μm region. C–H bonds in organic species have stretching modes at those wavelengths. High signal-to-noise is needed to be able to differentiate between different sets of organics within an asteroid. Currently, one usually just sees a broad feature that can be difficult to assign to specific species, since the phase of the material is solid. Organic materials in meteorites have been studied extensively, but the relationship to specific asteroids or locations is lacking (e.g., Pizzarello et al., 2006 and references therein).

Fortunately, comets can provide more insight about organic abundances, for the icy bodies at least, since the cometary activity naturally dredges up interior volatiles, making them visible in the coma as discussed earlier in this chapter. The difficulty is determining which volatiles are native to the cometary nucleus itself and which are products of chemistry that can occur within the collision zone of the coma, within a few radii of the nucleus's surface.

There has been a tremendous increase in the study of cometary organics since the late 1990s, owing to improvements in infrared spectrometers and to access to the large telescopes that are required. Thanks to these observations, a clearer picture is emerging of how various species – C_2H_2, CH_3OH, C_2H_6, H_2CO, etc. – are distributed among the comet population (Mumma and Charnley, 2011). Continued observation of comets – from all dynamic classes – is certainly warranted. The number statistics are still fairly low, so a census of the organics in even 10–20 more comets, both short and long period, would be very helpful to discern trends. The difficulty is that there are only a few comets per year that are bright

enough for this kind of observation. This suggests that JWST, representing potentially a tremendous jump forward in the number of faint targets that are accessible, could bring considerable data to the problem.

A sample return mission to a comet could in principle provide us with cometary species that could be studied in exquisite detail in the laboratory. This would be a boon for our understanding of planetesimal accretion and cometary evolution. Such a mission would be technically complex, however, since one problem to be solved is preserving organics and volatiles at low temperatures during the journey back to Earth so that no chemistry occurs along the way. The Stardust mission unfortunately was not able to bring back many organics since most of the organics sublimated away as the dust grains hit the collector aerogel at high relative speed. One interesting result however was the discovery of glycine in some of the Stardust samples (Elsila et al., 2009). We can look forward to the day when more amino acids and other complex species will be measured in cometary materials.

10.15.6.3 What Was the Thermal and Compositional Gradient in the Protoplanetary Disk? How Much Mixing Was There?

An apparent compositional gradient in the current solar system has been identified for several decades (Carvano et al., 2010; Gradie et al., 1989), as was described in **Section 10.15.2**. Recent dynamic modeling – in particular models like the Nice model and the Grand Tack model that have the giant planets migrating significantly and disrupting the orbital distribution of planetesimals – has suggested that the interpretation of this apparent, current gradient is not easy. The goal, after all, is to find the *primordial* compositional gradient. Two main problems in understanding what the primordial gradients were like remain: (a) there is uncertainty in what dynamic mixing has happened, and (b) we do not have enough compositional data to begin with. Detailed compositional studies of a wide range of small bodies will be necessary if we are to address the situation, and naturally, the first step is understanding composition as a function of object type and object's location in the solar system right now. We can then hope to make use of advances in our understanding of solar system dynamics to constrain the initial conditions.

Although it had been suspected earlier, strong evidence for tremendous mixing in the protoplanetary disk comes from the fact that Stardust brought back silicate dust grains from comet P/Wild 2 with a degree of crystallinity that could only have been formed in high temperatures (Zolensky et al., 2006). This result was discussed in **Section 10.15.5.3**. In fact, more than half of the Fe-bearing silicates show evidence of having been processed in the inner solar system (Ogliore et al., 2009).

There are several models that could explain the transport of small heated grains to the outer solar system. The Shu X-wind model (Shu et al., 1994, 2000) has been a leading hypothesis since it can explain astrophysical phenomena regarding disks and jets around young stellar objects. The model uses the magnetohydrodynamics of the star–disk interaction to fling material outward after it has had a chance to be heated close to the protostar. The magnetosphere of the accreting star transfers angular momentum to the disk, which induces an outward wind. While much of the wind blows along field lines out of the disk altogether, some grains that were heated in the stellar accretion region will be blown back into the disk at distances appropriate for cometary accretion. However, there are several significant problems with this scenario as the source of crystalline grains, including the possible lack of time to produce the inferred initial $^{26}Al/^{27}Al$ ratio (Boss, 2012; Desch et al., 2010).

Other possible explanations come from one- and two-dimensional hydrodynamic models of turbulent, viscous disks. These models explain the outward transport of grains through diffusion and/or midplane gas flows in the first 1–2 My of disk formation. These grains would have to be incorporated into icy bodies very early on, before they fell back to smaller radii (e.g., Hughes and Armitage, 2010). Additionally, in full 3-D models of 'marginally gravitationally unstable' (MGU) disks, the disk appears to evolve through one or more phases of gravitational instability, and self-gravitational torques can transport material both inward and outward (e.g., Boss, 2007). Each of these approaches has implications for mixing and heterogeneity in the disk at varying timescales.

In any case, one of the significant clues to the early protoplanetary disk lies in the solids with depleted initial ^{26}Al abundance. In meteorites, both chondrules and a fraction of the calcium–aluminum-rich inclusions show evidence for zero initial abundance, indicating they formed before or several million years after the event(s) that infused the disk with ^{26}Al. According to Boss (2012), better Pb–Pb isochron ages for the depleted inclusions, as well as tighter constraints on the initial heterogeneity of short-lived isotopes ^{60}Fe and ^{26}Al, will help us understand the initial conditions. Furthermore, measurements of the isotopic ratio of oxygen in molecules observed in protoplanetary disks will help us understand mechanisms for fractionation and spatial heterogeneity of oxygen isotopic abundances since these isotopes display evidence for mass-independent fractionation in our solar system (Boss, 2012; Clayton, 1993; Sakamoto et al., 2007).

While meteorites continue to be a source of samples, sample return missions represent a promising way to make further progress, since parent bodies can be chosen for their known composition and dynamic properties.

10.15.6.4 What Did Small Bodies Do to Earth?

The current dominant hypothesis is that Earth and the terrestrial planets likely formed too close to the young Sun in too warm a region to allow hydration at formation (Morbidelli et al., 2000). In simplistic terms, this was thought to indicate that there was a 'frost line' or 'snow line' in the protoplanetary disk that marked the boundary of where water could condense out of the gas phase. Recent work has shown this is indeed an oversimplification and that condensation in the real protoplanetary disk was more complicated, as well as time-dependent (e.g., Bell, 2010; Encrenaz, 2008; Morbidelli et al., 2012; van Dishoeck et al., 2014). While it has long been assumed that small bodies from the outer solar system brought water and organics to what would have otherwise been a dry Earth (e.g., Matsui and Abe, 1986), the lunar D/H ratio and the Earth's mantle composition both suggest that it was *possible* for there to have been enough water inside the snow line for Earth to have formed wet and thus that very little water was brought

from impactors (e.g., Marty, 2012; Saal et al., 2013). On the other hand, the composition and isotopic ratios in the mantle have also been used to argue in favor of contributions by both asteroids and comets (e.g., Halliday, 2013). Greater knowledge of isotopic ratios of small bodies and of the history of fractionation in the solar system will be a key part of understanding the origin of the Earth's water.

As discussed in Section 10.15.5.2, until 2010, the water D/H ratio in six Oort cloud comets showed that the D/H ratio was much higher than observed in the Earth's oceans (i.e., in SMOW). This made having comets as a source of the Earth's water problematic. Modeling suggested that if Jupiter were in a nearly circular orbit, then water could be delivered to the terrestrial planets by chondritic material from beyond the frost line (Raymond et al., 2004). The discovery that the JFC P/Hartley 2 has a water D/H ratio similar to SMOW (Hartogh et al., 2011) revives the possibility that comets could have delivered a significant fraction of the Earth's water. Furthermore, two other recent results on the D/H ratio – (a) the D/H measurement of less than 1.5 times SMOW in the Oort cloud comet C/2009 P1 (Garradd) by Bockelée-Morvan et al. (2012) and (b) the finding of an upper limit to the D/H ratio in comet P/Honda–Mrkos–Pajdušáková that is consistent with that of P/Hartley 2 (Lis et al., 2013) – demonstrate a possible continuum in cometary D/H. Clearly, the D/H ratio in comets is a more complicated issue than was previously thought. In any case, given the success of the asteroid models at delivering water, the answer may be that the Earth's volatiles were delivered by some combination of asteroids and comets – unless it turns out that the wet Earth hypothesis is correct. It is possible that we will need to develop and fly the technology to sample small-body noble gas isotopes before we are reasonably certain of the origin of the Earth's water.

It is clear from both this question and several of the others posed in this section that understanding the dynamic evolution of the small bodies is critical to being able to reconstruct the protoplanetary disk. The current dominant model of large-scale planetary migration in our solar system, the Nice model mentioned in earlier sections, has done an admirable job of explaining many observed phenomena, but the difficult part is using it to make a prediction that both (a) is observationally feasible and (b) would make a strong test of the idea's validity. Compositional information on the small bodies is one possible way – since, for example, the model would predict that one would see a similar primordial composition among the outer main-belt asteroids, Trojans, and trans-Neptunian objects. The difficulty is that it is still hard to interpret the surface composition due to a lack of diagnostic features. What is unknown is whether the surfaces would really be the same because of similar primordial condition or simply because of similar subsequent evolution. Sample return missions may be required before we know that answer.

Nongravitational forces are an important aspect to the dynamics of many objects, as it is now clear that over fairly short dynamic timescales, they can move asteroids and comets significantly around the solar system. In particular, for asteroids, the Yarkovsky and YORP effects need to be better understood – and this means understanding the thermal properties as well as the structural properties in the interior. This is important since the Yarkovsky effect affects the delivery of asteroids from the asteroid belt to near-Earth space, including those that could someday strike Earth. For comets, outgassing torques and forces – on the whole much stronger than Yarkovsky effects – can measurably change a comet's orbital elements on month- or year-long timescales, thereby making it more difficult to gauge just how significant the cometary impact risk is for Earth.

10.15.6.5 Forthcoming Breakthroughs

The next decade should bring tremendous insight into our understanding of comets and asteroids. First, the Rosetta spacecraft will rendezvous with comet P/Churyumov–Gerasimenko in 2014 and observe it close-up for several months. Rosetta is primarily a European Space Agency mission but NASA has contributed some of its instruments. For the first time, we will be able to watch a comet turn on as its activity gets started. The spacecraft also has a lander, Philae, that will be able to study the surface directly, our first such opportunity to do so on a comet. The spacecraft will arrive at comet P/Churyumov–Gerasimenko in May 2014 – when the comet is 4.0 AU from the Sun, outside the zone where water could sublimate – and will stay with the comet at least until December 2015. The comet's perihelion occurs in August 2015, when it will be 1.24 AU from the Sun.

Asteroid sample return should figure prominently in the next several years, with the United States, Europe, and Japan all potentially sending sample return missions to primitive asteroids. The Japanese mission, Hayabusa 2, is a follow-up to its successful Hayabusa mission that brought back samples from asteroid Itokawa in 2010. Hayabusa 2 will travel to (162173) 1999 JU3, which is a primitive asteroid. Launch would happen in 2014 or 2015, with asteroid arrival in 2018. The spacecraft would collect a sample and leave the asteroid in 2019, returning to Earth in 2020. The US mission, OSIRIS-REx, which stands for 'Origins Spectral Interpretation Resource Identification Security Regolith Explorer,' will retrieve samples from asteroid Bennu. This object is likewise a primitive asteroid. Launch will happen in 2016, with arrival to the asteroid in 2019. The spacecraft would study the asteroid for many months, departing likely in 2021 and getting back to Earth in 2023. Even if only one of these missions is successful, we can expect to have tremendous new insights into our understanding of primitive bodies in the 2020s.

10.15.6.6 Longer-Term Missions

In the farther future, significant scientific return can be obtained from robotic missions that visit Trojan asteroids, primitive main-belt asteroids, and dormant/extinct comets. In the United States, NASA has plans for human visitation of asteroids in the relatively near future, mid-2020s. However, it is unclear exactly what path toward that goal will be taken. Nonetheless, there are significant engineering obstacles to a successful manned mission to an asteroid that need to be overcome. Some of these obstacles – sometimes known as 'strategic knowledge gaps' – can be answered through telescopic observation and robotic visitation of the asteroids in question. Some of these questions include the following: Could astronauts actually operate in the nearly zero gravity

environment around an asteroid? How would the spacecraft rendezvous? What are the surface and immediate subsurface layers like? Can one grab onto the surface or is it too powdery? Could one anchor to it? What thermal variation would there be as the asteroid rotates in and out of sunlight? Is the asteroid in a principal-axis rotation state, or is it tumbling? How far down would one have to dig to get to more pristine material, if at all?

While these are difficult problems to solve, one cannot help but be excited about what secrets of the small bodies and of our solar system will be revealed in the coming years. The synergy of Earth-based telescopic observation (to provide the big picture about many objects) and spacecraft missions (to provide the detailed picture of a few key objects) is sure to continue to provide astronomers and geophysicists with new, thrilling insights.

Acknowledgments

We greatly appreciate the assistance of Michael Nolan and Patrick Taylor in preparing this manuscript. We also thank Peter Thomas and an anonymous reviewer for their careful reading and suggestions. Some of our figures made use of data archived by the Small Bodies Node of the NASA Planetary Data System. YRF and ESH acknowledge support from NSF (through Grant No. AST-1109855 to the Johns Hopkins University). LMW acknowledges support from NASA (through Grant No. NNX09AB71G issued through the Planetary Atmospheres program). The Arecibo Planetary Radar Program is supported by the National Aeronautics and Space Administration under Grant No. NNX12AF24G issued through the Near-Earth Object Observations Program. The Arecibo Observatory is currently operated by SRI International under a cooperative agreement with the National Science Foundation (AST-1100968) and in alliance with Ana G. Mendez-Universidad Metropolitana and the Universities Space Research Association. At the time of some of these observations, the Arecibo Observatory was operated by Cornell University under a cooperative agreement with the National Science Foundation.

10.16.1 Introduction

In our solar system, four planets stand out for their sheer mass and size. Jupiter, Saturn, Uranus, and Neptune indeed qualify as the 'giant planets' because they are larger than any terrestrial planet and much more massive than all other objects in the solar system, except the Sun, put together (Figure 1). Because of their gravitational might, they have played a key role in the formation of the solar system, tossing around many objects in the system, preventing the formation of a planet in what is now the asteroid belt, and directly leading to the formation of the Kuiper Belt and Oort Cloud. They also retain some of the gas (in particular hydrogen and helium) that was present when the Sun and its planets formed and are thus key witnesses in the search for our origins.

Because of a massive envelope mostly made of hydrogen–helium, these planets are *fluid*, with no solid or liquid surface. In terms of structure and composition, they lie in between stars (gaseous and mostly made of hydrogen and helium) and smaller terrestrial planets (solid and liquid and mostly made of heavy elements), with Jupiter and Saturn being closer to the former and Uranus and Neptune to the latter (see Figure 1).

The discovery of many extrasolar planets of masses from a few thousands down to a few Earth masses and the possibility to characterize them by the measurement of their mass and size prompt a more general definition of the giant planets. For this chapter, we will adopt the following: "a giant planet is a planet mostly made of hydrogen and helium and too light to ignite deuterium fusion." This is purposely relatively vague – depending on whether the inventory is performed by mass or by atom or molecule, Uranus and Neptune may be included or left out of the category. Note that Uranus and Neptune are indeed relatively different in structure than Jupiter and Saturn and are generally referred to as 'ice giants,' due to an interior

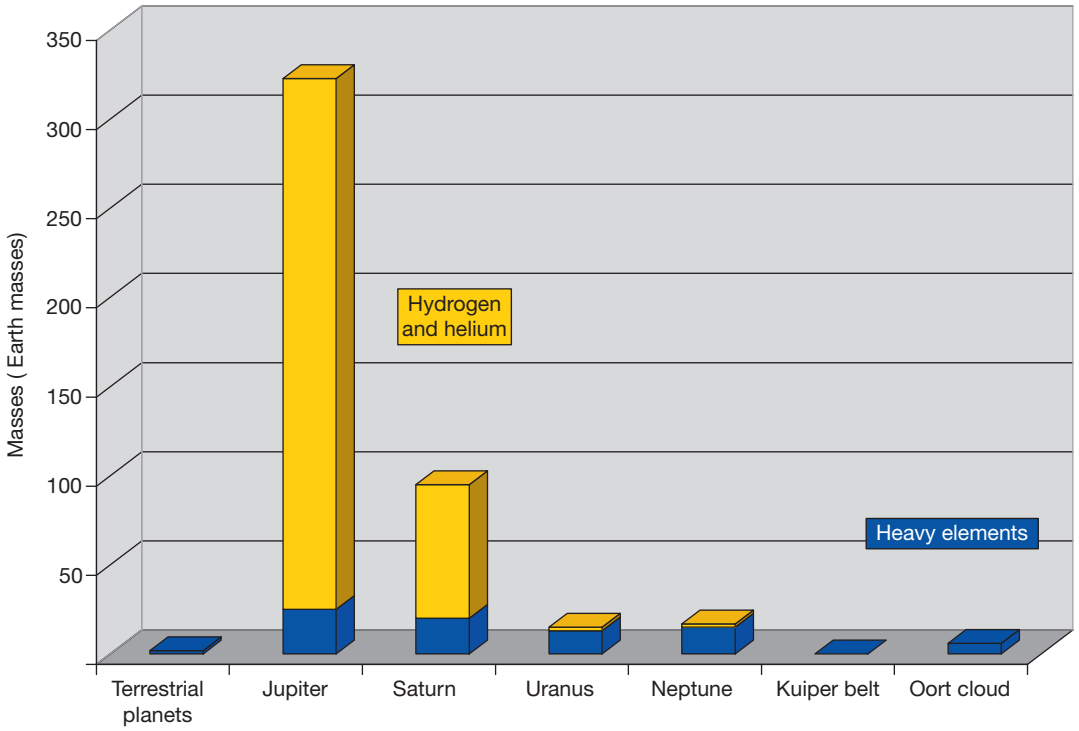

Figure 1 An inventory of hydrogen and helium and all other elements ('heavy elements') in the solar system excluding the Sun (the Sun has a total mass of 332 960 $M_\oplus$, including about 5000 $M_\oplus$ in heavy elements, 1 $M_\oplus$ being the mass of the Earth). The precise amount of heavy elements in Jupiter (10–40 $M_\oplus$) and Saturn (20–30 $M_\oplus$) is uncertain (see **Section 10.16.4.1**).

structure that is consistent with the presence of mostly 'ices' (a mixture formed from the condensation in the protoplanetary disk of low-refractivity materials such as H_2O, CH_4, and NH_3 and brought to the high-pressure conditions of planetary interiors – see in the succeeding text).

Globally, this definition encompasses a class of objects that have similar properties (in particular, a low viscosity and a non-negligible compressibility) and inherited part of their material directly from the same reservoir as their parent star. These objects can thus be largely studied with the same tools, and their formation is linked to that of their parent star and the fate of the circumstellar gaseous disk present around the young star.

We will hereafter present some of the key data concerning the giant planets in the solar system and outside. We will then present the theoretical basis for the study of their structure and evolution. On this basis, the constraints on their composition will be discussed and analyzed in terms of consequences for planet formation models.

10.16.2 Observations and Global Properties

10.16.2.1 Visual Appearances

In spite of its smallness, the sample of four giant planets in our solar system exhibits a large variety of appearances, shapes, colors, variability, etc. As shown in Figure 2, all four giant planets are flattened by rotation and exhibit a more or less clear zonal wind pattern, but the color of their visible atmosphere is very different (this is due mostly to minor species in the high planetary atmosphere), their clouds have different compositions (ammonia for Jupiter and Saturn and methane for Uranus and Neptune) and depths, and their global meteorology (number of vortexes, long-lived anticyclones such as Jupiter's Great Red Spot, the presence of planetary-scale storms, and convective activity) is different from one planet to the next.

We can presently only wonder about what is in store for us with extrasolar giant planets since we cannot image and resolve them. But with orbital distances from as close as 0.01 to 100 AU and more, a variety of masses, sizes, and parent stars, we should expect to be surprised!

10.16.2.2 Gravity Fields

The mass of our giant planets can be obtained with great accuracy from the observation of the motions of their natural satellites: 317.834, 95.161, 14.538, and 17.148 times the mass of the Earth ($1\ M_\oplus = 5.97369 \times 10^{27}$ g) for Jupiter, Saturn, Uranus, and Neptune, respectively. More precise measurements of their gravity field can be obtained through the analysis of the trajectories of a spacecraft during flyby, especially when they come close to the planet and preferably in a near-polar orbit. The gravitational field thus measured departs from a purely spherical function due to the planets' rapid rotation. The measurements are generally expressed by expanding the components of the gravity field in Legendre polynomials P_i of progressively higher orders:

Figure 2 Photomontage from images of Voyager 2 (Jupiter, Uranus, and Neptune) and Cassini (Saturn). The planets are shown to scale, with their respective axial inclinations.

$$V_{\text{ext}}(r,\theta) = -\frac{GM}{r}\left\{1 - \sum_{i=1}^{\infty}\left(\frac{R_{\text{eq}}}{r}\right)^{i} J_i P_i(\cos\theta)\right\} \qquad [1]$$

where $V_{\text{ext}}(r, \theta)$ is the gravity field evaluated outside the planet at a distance r and colatitude θ, R_{eq} is the equatorial radius, and J_i are the gravitational moments. Because the giant planets are very close to hydrostatic equilibrium, the coefficients of even order are the only ones that are not negligible. We will see how these gravitational moments, as listed in Table 1, help us constrain the planets' interior density profiles.

Table 1 also indicates the radii obtained with the greatest accuracy by radio-occultation experiments. An important consequence obtained is the fact that these planets have low densities, from 0.688 g cm^{-3} for Saturn to 1.64 g cm^{-3} for Neptune, to be compared with densities of 3.9–5.5 g cm^{-3} for the terrestrial planets in the solar system. Considering the compression that strongly increases with mass, one is led naturally to the conclusion that these planets contain an important proportion of light materials including hydrogen and helium. It also implies that Uranus and Neptune, which are less massive, must contain a relatively larger proportion of heavy elements than Jupiter and Saturn. This may lead to a subclassification between the hydrogen–helium giant planets Jupiter and Saturn and the 'ice giants' or 'subgiants' Uranus and Neptune.

The planets are also relatively fast rotators, with periods of ~10 h for Jupiter and Saturn and ~17 h for Uranus and Neptune. The fact that this fast rotation visibly affects the figure (shape) of these planets is seen by the significant difference between the polar and equatorial radii. It also leads to gravitational moments that differ significantly from a null value. However, it is important to stress that there is no unique rotation frame for these fluid planets: Atmospheric zonal winds imply that different latitudes rotate at different velocities (see Section 10.16.2.4), and the magnetic field provides another rotation period. Because the latter is tied to the deeper levels of the planet, it is believed to be more relevant when interpreting the gravitational moments. The rotation periods listed in Table 1 hence correspond to that of the magnetic field. The case of Saturn is complex and to be discussed in the next section.

10.16.2.3 Magnetic Fields

As the Earth, the Sun, and Mercury, our four giant planets possess their own magnetic fields. These magnetic fields **B** may be expressed in form of a development in spherical harmonics of the scalar potential W, such that $\mathbf{B} = -\nabla W$:

$$W = a\sum_{n=1}^{\infty}\left(\frac{a}{r}\right)^{n+1}\sum_{m=0}^{n}\left\{g_n^m\cos(m\phi) + h_n^m\sin(m\phi)\right\}P_n^m(\cos\theta) \qquad [2]$$

where r is the distance to the planet's center, a its radius, θ the colatitude, ϕ the longitude, and P_n^m the associated Legendre polynomials. The coefficients g_n^m and h_n^m are the magnetic moments that characterize the field. They are expressed in magnetic field units.

One can show that the first coefficients of relation [2] (for $n = 0$ and 1) correspond to the potential of a magnetic dipole such that $W = \mathbf{M}\cdot\mathbf{r}/r^3$ of moment:

$$M = a^3\left\{\left(g_1^0\right)^2 + \left(g_1^1\right)^2 + \left(h_1^1\right)^2\right\}^{1/2} \qquad [3]$$

As shown by the Voyager 2 measurements, Jupiter and Saturn have magnetic fields of essentially dipolar nature, of axis close to the rotation axis (g_1^0 is much larger than the other harmonics); Uranus and Neptune have magnetic fields that are intrinsically much more complex. To provide an idea of the intensity of the magnetic fields, the values of the dipolar moments for the four planets are 4.27 gauss R_J^3, 0.21 gauss R_S^3, 0.23 gauss R_{UI}^3, and 0.133 gauss R_N^3, respectively (Acuna et al., 1983; Connerney et al., 1982; Ness et al., 1986, 1989; see also **Chapter 10.06**).

A true surprise from *Voyager* that has been confirmed by the *Cassini–Huygens* mission is that Saturn's magnetic field is axisymmetric *to the limit of the measurement accuracy*: Saturn's magnetic and rotation axes are perfectly aligned (e.g., Russell and Dougherty, 2010). Voyager measurements indicated nevertheless a clear signature in the radio signal at $10^h39^m22.4^s$ believed to be a consequence of the rotation of the magnetic field. New measurements of a slower spin period of $10^h47^m6^s$ by Cassini (Giampieri et al., 2006; Gurnett et al., 2005) have shown that the kilometric radiation was not directly tied to the period of the magnetic field but resulted from a complex interplay between the spin of the planetary magnetic field and the solar wind (e.g., Cecconi and Zarka, 2005). New periods have been proposed: $10^h32^m35^s$ based on a minimization of the zonal differential rotation (Anderson and Schubert, 2007) and $10^h33^m13^s$ based on the latitudinal distribution of potential vorticity (Read et al., 2009). The problem still stands out.

These magnetic fields must be generated in the conductive parts of the interiors, that is, in metallic hydrogen at radii that

Table 1 Characteristics of the gravity fields and radii

	Jupiter	*Saturn*	*Uranus*	*Neptune*

$J_6 \times 10^4$	0.31(20)[a]	0.861(96)[b]		
$P_\omega \times 10^{-4}$ (s)	3.57297(41)[j]	3.83624(47)[j,k]	6.206(4)[l]	5.800(20)[m]
q	0.08923(5)	0.15491(10)	0.02951(5)	0.02609(23)
C/MR_{eq}^2	0.258	0.220	0.230	0.241

The numbers in parentheses are the uncertainty in the last digits of the given value. The value of the gravitational constant used to calculate the masses of Jupiter and Saturn is $G = 6.67259 \times 10^{-11}$ N m^2 kg^{-2} (Cohen and Taylor, 1987). The values of the radii and density correspond to the one bar pressure level (1 bar $= 10^5$ Pa). Gravitational moments are normalized at the reference radius R_{ref}. Only values published in refereed journals are considered.

are about 80% and 60% of the planetary radius for Jupiter and Saturn, respectively (see **Sections 10.16.3.2** and **10.16.4.1**; e.g., Stanley and Glatzmaier, 2010). Recent models that consistently join the slowly convecting metallic interior with the nonconducting outer molecular envelope dominated by zonal flows result in a mainly dipolar magnetic field similar to the observations and further show that Jupiter's stronger magnetic field and Saturn's broader equatorial jet (see next section) can be interpreted as resulting from the deeper location of the transition region in Saturn (Heimpel and Gómez Pérez, 2011). These explanations remain largely qualitative rather than quantitative and are further complicated by a necessary overforcing of the simulations (see Showman et al., 2011, and next section). The question of why Saturn's magnetic field is much more axisymmetric than Jupiter's remains. Dipolar fields are obtained relatively naturally through the forcing of zonal jets extending down to the conducting region (Guervilly et al., 2012) but why Jupiter differs is unexplained. A possibility is that both fields are nonaxisymmetric at deep levels but that Saturn's is filtered by a more extended helium sedimentation region (Stevenson, 1983), but in practice, a realistic solution yielding Saturn's measured field has not been found (Stanley and Glatzmaier, 2010, and references therein).

Within Uranus and Neptune, the magnetic field is believed to be generated within a layer in which water is in an ionic phase, below about 80% of their total radius (see Redmer et al., 2011, and **Section 10.16.4.2** hereafter). Their complex, multipolar magnetic fields has been thought to be a consequence of a strong stratification and of a dynamo generated in a thin shell (Stanley and Bloxham, 2004). However, this point of view is now challenged by new simulations that generate both planets' magnetic fields and zonal wind structures through a thick shell dynamo (Soderlund et al., 2013). Further work however must involve realistic variations of the interior density and conductivity.

10.16.2.4 Atmospheric Dynamics: Winds and Weather

The atmospheres of all giant planets are evidently complex and turbulent in nature. This can, for example, be seen from the mean zonal winds (inferred from cloud tracking), which are very rapidly varying functions of the latitude (see, e.g., Ingersoll et al., 1995): while some of the regions rotate at the same speed as the interior magnetic field (in the so-called 'system III' reference frame), most of the atmospheres do not. Jupiter and Saturn both have superrotating equators (+100 and +400 m s^{-1} in system III, for Jupiter and Saturn, respectively), and Uranus and Neptune have subrotating equators and superrotating high-latitude jets. Neptune, which receives the smallest amount of energy from the Sun, has the largest peak-to-peak latitudinal variations in wind velocity: about 600 m s^{-1}. It can be noted that, contrary to the case of the strongly irradiated planets to be discussed later, the winds of Jupiter, Saturn, Uranus, and Neptune are significantly slower than the planet itself under its own spin (from 12.2 km s^{-1} for Jupiter to 2.6 km s^{-1} for Neptune, at the equator).

It is not yet clear whether the observed winds are driven from the bottom or from the top. The first possibility is that surface winds are related to motions in the planets' interiors, which, according to the Taylor–Proudman theorem, should be confined by the rapid rotation to the plane perpendicular to the axis of rotation (Busse, 1978). This is now backed by simulations in the anelastic limit (i.e., accounting for compressibility), which show that the outcome strongly depends on the density stratification in the interior. A small density contrast (as expected in Jupiter and Saturn) leads to equatorial superrotation, whereas for a large one (as expected for Uranus and Neptune), the equatorial jet tends to subrotate (Gastine et al., 2013; Glatzmaier et al., 2009). However, the application of these numerical results to the true conditions prevailing in the giant planets requires an extrapolation over at least six orders of magnitude (Showman et al., 2011). The second possibility (not exclusive) is that winds are driven from the top by the injection of turbulence at the cloud level, which can also lead to the correct winds for the four giant planets (Lian and Showman, 2010; Liu and Schneider, 2011).

Information on the gravity field of the planets can be used to constrain the interior rotation profile, as in the case of Uranus and Neptune whose observed jets appear to only extend to the outer 0.15% and 0.20% of the mass (corresponding to pressures of 2 and 4 kbar) for Uranus and Neptune, respectively (Kaspi et al., 2013). The method is promising with the perspective of the Juno measurements at Jupiter (Liu et al., 2013).

Our giant planets also exhibit planetary-scale to small-scale storms with very different temporal variations. For example, Jupiter's Great Red Spot is a 12 000 km diameter anticyclone found to have lasted for at least 300 years (e.g., Simon-Miller et al., 2002). Storms developing over the entire planet have even been observed on Saturn (Sanchez-Lavega et al., 1996). Uranus and Neptune's storm system has been shown to have been significantly altered since the Voyager era (de Pater et al., 2011; Hammel et al., 2005; Rages et al., 2002). On Jupiter, small-scale storms related to cumulus-type cloud systems have been observed (e.g., Gierasch et al., 2000; Hueso et al., 2002), and lightning strikes have been monitored by Galileo (e.g., Little et al., 1999). These represent only a small arbitrary subset of the work concerning the complex atmospheres of these planets.

It is tempting to extrapolate these observations to the objects outside our solar system as well. However, two features governing the weather in these are not necessarily present for exoplanets (e.g., Guillot, 1999b): their rapid rotation and the presence of abundant condensing species and in particular one, water, whose latent heat can fuel powerful storms. But as we will see briefly in **Section 10.16.2.10** theoretical models for exoplanets are now complemented by measurements of wind speeds and of global temperature contrasts, offering the perspective of a global approach to planetary weather and atmospheric dynamics.

10.16.2.5 Energy Balance and Atmospheric Temperature Profiles

Jupiter, Saturn, and Neptune are observed to emit more energy than they receive from the Sun (see **Table 2**). The case of Uranus is less clear. Its intrinsic heat flux $F_{\rm int}$ is significantly smaller than that of the other giant planets. With this caveat, all four giant planets can be said to emit more energy than they receive from the Sun. Hubbard (1968) showed in the case of Jupiter that this can be explained simply by the progressive contraction and cooling of the planets.

A crucial consequence of the presence of an intrinsic heat flux is that it requires high internal temperatures ($\sim$10 000 K or more) and that consequently the giant planets are *fluid* (not solid) (Hubbard, 1968; see also Hubbard et al., 1995). Another consequence is that they are essentially convective and that their interior temperature profile is close to *adiabats*. We will come back to this in more detail.

The deep atmospheres (more accurately tropospheres) of the four giant planets are indeed observed to be close to adiabats, a result first obtained by spectroscopic models (Trafton, 1967), then verified by radio-occultation experiments by the Voyager spacecrafts, and by the in situ measurement from the Galileo probe (**Figure 3**). The temperature profiles show a temperature minimum, in a region near 0.2 bar called the tropopause. At higher altitudes, in the stratosphere, the temperature gradient is negative (increasing with decreasing pressure). In the regions that we will be mostly concerned with, in the troposphere and in the deeper interior, the temperature always increases with depth. It can be noticed that the slope of the temperature profile in **Figure 3** becomes almost constant

Table 2 Energy balance as determined from Voyager IRIS data

	Jupiter	*Saturn*	*Uranus*	*Neptune*
Absorbed power (10^{16} J s^{-1})	50.14 ± 2.48	11.14 ± 0.50	0.526 ± 0.037	0.204 ± 0.019
Emitted power (10^{16} J s^{-1})	83.65 ± 0.84	19.77 ± 0.32	0.560 ± 0.011	0.534 ± 0.029
Intrinsic power (10^{16} J s^{-1})	33.5 ± 2.6	8.63 ± 0.60	$0.034^{+0.038}_{-0.034}$	0.330 ± 0.035
Intrinsic flux (J s^{-1} M^{-2})	5.44 ± 0.43	2.01 ± 0.14	$0.042^{+0.047}_{-0.042}$	0.433 ± 0.046
Bond albedo	0.343 ± 0.032	0.342 ± 0.030	0.300 ± 0.049	0.290 ± 0.067
Effective temperature (K)	124.4 ± 0.3	95.0 ± 0.4	59.1 ± 0.3	59.3 ± 0.8
1 Bar temperature[a] (K)	165 ± 5	135 ± 5	76 ± 2	72 ± 2

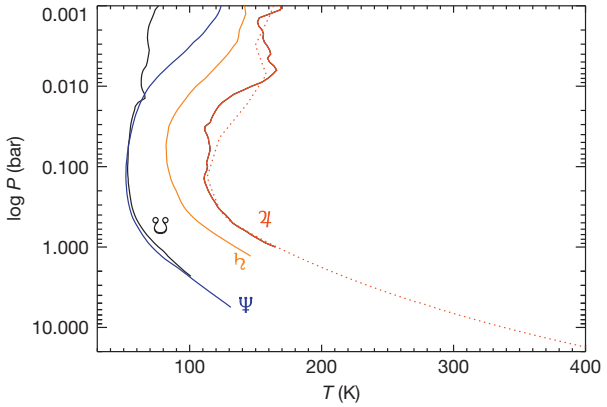

Figure 3 Atmospheric temperatures as a function of pressure for Jupiter, Saturn, Uranus, and Neptune, as obtained from Voyager radio-occultation experiments (see Lindal, 1992). The dotted line corresponds to the temperature profile retrieved by the Galileo probe, down to 22 bar and a temperature of 428 K (Seiff et al. 1998).

when the atmosphere becomes convective, at pressures of a fraction of a bar, in the four giant planets.

It should be noted that the 1 bar temperatures listed in Table 2 and the profiles shown in Figure 3 are retrieved from radio-occultation measurements using a helium–hydrogen ratio, which, at least in the case of Jupiter and Saturn, was shown to be incorrect. The new values of Y are found to lead to increased temperatures by $\sim$5 K in Jupiter and $\sim$10 K in Saturn (see Guillot, 1999a). However, the Galileo probe found a 1 bar temperature of 166 K (Seiff et al., 1998) and generally a good agreement with the Voyager radio-occultation profile with the wrong He/H_2 value.

When studied at low spatial resolution, it is found that all four giant planets, in spite of their inhomogeneous appearances, have a rather uniform brightness temperature, with pole-to-equator latitudinal variations limited to a few kelvins (e.g., Ingersoll et al., 1995). However, in the case of Jupiter, some small regions are known to be very different from the average of the planet. This is the case of hot spots, which cover about 1% of the surface of the planet at any given time but contribute to most of the emitted flux at 5 μm, due to their dryness (absence of water vapor) and their temperature brightness which can, at this wavelength, peak to 260 K.

10.16.2.6 Atmospheric Compositions

In fluid planets, the distinction between the atmosphere and the interior is not obvious. We name 'atmosphere' the part of the planet that can directly exchange radiation with the exterior environment. This is also the part that is accessible by remote sensing. It is important to note that the continuity between the atmosphere and the interior does not guarantee that compositions measured in the atmosphere can be extrapolated to the deep interior, even in a fully convective environment: Processes such as phase separations (e.g., Fortney and Hubbard, 2003; Salpeter, 1973; Stevenson and Salpeter, 1977b), phase transitions (e.g., Hubbard, 1989), chemical reactions (e.g., Fegley and Lodders, 1994), and cloud formation (e.g., Rossow, 1978) can occur and decouple the surface and interior compositions. Furthermore, imperfect mixing may also occur, depending on the initial conditions (e.g., Stevenson, 1985).

The conventional wisdom is however that these processes are limited to certain species (e.g., helium) or that they have a relatively small impact on the global abundances, so that the hydrogen–helium envelopes may be considered relatively uniform, from the perspective of the global abundance in heavy elements. An important caveat is that measurements must probe deeper than the condensation altitude for any volatile (e.g., ammonia and water). We first discuss measurements made in the atmosphere before inferring interior compositions from interior and evolution models.

10.16.2.6.1 Hydrogen and helium

The most important components of the atmospheres of our giant planets are also among the most difficult to detect: H_2 and He have a zero dipolar moment and hence absorb very inefficiently visible and infrared light. Absorption in the infrared becomes important only at high pressures as a result of collision-induced absorption (e.g., Borysow et al., 1997). On the other hand, lines due to electronic transitions correspond to very high altitudes in the atmosphere and bear little information on the structure of the deeper levels. The only robust result concerning the abundance of helium in a giant planet is by in situ measurement by the Galileo probe in the atmosphere of Jupiter (von Zahn et al., 1998). The helium mole fraction (i.e., number of helium atoms over the total number of species in a given volume) is $q_{He} = 0.1359 \pm 0.0027$. The helium mass mixing ratio Y (i.e., mass of helium atoms over total mass) is constrained by its ratio over hydrogen, $X{:}Y/(X+Y) = 0.238 \pm 0.05$. This ratio is by coincidence that found in the Sun's atmosphere, but because of helium sedimentation in the Sun's radiative zone, it was larger in the protosolar nebula: $Y_{proto} = 0.275 \pm 0.01$ and $(X+Y)_{proto} \approx 0.98$ (e.g., Bahcall et al., 1995). Less helium is therefore found in the atmosphere of Jupiter than inferred to be present when the planet formed. We will discuss the consequences of this measurement later: let us mention that the explanation invokes helium settling due to a phase separation in the interiors of massive and cold giant planets.

Helium is also found to be depleted compared to the protosolar value in Saturn's atmosphere. However, in this case, the analysis is complicated by the fact that Voyager radio-occultations combined with the far-IR sounding (to separate effects of helium from that of temperature) led to a wrong value for Jupiter when compared to the Galileo probe data and hence are suspect for the other planets. The current adopted value from IR data only is now $Y = 0.18 - 0.25$ (Conrath and Gautier, 2000), in agreement with values predicted by interior and evolution models (Guillot, 1999b; Hubbard et al., 1999).

Finally, as shown in Table 3 hereafter, Uranus and Neptune are found to have near-protosolar helium mixing ratios, but with considerable uncertainty.

10.16.2.6.2 Heavy elements

The abundance of elements other than hydrogen and helium (that we will call hereafter 'heavy elements') bears crucial information for the understanding of the processes that led to the formation of these planets. Table 3 summarizes the present

Table 3 Elemental abundances measured in the tropospheres of the giant planets

Element	*Carrier*	*Abundance ratio/H*[a]	*Protosun*[b]	*Planet/protosun*	*Method*
Jupiter					
He/H	He	$(7.85 \pm 0.18) \times 10^{-2}$	9.69×10^{-2}	0.810 ± 0.019	Galileo/GPMS[c]
C/H	CH_4	$(1.185 \pm 0.019) \times 10^{-3}$	2.75×10^{-4}	4.31 ± 0.07	Galileo/GPMS[d]
N/H	NH_3	$(3.3 \pm 1.3) \times 10^{-4}$	8.19×10^{-5}	4.05 ± 1.55	Galileo/GPMS[d]
O/H	H_2O[e]	$(1.49^{+0.98}_{-0.68}) \times 10^{-4}$	6.06×10^{-4}	$0.25^{+0.16}_{-0.11}$	Galileo/GPMS at 19 bar[d]
S/H	H_2S	$(4.5 \pm 1.1) \times 10^{-5}$	1.55×10^{-5}	2.88 ± 0.68	Galileo/GPMS[d]
Ne/H	Ne	$(1.20 \pm 0.12) \times 10^{-5}$	1.18×10^{-4}	0.10 ± 0.01	Galileo/GPMS[f]
Ar/H	Ar	$(9.10 \pm 1.80) \times 10^{-6}$	3.58×10^{-6}	2.54 ± 0.50	Galileo/GPMS[f]
Kr/H	Kr	$(4.65 \pm 0.85) \times 10^{-9}$	2.15×10^{-9}	2.16 ± 0.40	Galileo/GPMS[f]
Xe/H	Xe	$(4.45 \pm 0.85) \times 10^{-10}$	2.11×10^{-10}	2.11 ± 0.40	Galileo/GPMS[f]
P/H	PH_3[e]	$(1.11 \pm 0.06) \times 10^{-6}$	3.20×10^{-7}	3.45 ± 0.18	Cassini/CIRS[g]
Ge/H	GeH_4[e]	$(4.1 \pm 1.2) \times 10^{-10}$	4.44×10^{-9}	0.09 ± 0.03	Voyager/IRIS[h]
As/H	AsH_3[e]	$(1.3 \pm 0.6) \times 10^{-10}$	2.36×10^{-10}	0.54 ± 0.27	Ground/IR[i]
Saturn					
He/H	He	$(6.75 \pm 1.25) \times 10^{-2}$	9.69×10^{-2}	0.70 ± 0.13	Voyager/IRIS[j]
C/H	CH_4	$(2.67 \pm 0.11) \times 10^{-3}$	2.75×10^{-4}	9.72 ± 0.41	Cassini/CIRS[k]
N/H	NH_3[e]	$(2.27 \pm 0.57) \times 10^{-4}$	8.19×10^{-5}	2.77 ± 0.69	Cassini/VIMS[l]
S/H	H_2S	$(1.25 \pm 0.17) \times 10^{-4}$	1.55×10^{-5}	8.08 ± 1.10	Ground/radio[m]
P/H	PH_3[e]	$(4.65 \pm 0.32) \times 10^{-6}$	3.20×10^{-7}	14.5 ± 1.0	Cassini/CIRS[g]
		$(1.76 \pm 0.17) \times 10^{-6}$	3.20×10^{-7}	5.49 ± 0.53	Cassini/VIMS[k]
		$(4.0^{+1.7}_{-1.1}) \times 10^{-6}$	3.20×10^{-7}	$12.4^{+5.3}_{-3.5}$	Ground/IR[n]
Ge/H	GeH_4[e]	$(2.3 \pm 2.3) \times 10^{-10}$	4.44×10^{-9}	0.05 ± 0.05	Ground/IR[n]
As/H	AsH_3[e]	$(1.25 \pm 0.17) \times 10^{-9}$	2.36×10^{-10}	5.33 ± 0.73	Cassini/VIMS[k]
		$(1.71 \pm 0.57) \times 10^{-9}$	2.36×10^{-10}	7.3 ± 2.4	Ground/IR[n]
Uranus

situation after in situ measurements in Jupiter by the Galileo probe, as well as spectroscopic measurements from spacecraft and from the ground for the other planets.

The elemental abundances in the giant planets' atmospheres are most usefully compared to those in the Sun since they all originated from the protosolar disk. The solar abundances have seen very significant revisions in the past decade because it has been realized that convective motions in the Sun's atmosphere affect spectral lines more extensively than what was previously thought. It is not yet clear at this date whether the solar abundances have converged. Furthermore, as discussed for helium, heavy elements gradually settle toward the Sun's interior so that a proper reference for the giant planets is not the solar atmosphere today, but its value 4.5 billion years ago that is model-dependent. **Table 3** provides the values obtained for the protosun by Lodders et al. (2009). These are used as reference without accounting for their uncertainties.

The most abundant heavy elements in the envelopes of our four giant planets are O (presumably) and C, N, and S. It is possible to model the chemistry of gases in the tropospheres from the top of the convective zone down to the 2000 K temperature level (Fegley and Lodders, 1994). Models conclude that, whatever the initial composition in these elements of planetesimals that collapsed with hydrogen onto Jupiter and Saturn cores during the last phase of the planetary formation, C in the upper tropospheres of the giant planets is mainly in the form of gaseous CH_4, N in the form of NH_3, S in the form of H_2S, and O in the form of H_2O. All these gases but methane in Jupiter and Saturn condense in the upper troposphere and vaporize at deeper levels when the temperature increases. Noble gases do not condense even at the tropopauses of Uranus and Neptune, the coldest regions in these atmospheres.

Jupiter is the planet that has been best characterized, thanks to the measurements of the Galileo atmospheric probe that precisely measured the abundances of He, Ne, Ar, Kr, Xe, CH_4, NH_3, H_2S, and H_2O down to pressures around 22 bars. As helium, neon was found to be depleted compared to the protosolar value, in line with theoretical predictions that this atom would fall in with the helium droplets (Roulston and Stevenson, 1995; Wilson and Militzer, 2010; **Section 10.16.3.2.2**). C, N, and S were found to be supersolar by a factor 2.5–4.5 (Wong et al., 2004), which was not unexpected because condensation of nebula gases results in enriching icy grains and planetesimals. The surprise came from Ar, Kr, and Xe, which were expected to be solar because they are difficult to condense but turned out to be supersolar by a factor $\sim$2 (Owen et al., 1999; Wong et al., 2004).

H_2O is difficult to measure in all four giant planets because of its condensation being relatively deep. It was hoped that the Galileo probe would provide a measurement of its deep abundance, but the probe fell into one of Jupiter's 5 μm hot spots, now believed to be a dry region mostly governed by downwelling motions (e.g., Showman and Ingersoll, 1998). As a result and although the probe provided measurements down to 22 bars, well below water's canonical 5 bar cloud base, it is believed that this measurement of a water abundance equal to a fraction of the solar value is only a lower limit. An indirect determination comes from the measurement of the disequilibrium species CO that has to be transported fast from the deep levels where H_2O and CH_4 tend to form more CO (and H_2). This predicts a mostly solar to slightly supersolar (by a factor 2) abundance of O in Jupiter (Visscher and Moses, 2011) and much larger enrichments in Neptune (Lodders and Fegley, 1994). This however depends crucially on the reaction network and somewhat on assumptions on mixing, both of which are not well known. The abundance of oxygen, the most abundant element in the universe after hydrogen and helium and a crucial planetary building block, is essentially unknown for what concerns our four giant planets.

Three other species can help us probe the bulk elemental abundance inside Jupiter, although with larger difficulties perhaps because they are not necessarily in chemical equilibrium at the levels where they are detected and their measured abundances are thus not necessarily representative of their bulk abundance: these are PH_3, GeH_4, and AsH_3. All three were detected remotely rather than in situ. The first one is clearly supersolar in Jupiter, with an enrichment in between that measured for C and S. GeH_4 is clearly subsolar, but this is not surprising because of condensation into solid Ge and GeS (Fegley and Lodders, 1994). The same chemical models would predict that the measured abundance of AsH_3 should be close to its bulk abundance. The measured abundance therefore could be interpreted as a subsolar bulk abundance of As but with considerable uncertainty.

Table 3 shows that Saturn's atmosphere is more enriched in heavy elements than Jupiter. Unfortunately, unlike Jupiter, no in situ measurement has been performed in this planet and we can only rely on remote sensing. But we can confidently assess that the abundances of C, S, P, and As are significantly higher than in Jupiter. Saturn has about twice more C (as CH_4) and S (as H_2S) than Jupiter, for a given mass of atmosphere. The situation for PH_3 is unclear, because it is highly variable both vertically and latitudinally: the enrichment could be only slightly more than in Jupiter to more than four times that value (Fletcher et al., 2009a, 2011). Note that in the presence of horizontal variability (as for this molecule), **Table 3** indicates the maximum abundances measured – which should be closer to the bulk abundance, except if there exist mechanisms to preferentially trap certain species. The enrichment in N (as NH_3) is smaller than in Jupiter. This may be due to its condensation deeper as NH_4SH (Gulkis et al., 1978), although it does not explain why Jupiter and Saturn would be that different in that respect. The enrichment in As (as AsH_4) is considerably larger than in Jupiter, which is also a mystery (Fletcher et al., 2009b). At least, GeH_4 appears to be of equally low abundance in both planets, but this is probably more related to its condensation than to its bulk abundance.

Finally, Uranus and Neptune provide all signs of a significant enrichment in heavy elements, even though very few elements have been detected. Methane is the most important one, although the fact that it condenses in these planets complicates the interpretation of the spectroscopic measurements. Large-scale variations with latitude are observed, in particular in Uranus (Sromovsky et al., 2011), but less so in Neptune (Karkoschka and Tomasko, 2011). However, the deep abundances provided in **Table 3** are very similar for both planets, with a $\sim$90 times solar enrichment. This is much higher than

the ~30 times solar enrichments discussed in past reviews (e.g., Gautier et al., 1995) for two reasons: one is a decrease of the protosolar abundance itself. The other is the fact that it relied on spectroscopic measurements probing higher atmospheric levels affected by methane condensation (see Karkoschka and Tomasko, 2011).

The other key species detected in Uranus and Neptune thanks to ground-based radio observations is H_2S, which points to a 10–30 enrichment in sulfur (de Pater et al., 1991). Because this element condenses at even greater depths than methane, the bulk abundance of S in these planets may be larger if the global circulation is indeed important down to the deep levels probed by the radio waves. The measurement is however a difficult one, with other potential absorbers affecting the smooth microwave spectra yielding degenerate solutions.

Overall, the global picture that can be drawn is that of an increase of the abundance of heavy elements compared to the solar value with increasing distance to the Sun, from Jupiter that shows a ~2–4 enrichment, Saturn that shows a 3–10 one, and Uranus and Neptune that are enriched by a factor ~90 in carbon and by at least 10–30 in sulfur. In spite of their different atmospheric dynamics, and with the present accuracy of the measurements, the two ice giants have very similar abundances.

10.16.2.7 Isotopic Ratios

The measurement of isotopic ratios in planetary atmospheres is a powerful tool to understand their origin. Table 4 provides the ensemble of isotopic ratios measured in our giant planets and a comparison to their values in the Sun.

Of course, the Galileo probe and its onboard mass spectrometer have provided us a strikingly clear picture of Jupiter's atmosphere: it is directly formed from the same material as our Sun, with isotopic ratios that are, to the accuracy of the measurements, indistinguishable (i.e., within 2 sigma) from the solar values and for elements as diverse as D, He, C, N, Ne, Ar, and Xe with as many as six isotopes measured. This was expected because indeed Jupiter's composition is globally similar to that of the Sun, but given the fact that the abundances of elements are far from being Sun-like, it is perhaps surprising to find such a good match! By extension, this applies to Saturn although only the deuterium to hydrogen and $^{13}C/^{12}C$ isotopic ratios could be measured by remote spectroscopic observations. This confirms that the atmospheres and envelopes of Jupiter and Saturn originated from the same material that formed the Sun and that mechanisms leading to isotopic fractionation (e.g., atmospheric evaporation) were of limited importance.

In the case of Uranus and Neptune, only the deuterium to hydrogen ratio was measured, from the ground in the infrared (Irwin et al., 2014) and most precisely by recent far-infrared spectroscopy from Herschel (Feuchtgruber et al., 2013). Interestingly, it is about twice larger than the protosolar value and a factor two to six times smaller than the D/H value in comets. Given our present knowledge of the interiors of Uranus and Neptune, Feuchtgruber et al. (2013) concluded that either these planets contain much more rocks than expected or the ices in their interior have not been fully mixed.

Table 4 Isotopic ratios measured in the tropospheres of the giant planets

Isotope	*Isotopic ratio*	*Protosun*[a]	*Planet/protosun*	*Comments*
Jupiter				
D/H	$(2.25\pm0.35)\times10^{-5}$	1.94×10^{-5}	1.16 ± 0.18	ISO/SWS[b]

10.16.2.8 Moons and Rings

A discussion of our giant planets motivated by the opportunity to extrapolate the results to objects outside our solar system would be incomplete without mentioning the moons and rings that these planets all possess (see Chapters 10.08, 10.17, and 10.18). First, the satellites/moons can be distinguished from their orbital characteristics as regular or irregular. The first ones have generally circular, prograde orbits. The latter tend to have eccentric, extended, and/or retrograde orbits.

These satellites are numerous: After the Voyager era, Jupiter was known to possess 16 satellites, Saturn 18, Uranus 20, and Neptune 8. Recent extensive observation programs have seen the number of satellites increase considerably, with a growing list of satellites presently reaching 62, 56, 27, and 13 for Jupiter, Saturn, Uranus, and Neptune, respectively. All of the new satellites discovered since Voyager are classified as irregular.

The presence of regular and irregular satellites is due in part to the history of planet formation. It is believed that the regular satellites have mostly been formed in the protoplanetary subnebulae that surrounded the giant planets (at least Jupiter and Saturn) at the time when they accreted their envelopes. On the other hand, the irregular satellites are thought to have been captured by the planet. This is, for example, believed to be the case of Neptune's largest moon, Triton, which has a retrograde orbit.

A few satellites stand out by having relatively large masses: it is the case of Jupiter's Io, Europa, Ganymede, and Callisto; of Saturn's Titan; and of Neptune's Triton. Ganymede is the most massive of them, being about twice the mass of our Moon. However, compared to the mass of the central planet, these moons and satellites have very small weights: 10^{-4} and less for Jupiter, 1/4000 for Saturn, 1/25 000 for Uranus, and 1/4500 for Neptune. All these satellites orbit relatively closely to their planets. The farthest one, Callisto revolves around Jupiter in about 16 Earth days.

The four giant planets also have rings, whose material is probably constantly resupplied from their satellites. The ring of Saturn stands out as the only one directly visible with binoculars. In this particular case, its enormous area allows it to reflect a sizable fraction of the stellar flux arriving at Saturn and makes this particular ring as bright as the planet itself. The occurrence of such rings would make the detection of extrasolar planets slightly easier, but it is yet unclear how frequent they can be and how close to the stars rings can survive both the increased radiation and tidal forces.

10.16.2.9 Seismology

The best way to directly probe planetary (or stellar) interiors is through seismology, that is, by measuring the spectrum of waves propagating through the interior. Our knowledge of the interior structure of the Earth, the Sun, and even other stars is largely due to the ability to detect the oscillations of these objects. Because Jupiter (and by extent the other giant planets in our solar system) is similar in composition and density to the Sun, the possibility to detect pressure waves in their atmosphere has been proposed in the 1970s. In particular, Vorontsov et al. (1976) showed that waves with periods smaller than about 10 min would be trapped and reflected downward in Jupiter's and Saturn's atmospheres, creating the possibility for resonant waves similar to those observed in the Sun to exist. On the theoretical side, the possibility of how these waves may be excited has however remained problematic (e.g., Bercovici and Schubert, 1987).

After two decades of promising but slow progress, the case for the existence of detectable free oscillations of the giant planets has recently taken a new turn. First, using ground-based Doppler imaging of Jupiter, Gaulme et al. (2011) detected an oscillation pattern with frequencies between 0.8 and 2 mHz and a characteristic spacing of the peak of 155.3 ± 2.2 μHz, in agreement with theoretical models. Separately, Hedman and Nicholson (2013) confirmed that waves observed by the Cassini spacecraft in Saturn's rings cannot be caused by satellites and therefore must result from oscillations in Saturn, as had been proposed by Marley and Porco (1993).

Further observations are required to better characterize the oscillations of these planets and start using them as probes of the planetary interiors (e.g., Jackiewicz et al., 2012). This is very promising however and should lead to a revolution in our understanding of the giant planets.

10.16.2.10 Exoplanets

Huge progress has been made in the field of extrasolar planets since the detection of the first giant planet orbiting a solar-type star by Mayor and Queloz (1995). As shown in Figure 4, more than a thousand planets are known at the time of this chapter, and importantly, more than four hundred planets that transit their star at each orbital revolution have been identified (Schneider et al., 2011; Wright et al., 2011). These transiting planets are especially interesting because of the possibility to

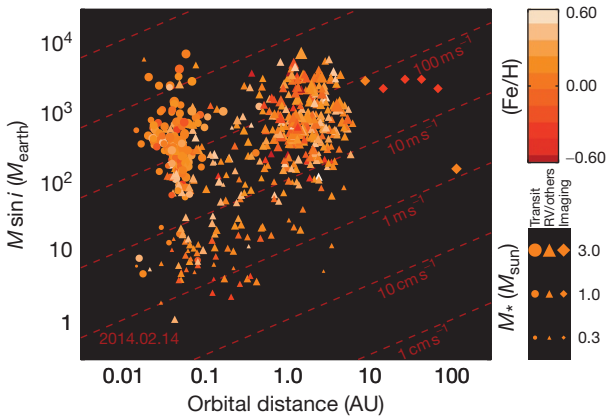

Figure 4 Masses and orbital distances of the extrasolar planets discovered by early 2014. Planets detected in transit are shown with circles, those detected by direct imaging with diamonds. All other systems (mostly detected by radial velocimetry) are shown as triangles. In the case of planets discovered by radial velocimetry, the displayed masses correspond to masses multiplied by the sine of the unknown inclination. The size of the symbols is proportional to the mass of the parent star (from 0.1 to 3.1 stellar masses). The color (from reddish to white) is proportional to the stellar metallicity (from [Fe/H] = −0.8 to 0.6). The radial velocimetry thresholds from 1 cm s^{-1} to 10 km s^{-1} are indicated as dashed lines.

measure both their mass and size and thus obtain constraints on their global composition.

In spite of their particular location just a few stellar radii away from their stars, the transiting giant planets that have been discovered bear some resemblance with their solar system cousins in the sense that they are also mostly made of hydrogen and helium (e.g., Baraffe et al., 2005; Burrows et al., 2000; Guillot, 2005). They are, however, much hotter due to the intense irradiation that they receive.

Although obtaining direct information on these planets represents a great observational challenge, several key steps have been accomplished: Atomic sodium, predicted to be detectable (Seager and Sasselov, 2000), has indeed been detected by transit spectroscopy(Charbonneau et al., 2002) early on and a tentative abundance measured in planet HD 209458 b. According to Sing et al. (2009), it appears to be oversolar by a factor ~ 2 at pressures deeper than about ~ 3 mbar and undersolar above that level (see also Vidal-Madjar et al., 2011). Hydrodynamically, escaping species (including hydrogen, oxygen, carbon, nitrogen, and heavier ions) have also been detected around the brightest hot Jupiters (e.g., Bourrier et al., 2013; Fossati et al., 2010; Vidal-Madjar et al., 2003). A theoretical study of the atmospheric dynamics of hot Jupiters (Showman and Guillot, 2002) predicted strong day–night temperature variations (up to 100s K), fast km s^{-1} zonal jets, and a displacement of the hottest point west of the substellar point. These have been confirmed by observations of transiting and nontransiting planets in the infrared (Harrington et al., 2006; Knutson et al., 2007) and by Doppler imaging of planetary CO lines (Snellen et al., 2010).

Unfortunately, the list of chemical species thought to have been detected (see Seager and Deming, 2010, for a review) has dwindled in recent years due to the realization that instrumental effects could mimic spectral signatures (e.g., Crouzet et al., 2012; Désert et al., 2009; Gibson et al., 2011), due to new observations with a better instrument (e.g., Deming et al., 2013) and generally because of the unexpected prevalence of hazes in these close-in exoplanets (e.g., Pont et al., 2013; Sing et al., 2009). After examination, claims of a high C/O ratio in some of these atmospheres also appear to be highly uncertain (Crossfield et al., 2012).

In any case, in spite of the hiccups, there is obviously a big potential for growth in this young field, and the comparison between fine observations made for the giant planets in our solar system and the more crude but also more statistically significant data obtained for planets around other stars promise to be extremely fruitful to better understand these objects.

10.16.3 The Calculation of Interior and Evolution Models

10.16.3.1 Basic Equations

The structure and evolution of a giant planet is governed by the following hydrostatic, thermodynamic, mass conservation, and energy conservation equations:

$$\frac{\partial P}{\partial r} = -\rho g \qquad [4]$$

$$\frac{\partial T}{\partial r} = \frac{\partial P}{\partial r}\frac{T}{P}\nabla_T \qquad [5]$$

$$\frac{\partial m}{\partial r} = 4\pi r^2 \rho \qquad [6]$$

$$\frac{\partial L}{\partial r} = 4\pi r^2 \rho\left(\dot{\varepsilon} - T\frac{\partial S}{\partial t}\right) \qquad [7]$$

where P is the pressure, ρ the density, and $g = Gm/r^2$ the gravity (m is the mass, r the radius, and G the gravitational constant). The temperature gradient $\nabla_T \equiv (d\ln T/d\ln P)$ depends on the process by which the internal heat is transported. L is the intrinsic luminosity, t is the time, S is the specific entropy (per unit mass), and $\dot{\varepsilon}$ accounts for the sources of energy due, for example, to radioactivity or more importantly nuclear reactions. Generally, it is a good approximation to assume $\dot{\varepsilon} \sim 0$ for objects less massive than ~ 13 M_J, that is, too cold to even burn deuterium (but we will see that in certain conditions, this term may be useful, even for low-mass planets).

The boundary condition at the center is trivial: $r = 0$; ($m = 0$, $L = 0$). The external boundary condition is more difficult to obtain because it depends on how energy is transported in the atmosphere. One possibility is to use the Eddington approximation and to write (e.g., Chandrasekhar, 1939): $r = R$; ($T_0 = T_{\text{eff}}$, $P_0 = 2/3\, g/\kappa$), where T_{eff} is the effective temperature (defined by $L = 4\pi R\sigma T_{\text{eff}}^4$, with σ being the Stefan–Boltzmann constant) and κ is a mean opacity. Note, for example, that in the case of Jupiter, $T_{\text{eff}} = 124$ K, $g = 26$ m s^{-2}, and $\kappa \approx 5 \times 10^{-3}(P/1\text{ bar})$ $m^2 kg^{-1}$. This implies $P_0 \approx 0.2$ bar (20 000 Pa), which, given the simplicity of the calculation, is surprisingly close to the location of Jupiter's real tropopause where $T \approx 110$ K. Actually, the properties of the opacities of important absorbing chemical species like water and their pressure dependence imply that photospheres around 0.1 bar should be common (Robinson and Catling, 2014).

However, the Eddington boundary condition should not be used in the case of irradiated atmospheres because it does not properly account for both the incoming flux (mostly at visible wavelengths for planets around solar-type stars) and the intrinsic flux (in the infrared). The fact that opacities differ at these wavelengths yields the possibility of thermal inversions (higher visible than infrared opacities) or a greenhouse effect (lower visible than infrared opacities) and thus a hotter interior, something that cannot be captured without accounting for the different fluxes. Analytical solutions of the radiative transfer problem exist in the semi-gray case (two opacities for the visible and infrared, respectively) (Guillot, 2010; Hansen, 2008) and can even be extended to include non-gray effects (Parmentier and Guillot, 2014). Numerical solutions in the nonirradiated, solar composition case are provided by Saumon et al. (1996) and for the irradiation levels and compositions relevant for the solar system giant planets by Fortney et al. (2011). In that case, a grid is used to relate the atmospheric temperature and pressure at a given level to the radius R, intrinsic luminosity L, and incoming stellar luminosity $L_{*\text{p}}$: $r = R$; ($T_0 = T_0(R, L, L_{*\text{p}})$, $P_0 = P_0(R, L, L_{*\text{p}})$). P_0 is chosen to satisfy the condition that the corresponding optical depth at that level should be much larger than unity.

10.16.3.2 High-Pressure Physics and Equations of State

10.16.3.2.1 Hydrogen

In terms of pressures and temperatures, the interiors of the giant planets lie in a region for which accurate equations of state (EOS) are extremely difficult to calculate. This is because molecules, atoms, and ions can all coexist, in a fluid that is partially degenerate (free electrons have energies that are determined by both quantum and thermal effects) and partially coupled (Coulomb interactions between ions are not dominant but must be taken into account). The presence of many elements and their possible interactions further complicate matters. For lack of space, this section will mostly focus on hydrogen whose EOS has seen the most important developments in recent years. A phase diagram of hydrogen (Figure 5) illustrates some of the important phenomena that occur in the giant planets.

The photospheres of the giant planets are generally relatively cold (50–3000 K) and at low pressure (0.1–10 bar, or 10^4–10^6 Pa), so that hydrogen is in molecular form and the perfect gas conditions apply. As one goes deeper into the interior, hydrogen and helium progressively become fluid. (The perfect gas relation tends to underestimate the pressure by 10% or more when the density becomes larger than about 0.02 g cm^{-3} ($P \gtrsim 1$ kbar in the case of Jupiter).)

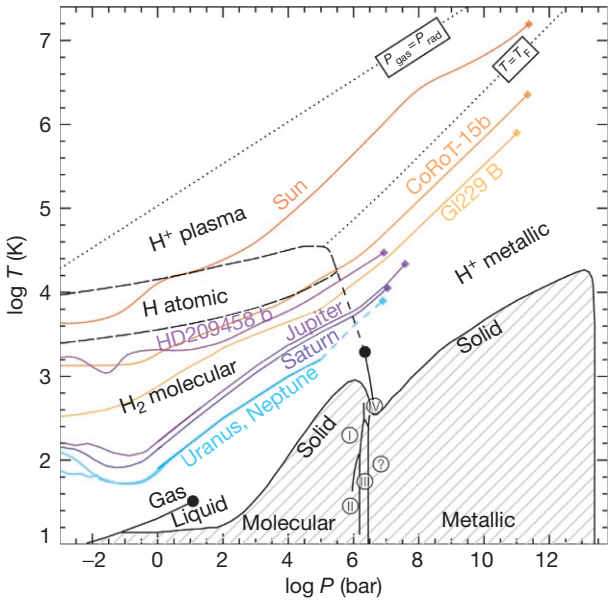

Figure 5 Phase diagram for hydrogen in the pressure–temperature plane, with pressure in bars (1 bar = 10^5 Pa = 10^6 dyn cm^{-2}). The thick lines indicate the first-order (discontinuous) phase transitions, the black circles, the critical points (McMahon et al., 2012; Morales et al., 2013b). Phase transitions in solid hydrogen with the different known phases are labeled I, II, III, and IV (McMahon et al., 2012). The region where 50% of all hydrogen is in atomic form (from Saumon et al., 1995) is shown by a thin contour. The approximate location of the molecular to metallic hydrogen (continuous) transition (Loubeyre et al., 2012; Morales et al., 2013b) is indicated by a dashed line. The $T = T_F$ line separates the nondegenerate region (at low pressures and high temperatures) from the region in which electrons are degenerate (see text). The $P_{gas} = P_{rad}$ line shows the region that is dominated by radiation pressure (at high temperatures). Colored lines show profiles for a selection of noteworthy substellar objects: giant planets from Uranus to Jupiter (Guillot, 2005), the hot Jupiter HD 209458 b (Burrows, 2013; Guillot and Showman, 2002), the brown dwarfs Gl 229 B (Marley et al., 1996), CoRoT-15 b (Bouchy et al., 2011), and our Sun (Christensen-Dalsgaard et al., 1996). The diamonds correspond to the conditions either at the core/envelope interface for Jupiter and Saturn or at the center for the other objects.

Characteristic interior pressures are considerably larger however: as implied by eqns [4] and [6], $P_c \approx GM^2/R^4$, of the order of 10–100 Mbar for Jupiter and Saturn. As shown in Figure 5, all the central pressures and temperatures of the giant planets and brown dwarfs (from Uranus to CoRoT-15b) lie in a regime of high pressures and temperatures lower than the corresponding Fermi temperature T_F, implying that electrons are degenerate: their pressure is mostly a function of the density of the material. In Jupiter and Saturn, the degeneracy parameter $\theta = T/T_F$ is always close to 0.03. Even for the warmer CoRoT-15b ($a \sim 60$ M_{Jup} brown dwarf discovered in transit in front of its parent star – see Bouchy et al., 2011), $\theta \approx 0.2$. This implies that for these objects, the thermal component is small so that the energy of electrons in the interior is expected to be only slightly larger than their nonrelativistic, fully degenerate limit: $u_e \geq 3/5\ kT_F = 15.6\ (\rho/\mu_e)^{2/3}$ eV, where k is Boltzmann's constant, μ_e is the number of nucleons per electron, and ρ is the density in g cm^{-3}. For pure hydrogen, when the density reaches $\sim$0.8 g cm^{-3}, the average energy of electrons becomes larger than hydrogen's ionization potential, even at zero temperature: hydrogen pressure ionizes and becomes metallic. This molecular to metallic transition occurs near Mbar pressures, but exactly how this happens is a result of the complex interplay of thermal, Coulomb, and degeneracy effects.

Recent laboratory measurements on fluid deuterium have been able to reach extremely high pressures up to 20 Mbar (Mochalov et al., 2012). Beyond that experimental feat, most of the progress of the decade in the domain has been the improvement in our understanding of the hydrogen metallization region at pressures of a fraction to a few Mbars, both from an experimental and numerical point of view (see the very complete review by McMahon et al., 2012). Already in the 1990s, gas-gun experiments had been able to measure a rise in the conductivity of molecular hydrogen up to $T \sim 3000$ K, $P \sim 1.4$ Mbar, a sign that metallization had been reached (Weir et al., 1996). A very sharp transition, probably discontinuous, was then later measured by isentropic convergent explosive shock experiments (Fortov et al., 2007) at pressures between 1.5 and 2.5 Mbar but uncertain temperatures below 4000 K (see McMahon et al., 2012). New experiments at higher temperatures using laser compression, directly (Sano et al., 2011) and from precompressed targets (Loubeyre et al., 2012), confirmed that this transition from a weakly conducting molecular fluid to a metal-like hydrogen fluid occurs around pressures near 1 Mbar and temperatures as high as 15 000 K, but that it is continuous at these temperatures. In parallel, ab initio calculations of the behavior of fluid hydrogen in this thermodynamical regime predicted the existence of a first-order liquid–liquid phase transition (the so-called PPT for *plasma phase transition*) with a critical point near $T \sim 1500$–2000 K and $P \sim 2.2$ Mbar (Morales et al., 2010, 2013b). This discontinuous transition at low temperatures merges into a continuous transition at temperatures above the critical point, in good agreement with the experimental data. The PPT is indicated by

a thick almost vertical line in Figure 5. It is prolonged by a dashed line indicating the location of the continuous transition from molecular to metallic hydrogen that extends up to the region of thermal dissociation and ionization of hydrogen.

The controversy that had arisen between laser-induced shock compression (Collins et al., 1998; da Silva et al., 1997) and pulsed-power shock compression (Knudson et al., 2004) regarding the maximum compression of deuterium along the principal shock Hugoniot has now been resolved in favor of the latter, thanks to new experiments (Boriskov et al., 2005; Hicks et al., 2009) and the realization that the equation of state of quartz used to calibrate the laser-induced shock experiments was incorrect (Knudson and Desjarlais, 2009). Similarly, the existence of a PPT of hydrogen at high temperatures in a regime crossing the adiabats of Jupiter and Saturn (Saumon et al., 1995) has now been shown to be a spurious effect resulting from the different treatment of molecules, atom, and ions within the so-called chemical picture (Chabrier et al., 2007). Both laboratory experiments and independent models based on first principles (Bonev et al., 2004; Desjarlais, 2003; French et al., 2012; Militzer et al., 2001; Vorberger et al., 2007) now agree and show that the transition from molecular to metallic hydrogen should occur continuously in all known giant planets.

Progress has also been made on the issue of the solidification of hydrogen (see McMahon et al., 2012, and references therein). This has led to the confirmation that the interiors of the hydrogen–helium giant planets and brown dwarfs are *fluid* whatever their age, a result expected since the pioneering study by Hubbard (1968). Of course, because of their initial gravitational energy, these objects are warm enough to avoid the critical point for the liquid–gas transition in hydrogen and helium, at very low temperatures, but they also lie comfortably above the solidification lines for hydrogen and helium. (An *isolated* Jupiter should begin partial solidification only after at least $\sim 10^3$ Ga of evolution.) They are considered to be fluid because at the high pressures and relatively modest temperatures in their interiors, Coulomb interactions between ions play an important role in the EOS and yield a behavior that is more reminiscent of that of a liquid than that of a gas, contrary to what is the case in, for example, solar-like stars. For Uranus and Neptune, the situation is actually more complex because at large pressures, they are not expected to contain a significant amount of hydrogen (see next section).

As Figure 5 highlights, while some highly irradiated planets and brown dwarfs like CoRoT-15b have temperature profiles that get close to the hydrogen thermal dissociation line, most of them are well within the molecular hydrogen regime at low pressures and in the metallic, degenerate regime at high pressures. Stars like our Sun lie in a higher temperature regime for which the EOS is dominated by thermal effects and electrons are essentially nondegenerate.

10.16.3.2.2 Other elements and mixtures

Hydrogen is of course a key element, but it is not sufficient to describe the structure of all giant planets. A description of the high-pressure behavior of other elements would go beyond the scope of the present review. We only sketch a few important results here.

In order to obtain tractable EOS in the entire domain of pressure and temperature spanned by the planets during their evolution, one has to consider simplifications, among which the first one is to consider that an element (e.g., hydrogen) dominates and that others can be considered as a perturbation. This is done for the hydrogen–helium mixture for the now classical EOS by Saumon et al. (1995) and now with more up-to-date EOSs (Caillabet et al., 2011; Militzer and Hubbard, 2013; Nettelmann et al., 2012). The addition of other elements can be done through the so-called additive volume rule that is generally a good approximation given other sources of uncertainty (Vorberger et al., 2007; see also Chabrier and Ashcroft, 1990).

EOS for elements other than hydrogen and helium in the parameter range relevant for giant planetary interiors have traditionally been difficult to obtain and are often not easily shared. Beyond an extrapolation from the classical ANEOS and Sesame tables (see Saumon and Guillot, 2004, and references therein), new results have become available. In particular, ab initio simulations revealed that when compressing water or ammonia along an isentrope from conditions relevant to the atmospheres of Uranus and Neptune, they transition from a molecular to an ionic fluid, then to a superionic fluid, and finally to a plasma (Cavazzoni et al., 1999). The superionic fluid corresponds to a state in which protons move relatively freely among a lattice of oxygen atoms. An equation of state for water has been calculated from first principles by French et al. (2009) and is found to be in good agreement with experiments (Knudson et al., 2012). A similar equation of state for ammonia is presented by Bethkenhagen et al. (2013). In models of Uranus and Neptune, for water, the ionic transition occurs near 0.1 Mbar and the superionic transition near 1 Mbar (Redmer et al., 2011).

In some cases, however, generally at low enough temperatures for a given pressure range, mixtures cannot remain homogeneous. This further complicates the calculation of the EOS and has important physical consequences for the planetary structure: the two components having different molecular weights, they tend to be separated by gravity so that the heavier component settles down under the lighter one. This is the case of the hydrogen and helium mixture for which it was proposed that such a separation would occur in Saturn already in the 1970s (Salpeter, 1973; Stevenson and Salpeter, 1977a), but for which realistic calculations have only become possible in the past decade or so (see Lorenzen et al., 2011; Morales et al., 2009, 2013a). Figure 6 shows the comparison between two of these calculations based on first-principles simulations. According to these calculations, Saturn's interior is in the phase separation region below 1 Mbar but whether Jupiter is too depends on which calculation is considered.

The separation of other mixtures has also been calculated and is relevant to understand the initial formation and subsequent possible erosion of the cores of the giant planets (see Guillot et al., 2004). First-principles calculations of the water in metallic hydrogen (at pressures above 10 Mbar) predict a critical phase separation temperature of less than 4000 K (Wilson and Militzer, 2010), implying that water is completely soluble in hydrogen in the interiors of Jupiter, Saturn, and generally gas giants. This is also the case of iron, with a critical

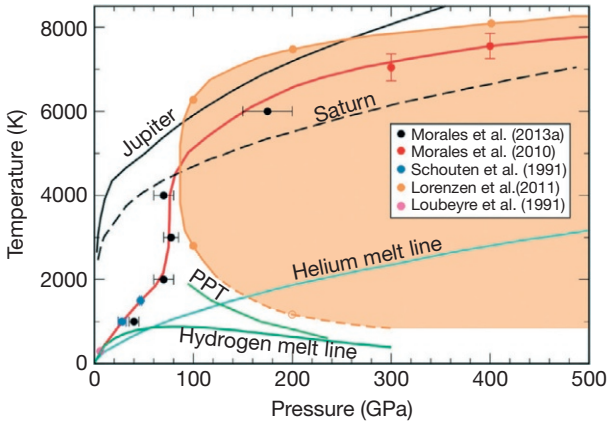

Figure 6 Phase diagram for the hydrogen–helium mixture for a helium mole concentration of 8%. The orange region shows where the two elements are expected to separate from each other according to the calculations of Lorenzen et al. (2011). The red curve corresponds to the critical temperature for that separation according to Morales et al. (2013a). Numerical results by Schouten et al. (1991) and experimental determinations by Loubeyre et al. (1991) are also shown. The back curves show the isentropes of Jupiter (plain) and Saturn (dashed), respectively. Reproduced from Morales MA, Hamel S, Caspersen K, and Schwegler E (2013) Hydrogen-helium demixing from first principles: From diamond anvil cells to planetary interiors. *Physical Review B* 87(17): 174105.

temperature of around 2000 K (Wahl et al., 2013). Finally, mixing rocks (specifically MgO) and metallic hydrogen is also relatively easy, even though the critical temperature for the same pressure range is higher, of order 10 000 K or less (Wilson and Militzer, 2012).

10.16.3.3 Heat Transport

The giant planets possess hot interiors, implying that a relatively large amount of energy has to be transported from the deep regions of the planets to their surface. This can be done by either radiation, conduction, or, if these processes are not sufficient, convection. Convection is generally ensured by the rapid rise of the opacity with increasing pressure and temperature. At pressures of a bar or more and relatively low temperatures (<1000 K), the three dominant sources of opacities are water, methane, and collision-induced absorption by hydrogen molecules.

However, in the intermediate temperature range between $\sim$1200 and 1500 K, the Rosseland opacity due to the hydrogen and helium absorption behaves differently: the absorption at any given wavelength increases with density, but because the temperature also rises, the photons are emitted at shorter wavelengths, where the monochromatic absorption is smaller. As a consequence, the opacity can decrease. This was shown by Guillot et al. (2004) to potentially lead to the presence of a deep radiative zone in the interiors of Jupiter, Saturn, and Uranus.

This problem must however be reanalyzed in the light of observations and analyses of brown dwarfs. Their spectra show unexpectedly wide sodium and potassium absorption lines (see Burrows et al., 2000), in spectral regions where hydrogen, helium, water, methane, and ammonia are relatively transparent. It thus appears that the added contribution of these elements (if they are indeed present) would wipe out any radiative region at these levels (Guillot et al., 2004).

At temperatures above 1500–2000 K, two important sources of opacity appear: (i) the rising number of electrons greatly enhances the absorption of H_2^- and H^-; (ii) TiO, a very strong absorber at visible wavelengths, is freed by the vaporization of $CaTiO_3$. Again, the opacity rises rapidly that ensures a convective transport of the heat. Still deeper, conduction by free electrons becomes more efficient, but the densities are found not to be high enough for this process to be significant, except perhaps near the central core (see Hubbard, 1968; Stevenson and Salpeter, 1977b).

While our giant planets seem to possess globally convective interiors, strongly irradiated extrasolar planets must develop a radiative zone just beneath the levels where most of the stellar irradiation is absorbed. Depending on the irradiation and characteristics of the planet, this zone may extend down to kbar levels, the deeper levels being convective. In this case, a careful determination of the opacities is necessary (but generally not possible) as these control the cooling and contraction of the deeper interior (see Freedman et al., 2008, for a discussion of opacities and tables for substellar atmospheres and interiors).

10.16.3.4 The Contraction and Cooling Histories of the Giant Planets

The interiors of the giant planets are expected to evolve with time from a high entropy, high θ value, hot initial state to a low entropy, low θ, cold degenerate state. The essential underlying physics can be derived from the well-known virial theorem and the energy conservation that link the planet's internal energy E_i, gravitational energy E_g, and luminosity through:

$$\xi E_i + E_g = 0 \quad [8]$$

$$L = -\frac{\xi - 1}{\xi}\frac{dE_g}{dt} \quad [9]$$

where $\xi = \int_0^M 3(P/\rho)dm \int_0^M udm \approx \langle 3P/\rho u \rangle$ the brackets indicating averaging, and u is the specific internal energy. For a diatomic perfect gas, $\xi = 3.2$; for fully degenerate nonrelativistic electrons, $\xi = 2$.

Thus, for a giant planet or brown dwarf beginning its life mostly as a perfect H_2 gas, two-thirds of the energy gained by contraction is radiated away, one-third being used to increase E_i. The internal energy being proportional to the temperature, the effect is to heat up the planet. This represents the slightly counterintuitive but well-known effect that a star or giant planet initially heats up while radiating a significant luminosity (e.g., Kippenhahn and Weigert, 1994).

Let us now move further in the evolution, when the contraction has proceeded to a point where the electrons have become degenerate. For simplicity, we will ignore Coulomb interactions and exchange terms, and assume that the internal energy can be written as $E_i = E_{el} + E_{ion}$ and that furthermore $E_{el} \gg E_{ion}$ (θ is small). Because $\xi \approx 2$, we know that half of the gravitational potential energy is radiated away and half of it

goes into internal energy. The problem is to decide how this energy is split into an electronic and an ionic part. The gravitational energy changes with some average value of the interior density as $E_g \propto 1/R \propto \rho^{1/3}$. The energy of the degenerate electrons is essentially the Fermi energy: $E_{el} \propto \rho^{2/3}$. Therefore, $\dot{E}_g \approx 2(E_g/E_{el})\dot{E}_{el}$. Using the virial theorem and specifically eqn [8], we get that $\dot{E}_g \approx -\dot{E}_{el}$. The luminosity is by definition $L = -(\dot{E}_g + \dot{E}_i)$ and therefore

$$L \approx -\dot{E}_{ion} \propto -\dot{T} \qquad [10]$$

In this limit, the gravitational energy lost is entirely absorbed by the increase in pressure of the degenerate electrons and the observed luminosity is due to the thermal cooling of the ions. The luminosity can be written in terms of a modified Kelvin–Helmholtz formula:

$$L \approx \eta \frac{GM^2}{R\tau} \qquad [11]$$

where τ is the age and η is a factor that hides most of the complex physics. In the approximation that Coulomb and exchange terms can be neglected, $\eta \approx \theta/(\theta+1)$. The poor compressibility of the giant planets in their mature evolution stages implies that $\eta \ll 1$ ($\eta \sim 0.03$ for Jupiter): the luminosity is not obtained from the entire gravitational potential but from the much more limited reservoir constituted by the thermal internal energy. Equation [11] shows that to first order, $\log L \propto -\log \tau$: very little time is spent at high luminosity values. In other words, the problem is (in most cases) weakly sensitive to initial conditions. However, it is to be noticed that with progress in our capability to detect very young objects, that is, planets and brown dwarfs of only a few million years of age, the problem of the initial conditions does become important (Marley et al., 2007). Interestingly, at these early stages, their luminosity appears to strongly depend on their core mass (Mordasini, 2013).

Figure 7 shows more generally how not only the giant planets but also brown dwarfs and small stars see their luminosities evolve as a function of time. The $1/\tau$ slope is globally conserved, with some variations for brown dwarfs, during the transient epoch of deuterium burning, and of course for stars, when they begin burning efficiently their hydrogen and settle

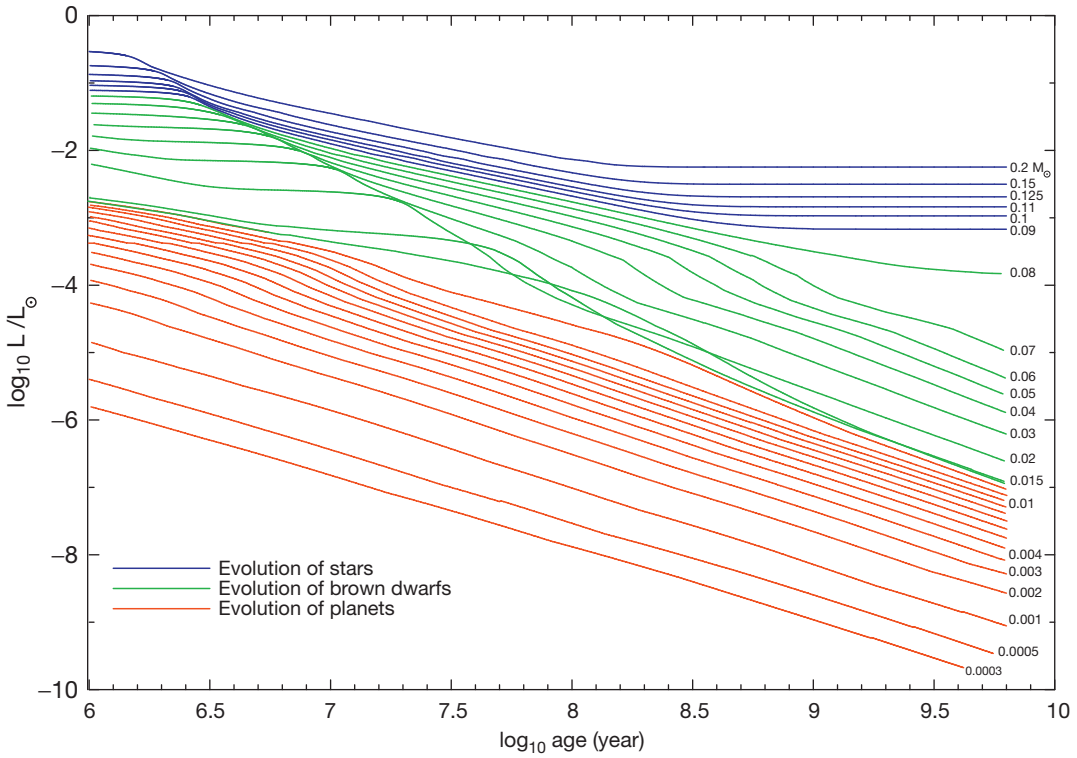

Figure 7 Evolution of the luminosity (in $L_\odot$) of solar-metallicity M dwarfs and substellar objects versus time (in year) after formation. In this figure, 'brown dwarfs' are arbitrarily designated as those objects that burn deuterium, while those that do not are tentatively labeled 'planets.' Stars are objects massive enough to halt their contraction due to hydrogen fusion. Each curve is labeled by its corresponding mass in $M_\odot$, with the lowest three corresponding to the mass of Saturn, half the mass of Jupiter, and the mass of Jupiter. Reproduced from Burrows A, Marley M, Hubbard WB, et al. (1997) A nongray theory of extrasolar giant planets and brown dwarfs. *Astrophysical Journal* 491: 856.

on the main sequence: in that case, the tendency of the star to contract under the action of gravity is exactly balanced by thermonuclear hydrogen fusion.

10.16.3.5 Mass–Radius Relation

The relation between mass and radius has very fundamental astrophysical applications. Most importantly, it allows one to infer the gross composition of an object from a measurement of its mass and radius. This is especially relevant in the context of the discovery of extrasolar planets with both radial velocimetry and the transit method, as the two techniques yield relatively accurate determination of M and R, these determinations being often limited by the uncertainty on the stellar parameters themselves.

Figure 8 shows mass–radius relations for compact degenerate objects from the giant planets to brown dwarfs and low-mass stars. The right-hand side of the diagram shows a rapid increase of the radius with mass in the stellar regime that is directly due to the onset of stable thermonuclear reactions. In this regime, observations and theoretical models agree (see however Ribas, 2006, for a more detailed discussion). The left-hand side of the diagram is obviously more complex, and this can be understood by the fact that planets have much larger variations in composition than stars and because external factors such as the amount of irradiation they receive do affect their contraction in a significant manner.

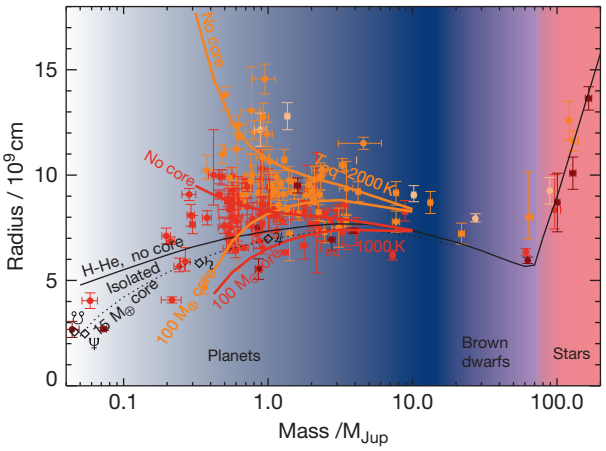

Figure 8 Theoretical and observed mass–radius relations. The black line is applicable to the evolution of solar composition planets, brown dwarfs, and stars, when isolated or nearly isolated (as Jupiter, Saturn, Uranus, and Neptune, defined by diamonds and their respective symbols), after 5 Ga of evolution. The dotted line shows the effect of a 15 $M_\oplus$ core on the mass–radius relation. Orange and yellow curves represent the mass–radius relations for heavily irradiated planets with equilibrium temperatures of 1000 and 2000 K, respectively, and assuming that 0.5% of the incoming stellar luminosity is dissipated at the center (see **Section 10.16.4.3**). For each irradiation level, two cases are considered: a solar composition planet with no core (top curve) and one with a 100 $M_\oplus$ central core (bottom curve). Circles with error bars correspond to known planets, brown dwarfs, and low-mass stars, color-coded as a function of their equilibrium temperature (below 750, 1500, 2250 K, and above 2250 K, respectively, from darkest to lightest).

Let us first concentrate on isolated or nearly isolated gaseous planets. The black curves have a local maximum near 4 M_J: At small masses, the compression is small so that the radius increases with mass. At large masses, degeneracy sets in and the radius decreases with mass.

This can be understood on the basis of polytropic models based on the assumption that $P = K\rho^{1+1/n}$, where K and n are constants. Because of degeneracy, a planet of large mass will tend to have $n \to 1.5$, while a planet of smaller mass will be less compressible ($n \to 0$). Indeed, it can be shown that in their inner 70–80% in radius, isolated solar composition planets of 10, 1, and 0.1 M_J have $n = 1.3$, 1.0, and 0.6, respectively. From polytropic equations (e.g., Chandrasekhar, 1939):

$$R \propto K^{n/(3-n)} M^{(1-n)/(3-n)} \qquad [12]$$

Assuming that K is independent of mass, one gets $R \propto M^{0.16}$, M^0, and M^{-018} for $M = 10$, 1, and 0.1 M_J, respectively, in relatively good agreement with Figure 8 (the small discrepancies are due to the fact that the intrinsic luminosity and hence K depend on the mass considered).

Figure 8 shows already that the planets in our solar system are not made of pure hydrogen and helium and require an additional fraction of heavy elements in their interior, either in the form of a core or distributed in the envelope (dotted line).

For extrasolar planets, the situation is complicated by the fact that the intense irradiation that they receive plays a major role in their evolution. The present sample is already quite diverse, with equilibrium temperature (defined as the effective temperature corresponding to the stellar flux received by the planet) ranging from 1000 to 2500 K. Their compositions are also quite variable, with some planets having large masses of heavy elements (Guillot et al., 2006; Sato et al., 2005). The orange and yellow curves in Figure 8 show theoretical results for equilibrium temperatures of 1000 and 2000 K, respectively. Two extreme models have been plotted: assuming a purely solar composition planet (top curve) and assuming the presence of a 100 $M_\oplus$ central core (bottom curve). In each case, an additional energy source proportional to 0.5% of the incoming luminosity was also assumed (see discussion in **Section 10.16.4.3** hereafter).

The increase in radius for decreasing planetary mass for irradiated, solar composition planets with little or no core can be understood using the polytropic relation (eqn [12]) but accounting for variations of K as defined by the atmospheric boundary condition. Using the Eddington approximation, assuming $\kappa \propto P$ and a perfect gas relation in the atmosphere, one can show that $K \propto (M/R^2)^{-1/2n}$ and that therefore $R \propto M^{(1/2-n)/(2-n)}$. With $n = 1$, one finds $R \propto M^{-1/2}$. Strongly irradiated hydrogen–helium planets of small masses are hence expected to have the largest radii that qualitatively explain the positions of the extrasolar planets in Figure 8. Note that this estimate implicitly assumes that n is constant throughout the planet. The real situation is more complex because of the growth of a deep radiative region in most irradiated planets and because of structural changes between the degenerate interior and the perfect gas atmosphere (Guillot, 2005).

In the case of the presence of a fixed mass of heavy elements, the trend is inverse because of the increase of mean

molecular mass (or equivalently core/envelope mass) with decreasing total mass. Thus, small planets with a core are much more tightly bound and less subject to evaporation than those that have no core.

10.16.3.6 Rotation and the Figures of Planets

The mass and radius of a planet informs us on its global composition. Because planets are also rotating, one is allowed to obtain more information on their deep interior structure. The hydrostatic equation becomes more complex however:

$$\frac{\nabla P}{\rho} = \nabla\left(G\iiint\frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}d^3\mathbf{r}'\right) - \boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\mathbf{r}) \qquad [13]$$

where $\boldsymbol{\Omega}$ is the rotation vector. The resolution of eqn [13] is a complex problem. It can however be somewhat simplified by assuming that $|\boldsymbol{\Omega}| = \omega$ is such that the centrifugal force can be derived from a potential. The hydrostatic equilibrium then writes $\nabla P = \rho\nabla U$, and the *figure* of the rotating planet is then defined by the $U = constant$ level surface.

One can show (e.g., Zharkov and Trubitsyn, 1978) that the hydrostatic equation of a fluid planet can then be written in terms of the mean radius $\bar{r}$ (the radius of a sphere containing the same volume as that enclosed by the considered equipotential surface):

$$\frac{1}{\rho}\frac{\partial P}{\partial \bar{r}} = -\frac{Gm}{\bar{r}^2} + \frac{2}{3}\omega^2\bar{r} + \frac{GM}{\bar{R}^3}\bar{r}\varphi_\omega \qquad [14]$$

where M and $\bar{R}$ are the total mass and mean radius of the planet and φ_ω is a slowly varying function of $\bar{r}$. (In the case of Jupiter, φ_ω varies from about 2×10^{-3} at the center to 4×10^{-3} at the surface.) Equations [5]–[7] remain the same with the hypothesis that the level surfaces for the pressure, temperature, and luminosity are equipotentials. The significance of rotation is measured by the ratio of the centrifugal acceleration to the gravity:

$$q = \frac{\omega^2 R_{eq}^3}{GM} \qquad [15]$$

As discussed in **Section 10.16.2.2**, in some cases, the external gravity field of a planet can be accurately measured in the form of gravitational moments J_k (with zero odd moments for a planet in hydrostatic equilibrium) that measure the departure from spherical symmetry. Together with the mass, this provides a constraint on the interior density profile (see Zharkov and Trubitsyn, 1974; see also **Chapters 10.02** and **10.04**):

$$M = \iiint\rho(r,\theta)d^3\tau$$
$$J_{2i} = -\frac{1}{MR_{eq}^{2i}}\iiint\rho(r,\theta)r^{2i}P_{2i}(\cos\theta)d^3\tau$$

where $d\tau$ is a volume element and the integrals are performed over the entire volume of the planet.

Figure 9 shows how the different layers inside a planet contribute to the mass and the gravitational moments. The figure applies to Jupiter but would remain relatively similar for other planets. Note however that in the case of Uranus and Neptune, the core is a sizable fraction of the total planet and contributes to both J_2 and J_4. Measured gravitational moments

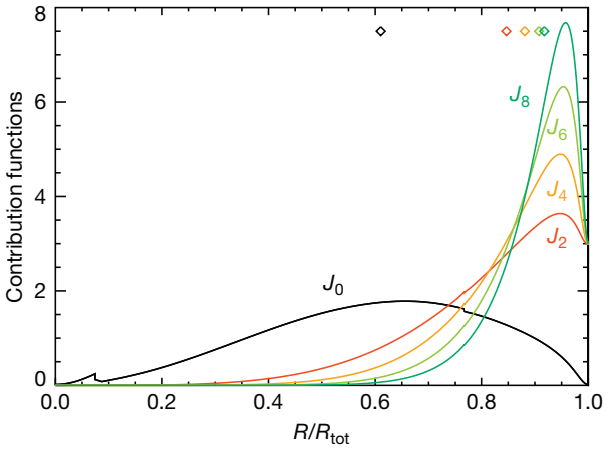

Figure 9 Contribution of the level radii to the gravitational moments of Jupiter. J_0 is equivalent to the planet's mass. The small discontinuities are caused by the following transitions, from left to right: core/envelope, helium-rich/helium-poor (metallic/molecular). Diamonds indicate the median radius for each moment. They correspond to pressures of 9.1, 1.3, 0.75, 0.45, and 0.35 Mbar, respectively, from left to right (J_0–J_8).

thus provide information on the external levels of a planet. It is only indirectly, through the constraints on the outer envelope that the presence of a central core can be inferred. As a consequence, it is impossible to determine this core's state (liquid or solid), structure (differentiated, partially mixed with the envelope), and composition (rock, ice, helium, etc.) from the gravity field data.

The Juno (Bolton, 2010) and Cassini Solstice (Spilker, 2012) missions are expected to yield considerable improvements in our determination of the gravity fields of Jupiter and Saturn, respectively. Because the theory of figures is limited by its expansion in terms of the rotation parameter q and because purely barotropic solutions are possible only in the limit of solid-body rotation and of pure rotation on cylinders, these high-precision measurements will require new approaches to include rotation in planetary models (se Hubbard, 1999, 2013). Separately, these measurements will enable new constraints such as the determination of the planets' angular momentum through the measurement of the relativistic Lense–Thirring effect (Iorio, 2010) and the determination of their moment of inertia (Helled, 2011; Helled et al., 2011b). But probably, the most important prospects lie in the possibility to couple measurements on gravity field, magnetic fields, and wind speeds with combined tridimensional magnetohydrodynamic models (see **Sections 10.16.2.3** and **10.16.2.4**).

For planets outside the solar system, although measuring their gravitational potential is presently beyond reach, an indirect measurement of the planets' Love number k_2 may be possible in systems of planets in which one is locked into a so-called fixed-point eccentricity. So far, one such transiting system is known, HAT-P-13 (Batygin et al., 2009; Mardling, 2010), because it contains a transiting planet, HAT-P-13b, and a companion, HAT-P-13c, whose minimum mass $M\sin i$ and orbital eccentricity are known (Bakos et al., 2009). The value of k_2 constrains the interior structure in a way that is very similar to J_2 and has been used to obtain first constraints on the interior structure of this planet (Kramm et al., 2012).

10.16.4 Interior Structures and Evolutions

10.16.4.1 Jupiter and Saturn

As illustrated by Figure 10, the simplest interior models of Jupiter and Saturn matching all observational constraints assume the presence of three main layers: (i) an outer hydrogen–helium envelope, whose global composition is that of the deep atmosphere; (ii) an inner hydrogen–helium envelope, enriched in helium because the whole planet has to fit the H/He protosolar value; and (iii) a central dense core. Because the planets are believed to be mostly convective, these regions are expected to be globally homogeneous. (Many interesting thermochemical transformations take place in the deep atmosphere, but they are of little concern to us.)

The transition from a helium-poor upper envelope to a helium-rich lower envelope is thought to take place through the formation of helium-rich droplets that fall deeper into the planet due to their larger density. These droplets form when the temperature–pressure profiles enter the separation region for the initial helium abundance, as shown in Section 10.16.3.2.2. Three-layer models implicitly make the hypothesis that this region is adiabatic (this is justified only if convection is not inhibited by the formation of helium droplets, as discussed by Stevenson and Salpeter (1977a)) and narrow. Figure 6 shows that this zone may be extended, especially in present-day Saturn (see also Fortney and Hubbard, 2003).

As discussed by Stevenson and Salpeter (1977a) and Stevenson (1982), the planets would start from an initially hot and homogeneous state and would start entering the phase separation region progressively, leading to a depletion of helium in the outer region and its increase in the deeper interior. According to the calculations by Lorenzen et al. (2011) and Morales et al. (2013a), the separation would first occur at a pressure between 1 and 2 Mbar and the inhomogeneous region would grow inward but not so much toward lower pressures because of the higher solubility of helium in molecular hydrogen. According to the simulations, although needed to explain the abundances in Jupiter's atmosphere (Section 10.16.2.6), it is not yet clear that the process has begun in this planet. Fully consistent calculations that account both for the constraints on the planets' gravitational moments and their atmospheric composition should become possible, especially with the additional information brought by the Juno (Bolton, 2010) and Cassini Solstice (Spilker, 2012) space missions.

In the absence of these calculations, adiabatic three-layer models can be used as a useful guidance to a necessarily hypothetical ensemble of allowed structures and compositions of Jupiter and Saturn. A relatively extensive exploration of the parameter space has been performed by several authors (Fortney and Nettelmann, 2010; Helled and Guillot, 2013; Nettelmann et al., 2012, 2013b; Saumon and Guillot, 2004). The calculations account for a transition from a helium-poor outer envelope to a helium-rich inner envelope. The abundance of heavy elements may or may not be held constant across this transition. Many sources of uncertainties are taken into account however; among them, the most significant are on the EOS of hydrogen and helium, the uncertain values of J_4 and J_6, the presence of differential rotation deep inside the planet, the location of the helium-poor to helium-rich region, and the uncertain helium to hydrogen protosolar ratio.

Their results indicate that Jupiter's core is smaller than $\sim 10\ M_\oplus$ and that its global composition is pretty much unknown (between 10 and 42 $M_\oplus$ of heavy elements in total). The models indicate that Jupiter is enriched compared to the solar value by a factor 1.5–8 times the solar value. This enrichment is compatible with a global uniform enrichment of all species near the atmospheric Galileo values but allows many other possibilities as well.

Other models of Jupiter based on an ab initio equation of state by Militzer et al. (2008) led to a solution with a large core mass and a very small enrichment in heavy elements in the

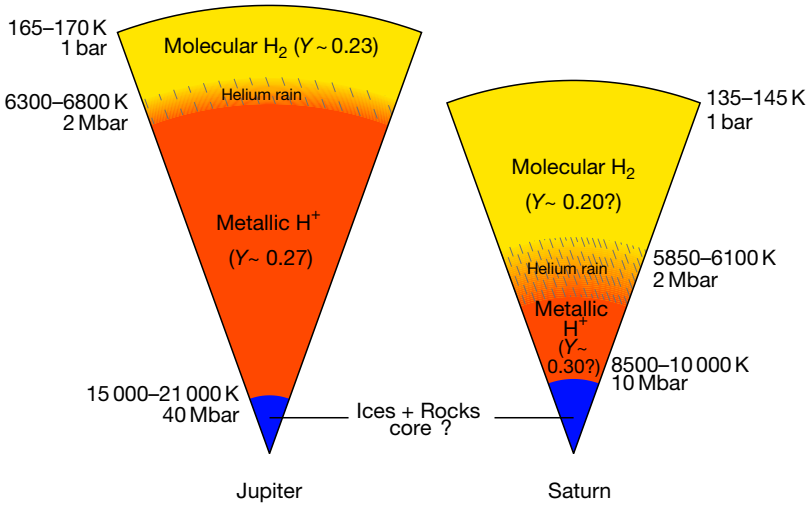

Figure 10 Schematic representation of the interiors of Jupiter and Saturn. The range of temperatures is estimated using homogeneous models and including a possible radiative zone indicated by the hashed regions. Helium mass mixing ratios Y are indicated. The size of the central rock and ice cores of Jupiter and Saturn is very uncertain (see text). In the case of Saturn, the inhomogeneous region may extend down all the way to the core, which would imply the formation of a helium core. Adapted from Guillot T (1999) Interior of giant planets inside and outside the solar system. *Science* 286: 72–77.

envelope incompatible with either the Galileo probe measurements or the protosolar helium abundance. A significant update in the EOS is presented by Militzer and Hubbard (2013). This updated EOS yields a warmer interior than the 2008 models and should therefore lead to a smaller core mass and larger amount of heavy elements in the envelope, in line with the other results. At the same time, the Militzer and Hubbard (2013) EOS is much more accurate than the range of EOSs used by Saumon and Guillot (2004), and it differs slightly from the other ab initio EOS used by Nettelmann et al. (2012) and Nettelmann et al. (2013b). New constraints should therefore be derived on the basis of those new data.

In the case of Saturn, the solutions depend less on the hydrogen EOS because the Mbar pressure region is comparatively smaller. The total amount of heavy elements present in the planet can therefore be estimated with a better accuracy than for Jupiter and is between 16 and 30 $M_\oplus$ (Helled and Guillot, 2013; Nettelmann et al., 2013b). The uncertainty on the core mass is found to be larger than for Jupiter because a heavy element-rich inner envelope can mimic the gravitational signature of the core. As a result, only an upper limit on the core mass of 20 $M_\oplus$ is derived.

Concerning the *evolutions* of Jupiter and Saturn, the three main sources of uncertainty are, by order of importance, (1) the magnitude of the helium separation, (2) the EOS, and (3) the atmospheric boundary conditions. **Figure 11** shows an ensemble of possibilities that attempts to bracket the minimum and maximum cooling. In all these quasi-adiabatic cases, helium sedimentation is needed to explain Saturn's present luminosity (see Fortney and Hubbard, 2003; Hubbard, 1977; Hubbard et al., 1999; Salpeter, 1973; Stevenson and Salpeter, 1977a). In the case of Jupiter, the sedimentation of helium that appears to be necessary to explain the low atmospheric helium abundance poses a problem for evolution models because it appears to generally prolong its evolution beyond 4.55 Ga, the age of the solar system (Fortney et al., 2011; Nettelmann et al., 2012). However, different solutions are possible, including improvements of the EOS and atmospheric boundary conditions or even the possible progressive erosion of the central core that would yield a lower luminosity of Jupiter at a given age (Guillot et al., 2004).

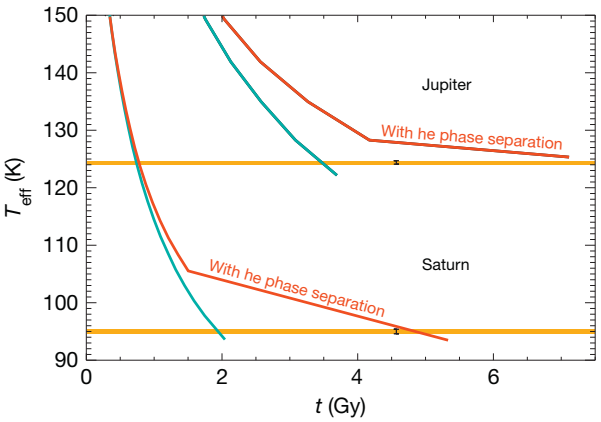

Figure 11 Final stages of evolution of Jupiter and Saturn. The present effective temperatures, reached after ~4.55 Ga of evolution, are indicated as horizontal orange lines. For each planet, two models represent attempts to bracket the ensemble of possibilities, with the faster evolution corresponding to that of a homogeneous planet, while the slowest evolution includes the effect of helium settling in the last evolution phase. Adapted from Hubbard WB (1999) NOTE: Gravitational signature of Jupiter's deep zonal flows. *Icarus* 137: 357–359; Fortney JJ and Hubbard WB (2003) Phase separation in giant planets: Inhomogeneous evolution of Saturn. *Icarus* 164: 228–243.

A different set of solutions appears when one considers the possibility that the envelopes of Jupiter and Saturn are *not* homogeneous and adiabatic on large scales, but are instead of variable composition, with heavier elements at the bottom. In that case, convection can be strongly inhibited that requires the temperature gradient to be larger in order to transport the same intrinsic luminosity. In the case of the giant planets, this process, known as semiconvection or diffusive convection, leads to the formation of a nonstatic staircase structure with diffusive interfaces with abrupt variations of temperature and composition and a homogeneous adiabatic structure in between (Rosenblum et al., 2011; Stevenson, 1985). By assuming that this structure is maintained over the entire envelopes of Jupiter and Saturn, Leconte and Chabrier (2012) derived much warmer interior structures with also 30–60% more heavy elements than in conventional models. However, the assumption that this inhomogeneous composition is maintained in the entire envelopes is ad hoc. In reality, one may expect semiconvection to be confined to a much smaller region and thus have a more limited effect. The problem is open however and requires further study. Its understanding is also critical for deciding whether Jupiter's core can erode into its envelope (see Guillot et al., 2004; Wilson and Militzer, 2012).

As discussed in **Sections 10.16.2.3** and **10.16.2.4**, classical interior models of Jupiter and Saturn based on the assumption of a homogeneous structure in the molecular envelope and an increase of the conductivity mainly due to hydrogen metallization do yield solutions for their magnetic fields and atmospheric zonal winds that globally match the observations. However, important 'details' such as why Saturn's magnetic field is axisymmetric and Jupiter's is not remain unexplained. Coupling interior and dynamical models in order to fit both Jupiter and Saturn's gravity and magnetic fields as well as their observed zonal winds (see **Sections 10.16.2.3** and **10.16.2.4**) should bring a more global understanding of the planetary structures.

10.16.4.2 Uranus and Neptune

Although the two planets are relatively similar, **Table 3** already shows that Neptune's larger mean density compared to Uranus has to be due to a slightly different composition: either more heavy elements compared to hydrogen and helium or a larger rock to ice ratio. The gravitational moments impose that the density profiles lie close to that of 'ices' (a mixture initially composed of, for example, H_2O, CH_4, and NH_3 but that rapidly becomes an ionic fluid of uncertain chemical composition in the planetary interior), except in the outermost layers, which have a density closer to that of hydrogen and helium (Marley et al., 1995; Podolak et al., 2000). As illustrated in **Figure 12**, three-layer models of Uranus and Neptune consisting of a central 'rocks' core (magnesium silicate and iron material), an ice layer, and a hydrogen–helium gas envelope have been

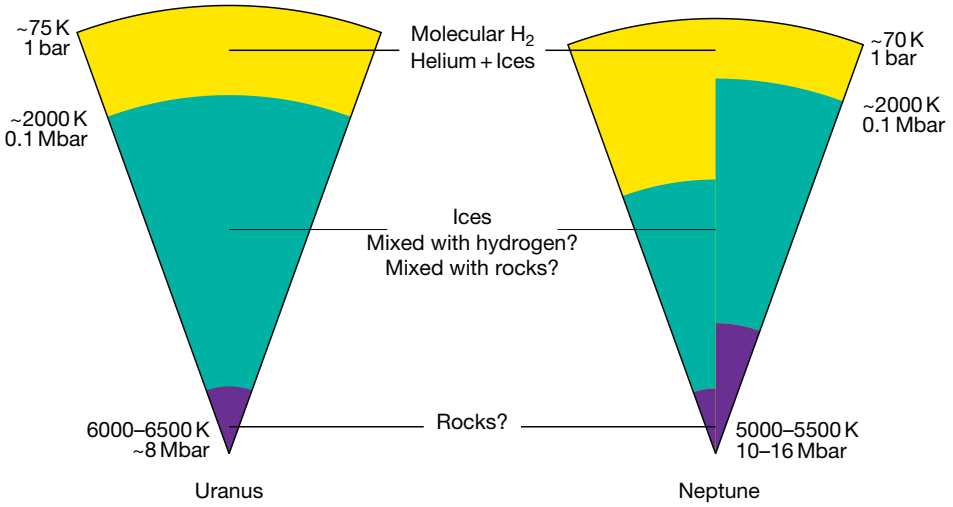

Figure 12 Schematic representation of the interiors of Uranus and Neptune. The ensemble of possibilities for Neptune is larger. Two possible structures are shown. Adapted from Guillot T (1999) Interior of giant planets inside and outside the solar system. *Science* 286: 72–77 using results from Nettelmann N, Helled R, Fortney JJ, and Redmer R (2013) New indication for a dichotomy in the interior structure of Uranus and Neptune from the application of modified shape and rotation data. *Planetary and Space Science* 77: 143–151.

calculated (Fortney and Nettelmann, 2010; Helled et al., 2011a; Hubbard et al., 1995; Nettelmann et al., 2013a; Podolak et al., 1991).

According to the models of Nettelmann et al. (2013a), Uranus contains a minimum of 1.8–2.2 $M_\oplus$ of hydrogen and helium and Neptune 2.7–3.3 $M_\oplus$. The global ice to rock ratio that is derived is very high (19–36) in Uranus, while Neptune has a wide range of solutions from 3.6 to 14. These values are much larger than the canonical ice to rock ratio of 2–3 for the protosun that accounts for the abundances of all elements condensing at low temperatures ('ices') versus that of more refractory elements ('rocks'). The fact that either planet would have accreted much less rocks than ices is puzzling and unexplained by formation models. It is probably an artifact from assuming ices being confined to the envelope and rocks to the core.

The evolution of the two planets also remains a mystery. While Neptune's present luminosity may be explained by the adiabatic cooling of the planet over the age of the solar system, this is not the case of Uranus's very low luminosity (Fortney et al., 2011; Nettelmann et al., 2013a; Podolak et al., 1995). This could be explained by the presence of a strongly inhibiting compositional gradient decoupling an inner region that would remain hot and an outer envelope that would cool progressively (Podolak et al., 1995). Such regions could also be present in Neptune but considerably deeper. Unfortunately, this qualitative explanation cannot be tied to the inferred interior structures. Apart from the latest models by Nettelmann et al. (2013a), the models of Uranus and Neptune are too similar (and so are their magnetic fields – see **Section 10.16.2.3**) to explain why Uranus would have such a small intrinsic heat flux and not Neptune.

In fact, it is likely that all present models of Uranus and Neptune are inadequate because of the assumption of an adiabatic temperature structure across interfaces with different compositions. Instead, diffusive convection should occur and lead to strongly superadiabatic temperature gradient (e.g., Rosenblum et al., 2011). As in the case of Jupiter and Saturn (see Leconte and Chabrier, 2012), this would lead to higher temperatures in the interior and very different constraints on the interior composition. The amount of rocks required to fit the mean density and gravitational moments would certainly rise, potentially solving the ice to rock ratio problem. The evolution of the planets would be very different as the present-day luminosity would be mostly governed by the leak of heat from the hot interior by diffusion at the interfaces.

10.16.4.3 Irradiated Giant Planets

10.16.4.3.1 Interior structure and dynamics

The physics that governs the calculation of the interior structure and evolution models of the giant planets described in the previous sections can be applied in principle to any gaseous exoplanet and brown dwarf. We focus the discussion on the ones that orbit extremely close to their star because of the possibility to directly characterize them and measure their mass, radius, and in some cases even the properties of their atmosphere. Two planets are proxies for this new class of objects: the first extrasolar giant planet discovered, 51 Peg b, with an orbital period of $P = 4.23$ days, and the first *transiting* extrasolar giant planet, HD 209458 b, with $P = 3.52$ days. Following widespread usage, we call these planets 'hot Jupiters' (aka 'Pegasids' since these two archetypes have been discovered in the Pegasus constellation).

With such a short orbital period, these planets are for most of them subject to an irradiation from their central star that is so intense that the absorbed stellar energy flux can be about $\sim 10^4$ times larger than their intrinsic flux. The atmosphere is thus prevented from cooling, with the consequence that a radiative zone develops and governs the cooling and contraction of the interior (Guillot et al., 1996). Typically, for a planet like HD 209458 b, this radiative zone extends to kbar levels, $T \sim 4000$ K, and is located in the outer 5% in radius (0.3% in mass) (Guillot and Showman, 2002).

Problems in modeling the evolution of hot Jupiters arise because of the uncertain outer boundary condition. The intense stellar flux implies that the atmospheric temperature profile is extremely dependent upon the opacity sources considered. Depending on the chosen composition, the opacity data used, the assumed presence of clouds, and the geometry considered, resulting temperatures in the deep atmosphere can differ by up to ~600 K (Barman et al., 2001; Fortney et al., 2006; Goukenleuque et al., 2000; Iro et al., 2005; Seager and Sasselov, 2000; Sudarsky et al., 2003). Furthermore, as illustrated by **Figure 13**, the strong irradiation and expected synchronization of the planets' spin implies that strong inhomogeneities should exist in the atmosphere with in particular strong (~500 K) day–night and equator-to-pole differences in effective temperatures (Barman et al., 2005; Cooper and Showman, 2005; Iro et al., 2005; Showman and Guillot, 2002).

Figure 14 illustrates the expected structure for the atmosphere of HD 209458b from a modern, tridimensional global circulation model coupled with a one-dimensional radiative transfer algorithm (Parmentier et al., 2013). All the caveats concerning these overforced simulations discussed in **Section 10.16.2.4** of course also apply and add to the uncertainties stemming from the poorly known chemical composition. For example, the particular simulation of **Figure 14** assumes the presence of TiO in the atmosphere, which yields very high temperatures at low pressures on the dayside of the planet. It is not clear that this molecule is present or has condensed at deeper levels (see also Spiegel et al., 2009). Aside from that, the eastward equatorial circulation and the strong equator-to-pole gradient now appear to be a robust feature of these simulations (e.g., Parmentier et al., 2013; Rauscher and Menou, 2013; Showman and Guillot, 2002). As seen in **Figure 14**, the equatorial jet redistributes heat between the dayside and the nightside relatively efficiently at large pressures and on the equator, but this is not the case at the poles, and at low pressures, in line with the observational constraints (see **Section 10.16.2.10**).

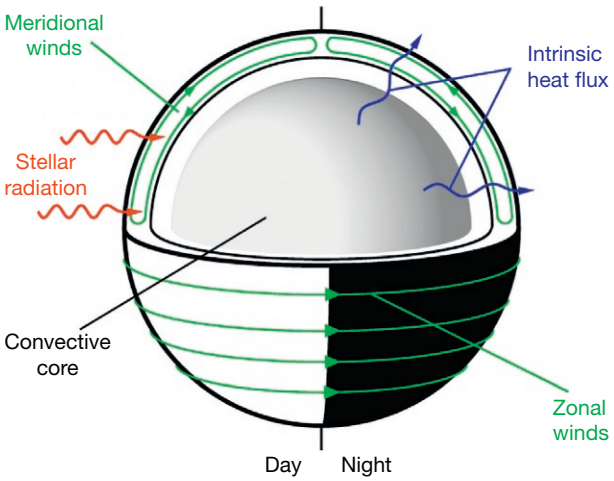

Figure 13 Conjectured dynamical structure of hot Jupiters (strongly irradiated extrasolar giant planets): At pressures larger than about 0.1 to 1 kbar, the intrinsic heat flux must be transported by convection. The convective core is at or near synchronous rotation with the star and has small latitudinal and longitudinal temperature variations. At lower pressures, a radiative envelope is present. The top part of the atmosphere is penetrated by the stellar light on the dayside. The spatial variation in insolation should drive winds that transport heat from the dayside to the nightside. Reproduced from Showman AP and Guillot T (2002) Atmospheric circulation and tides of "51 Pegasus b-like" planets. *Astronomy and Astrophysics* 385: 166–180.

These strong temperature variations must influence at some point the cooling and contraction histories of hot Jupiters. When opacities variations are not included, they result in more loss of the intrinsic heat and a faster contraction than when assuming that the stellar irradiation is homogeneously redistributed across the planetary surface (Budaj et al., 2012; Guillot, 2010; Guillot and Showman, 2002; Spiegel and Burrows, 2013). However, given other uncertainties (e.g., on the chemical composition and opacities to be used), this has been neglected in planetary evolution models thus far.

10.16.4.3.2 Thermal evolution and inferred compositions

We have seen in **Figure 8** that the measured masses and radii of transiting planets can be globally explained in the framework of an evolution model including the strong stellar irradiation and the presence of a variable mass of heavy elements, either in the form of a central core or spread in the planet interior. However, when analyzing the situation for each planet, it appears that several planets are too large to be reproduced by standard models, that is, models using the most up-to-date EOS, opacities, and atmospheric boundary conditions and assuming that the planetary luminosity governing its cooling is taken solely from the lost gravitational potential energy (see **Section 10.16.3.4**).

Figure 15 illustrates the situation for the particular case of HD 209458b: unless using an unrealistically hot atmosphere, or arbitrarily increasing the internal opacity, or decreasing the helium content, one cannot reproduce the observed radius that is 10–20% larger than calculated using standard models (Baraffe et al., 2003; Bodenheimer et al., 2001, 2003; Guillot and Showman, 2002). The fact that the measured radius corresponds to a low-pressure (~mbar) level while the calculated radius corresponds to a level near 1 bar is not negligible (Burrows et al., 2003) but too small to account for the difference. This is problematic because while it is easy to invoke the presence of a massive core to explain the small size of a planet, a large size such as that of HD 209458b requires an additional energy source or significant modifications in the data/physics involved.

The discovery of many transiting hot Jupiters has shown that this phenomenon is widespread, with at least a third of them being oversized compared to predictions from the standard evolution of a solar composition planet with no core (Guillot, 2008; Guillot et al., 2006; Laughlin et al., 2011). Numerous explanations have been put forward to explain this large size. The first ones, invoking tidal dissipation of eccentricity (Bodenheimer et al., 2001) or inclination (Winn and Holman, 2005), imply that orbital energy is transferred to the planet. These are generally too short-lived (e.g., Leconte et al., 2010) or of a low probability of occurrence (Levrard et al., 2007). The second ones posit that part of the irradiation energy is transferred into kinetic energy and is then dissipated deeper into the planet. This is the case of weather noise (Showman and Guillot, 2002), ohmic dissipation (Batygin

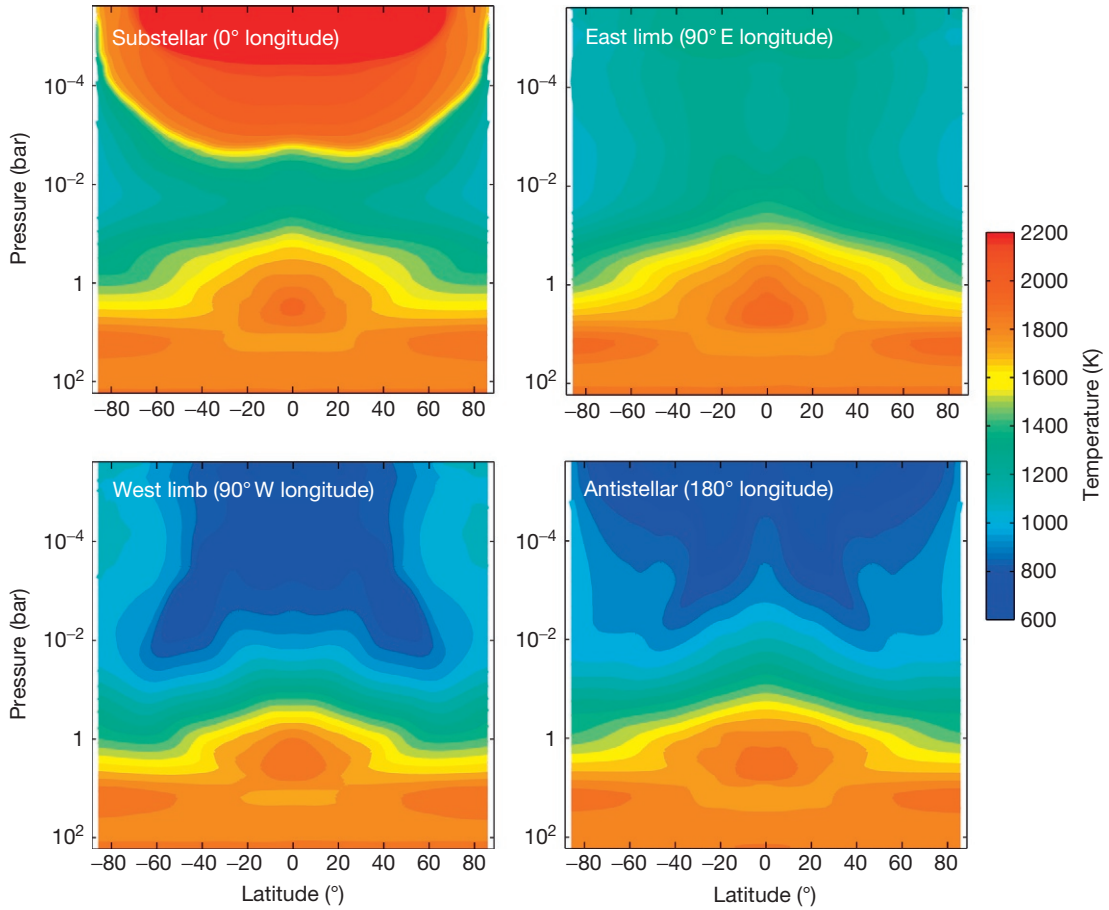

Figure 14 Simulated temperatures as a function of latitude (0° at the equator, ±90° at the poles) and pressure for HD 209458b obtained from a global 3D global circulation model. The four panels correspond to cuts from pole to pole at different longitudes (clockwise from the upper left): 0° (crossing the substellar point), 90° E (along the east limb), 180° E (crossing the antistellar point), and 270° E (along the west limb). A superrotating equatorial jet (0° latitude) is present and characterized by warmer temperatures than its surrounding at pressures of a few bars. The globally west to east circulation is responsible for a pronounced asymmetry between the warmer east limb and colder west limb. Reproduced from Parmentier V, Showman AP, and Lian Y (2013) 3D mixing in hot Jupiter's atmospheres. I. Application to the day/night cold trap in HD 209458b. *Astronomy and Astrophysics* 558: A91. Courtesy of V. Parmentier.

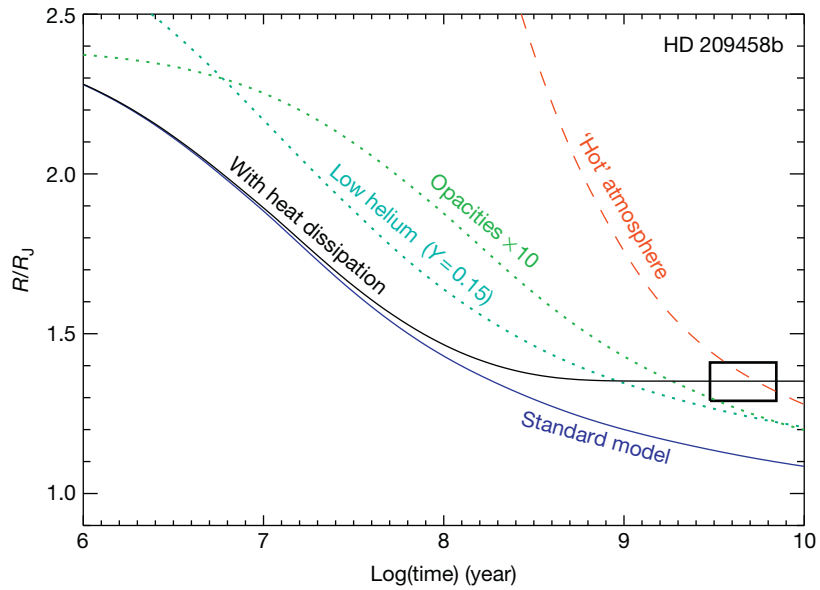

Figure 15 The contraction of HD 209458b as a function of time can be compared to its measured radius and inferred age shown by the black box. Standard models (blue curve) for the evolution of that 0.69 M_J planet generally yield a radius that is too small compared to the observations, even for a solar composition and no central core (a larger core and – in most cases – larger amounts of heavy elements in the planet imply an even smaller size for a given age). Unrealistically low helium abundances or high opacities models lead to evolution tracks that barely cross the observational box. A possibility is that heat is dissipated into the deep interior by stellar tides, either related to a nonzero orbital eccentricity forced by an unseen companion or because of a constant transfer of angular momentum from the heated atmosphere to the interior (black curve). Alternatively, the atmosphere may be hotter than predicted due to heating by strong zonal winds and shear instabilities (red curve).

and Stevenson, 2010), thermal tides (Arras and Socrates, 2010), and turbulent burial (Youdin and Mitchell, 2010) models. These mechanisms appear quite promising as they are long-lived and generally require only a small fraction of order 1% or less of the irradiation luminosity to be transported and dissipated at deeper levels to explain the observed planets (Guillot and Showman, 2002). Finally, a third class of models is based on a reduced cooling, either through an ad hoc increase of opacities (Burrows et al., 2007) or inefficient heat transport due to semiconvection (Chabrier and Baraffe, 2007). Validating these models is becoming possible, thanks to a large number of planets allowing statistical tests (see Laughlin et al., 2011), but will require further work.

In any case, the fact that a large number of planets are oversized lends weight to a mechanism that would apply to each planet. Masses of heavy elements can then be derived by imposing that all planets should be fitted by the same model with the same hypotheses. This can be done by inverting the results of **Figure 8**, as proposed by Guillot et al. (2006). On the basis of this hypothesis, **Figure 16** shows that some of the hot Jupiters contain a large fraction of heavy elements in their interior and that this fraction is correlated with the metallicity of the parent star. The large fraction of heavy elements is inferred both for relatively small giant planets (i.e., Saturn mass) and for planets that are several times the mass of Jupiter. A typical archetype of the first is HD 149026b that must contain around 70 $M_\oplus$ of heavy elements, a conclusion that is hard to escape because of the low total mass and high irradiation of the planet (see Fortney et al., 2006; Ikoma et al., 2006). For the latter, CoRoT-20b appears to push the models to the limit, with predicted masses of heavy elements in excess of 400 $M_\oplus$ (Deleuil et al., 2012).

The correlation between mass of heavy elements in hot Jupiters and stellar metallicity first obtained by Guillot et al. (2006) appears to stand the trial of time (Burrows et al., 2007; Guillot, 2008; Laughlin et al., 2011; Moutou et al., 2013) and remains valid when applied to planets with low irradiation levels that do not require additional physics to explain their large sizes (Miller and Fortney, 2011). It is important to realize that simply accreting slightly more metal-rich gas with the composition of the parent star would lead to a much smaller increase of a few percent at most. This correlation requires an efficient mechanism to collect solids in the protoplanetary disk and bring them into the hot Jupiters, something that is just beginning to be included into planet formation models (Mordasini et al., 2012).

Another intriguing possibility concerning hot Jupiters is that of a sustained mass loss due to the high irradiation dose that the planets receive. Indeed, this effect was predicted (Burrows and Lunine, 1995; Guillot et al., 1996; Lammer et al., 2003) and detected (Bourrier et al., 2013; Fossati et al., 2010; Vidal-Madjar et al., 2003). While its magnitude is still uncertain, it appears to have sculpted the population of planets in very close orbits around their star (e.g., Lopez et al., 2012).

The harvest of the Kepler and CoRoT missions opens the possibility to extend these studies to smaller planets. These objects are especially interesting but pose difficult problems in terms of structure because depending on their formation history, precise composition, and location, they may be fluid or solid or they may even possess a global liquid ocean (see Kuchner, 2003; Léger et al., 2004).

10.16.5 Implications for Planetary Formation Models

The giant planets in our solar system have in common a large mass of hydrogen and helium, but they are obviously quite different in their appearances, compositions, and internal

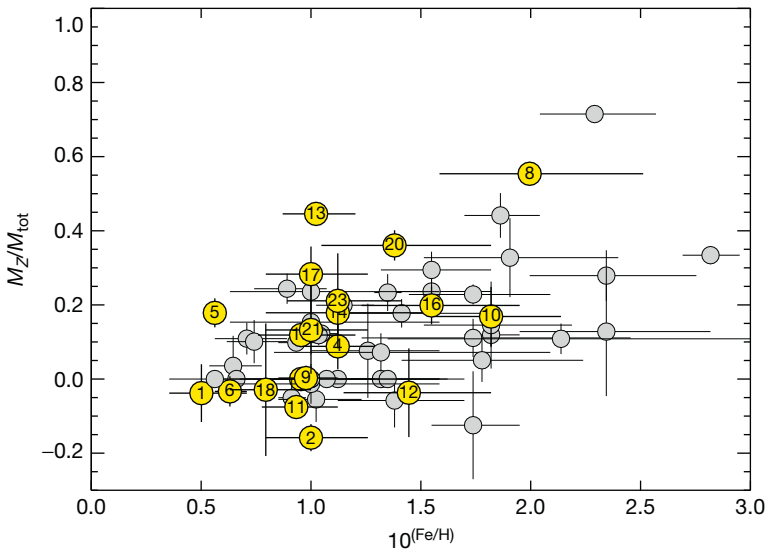

Figure 16 Mass fraction of heavy elements in the planets as a function of the metal content of their parent star expressed in solar units (e.g., $10^{[Fe/H]} = 3$ implies that the star contains three times more iron than our Sun). The evolution model assumes that 0.25% of the incoming irradiation flux is dissipated at the planet's center. Circles that are labeled 1–23 correspond to the CoRoT giant planets. Gray symbols correspond to a subset of known transiting systems (Guillot, 2008; Laughlin et al., 2011). Unphysical negative values for M_Z correspond to insufficient heat sources leading to a radius that is larger than observed. Reproduced from Moutou C, Deleuil M, Guillot T, et al. (2013) CoRoT: Harvest of the exoplanet program. *Icarus* 226: 1625–1634.

structures. Although studies cannot be conducted with the same level of details, we can safely conclude that extrasolar planets show a greater variety of compositions and structures, and imagine that their appearances differ even more significantly.

A parallel study of the structures of our giant planets and of the giant planets orbiting around other stars should provide us with key information regarding planet formation in the next decade or so. But, already, some conclusions, some of them robust, others still tentative, can be drawn:

The giant planets formed in circumstellar disks, before these were completely dissipated: This is a relatively obvious consequence of the fact that the giant planets are mostly made of hydrogen and helium: these elements had to be acquired when they were still present in the disk. Because the observed lifetime of gaseous circumstellar disks is of the order of a few million years, this implies that these planets formed (i.e., acquired most of their final masses) in a few million years also, quite faster than terrestrial planets in the solar system.

The giant planets migrated: The observed orbital distribution of extrasolar planets and the presence of planets extremely close to their star is generally taken as a strong evidence for an inward migration of planets, and various mechanisms have been proposed for that (see Alibert et al., 2005; Ida and Lin, 2004a; Moorhead and Adams, 2005, etc.). Separately, it was shown that several properties of our solar system can be explained if Jupiter, Saturn, Uranus, and Neptune ended the early formation phase in the presence of a disk with quasi-circular orbit, and with Saturn, Uranus, and Neptune significantly closer to the Sun than they are now, and that these three planets subsequently migrated outward (Tsiganis et al., 2005).

Accretion played a key role for the giant planet formation: Although formation by direct gas instability still remains a possibility (e.g., Boley et al., 2011; Helled and Bodenheimer, 2011), several indications point toward a formation of the giant planets that is dominated by accretion of heavy elements: First, Jupiter, Saturn, Uranus, and Neptune are all significantly enriched in heavy elements compared to the Sun. This feature can be reproduced by core-accretion models, for Jupiter and Saturn at least (Alibert et al., 2005). Second, the probability to find a giant planet around a solar-type star (with stellar type F, G, or K) is a strongly rising function of stellar metallicity (Fischer and Valenti, 2005; Gonzalez, 1998; Santos et al., 2004), a property that is also well-reproduced by standard core-accretion models (Alibert et al., 2005; Ida and Lin, 2004b). Third, the large masses of heavy elements inferred in some transiting extrasolar planets as well as the apparent correlation between mass of heavy elements in the planet and stellar metallicity (Burrows et al., 2007; Guillot, 2008; Guillot et al., 2006; Laughlin et al., 2011) are a strong indication that accretion was possible and that it was furthermore efficient.

The giant planets were enriched in heavy elements by core accretion, planetesimal delivery, and/or formation in an enriched protoplanetary disk: The giant planets in our solar system are unambiguously enriched in heavy elements compared to the Sun, both globally and when considering their atmosphere. This may also be the case of extrasolar planets, although the evidence is still tenuous. The accretion of a central core can explain part of the global enrichment, but not that of the atmosphere. The accretion of planetesimals may be a possible solution, but in the case of Jupiter at least, the rapid drop in accretion efficiency as the planet reaches appreciable masses ($\sim 100\ M_\oplus$ or so) implies that such an enrichment would have originally concerned only very deep layers and would require a relatively efficient upper mixing of these elements and possibly an erosion of the central core (Guillot et al., 2004; Wilson and Militzer, 2012).

Although not unambiguously explained, the fact that Jupiter is also enriched in noble gases compared to the Sun is a key observation to understand some of the processes occurring in the early solar system. Indeed, noble gases are trapped into solids only at very low temperatures, and this tells us that either most of the solids that formed Jupiter were formed at very low temperature to be able to trap gases such as argon, probably as clathrates (Gautier et al., 2001; Hersant et al., 2004; Mousis et al., 2012), or that the planet formed in an enriched disk as it was being evaporated (Guillot and Hueso, 2006). The fact that in Jupiter, argon, krypton, and xenon have a comparable enrichment over the solar value within the error bars (see Lodders, 2008, and **Table 3**) slightly favors the latter explanation.

10.16.6 Future Prospects

We have shown that the compositions and structures of the giant planets remain very uncertain. This is an important problem when attempting to understand and constrain the formation of planets, and the origins of the solar system. However, the parallel study of the giant planets in our solar system by space missions, such as Galileo and Cassini, and of extrasolar planets by both ground-based and space programs has led to rapid improvements in the field, with in particular a precise determination of the composition of Jupiter's troposphere, and constraints on the compositions of a dozen of extrasolar planets.

Improvements in our knowledge of the giant planets require a variety of efforts. Fortunately, nearly all of these are addressed at least partially by adequate projects in the next few years. The efforts that are necessary thus include (but are not limited to):

- Continue progresses on EOSs in order to obtain reliable results that can be used for a wide range of temperatures and pressures in the astrophysical context. This should be done with the help of laboratory experiments, for instance, by using powerful lasers such as the NIF in the United States and the MégaJoule laser in France. Extensive numerical calculations should be performed as well, in particular with mixtures of elements.
- Calculate phase diagrams for a variety of mixtures, in particular involving superionic water, rocks, and iron (and hydrogen). The hydrogen–helium phase diagram should

also be refined because it is critical to understand the evolution and structure of Jupiter and Saturn.

- Have a better yardstick to measure solar and protosolar compositions. This has not been fully addressed by the Genesis mission and may require another mission and/or progresses in modeling the Sun's composition.
- Improve the measurement of Jupiter's gravity and magnetic fields, and determine the abundance of water in the deep atmosphere. This will be done by the Juno mission (Bolton, 2010) that is to arrive at Jupiter in 2016 and whose polar orbit skimming a mere 5000 km above the cloud tops should enable exquisite measurements of these quantities.
- Measure with high-precision Saturn's gravity field. Saturn's gravitational moments have already been improved, but an important increase in accuracy can be obtained as part of the Cassini Solstice mission (Spilker, 2012), while the spacecraft plunges onto the planet. This should lead to better constraints and possibly a determination of whether the interior of Saturn rotates as a solid body.
- Pursue the discovery of transiting extrasolar planets including some with longer orbital periods and around bright stars. A large number of these objects will enable detailed statistical studies that will be key in understanding this population of objects.
- Develop consistent models for the formation, evolution, present structure, and magnetic field of Uranus and Neptune, in order to understand ice giants as a class of planets.
- It would be highly desirable to send a probe similar to the Galileo probe into Saturn's atmosphere (e.g., Marty et al., 2009). The comparison of the abundance of noble gases would discriminate between different models of the enrichment of the giant planets, and the additional measurement of key isotopic ratio would provide further tests to understand our origins.
- In the long term, a mission to the ice giants Uranus or Neptune would bring new views of these fascinating planets and help to complete our knowledge of the outer solar system.

Clearly, there is a lot of work on the road, but the prospects for a much improved knowledge of the giant planets and their formation are bright.

Acknowledgments

The manuscript improved significantly, thanks to the insightful reviews of Nadine Nettelmann and another reviewer. The authors also wish to thank Vivien Parmentier, Leigh Fletcher, Didier Saumon, Emmanuel Lellouch, Paul Loubeyre, Ravit Helled, Bill Hubbard, Erich Karkoschka, Imke De Pater, and Miguel Morales for very useful comments and suggestions.

10.17.1 Introduction

This chapter is an update to the chapter of the same title in the first edition of this volume of the *Treatise on Geophysics*. The information on, for example, the Mars and Neptune systems has not changed much, whereas new research and observations have motivated significant changes in the discussions of especially the Earth–Moon, Pluto, Saturn, and Uranus systems. This chapter will not be all inclusive, but we will attempt to select those thoughts and mechanisms that are currently prominent in the literature and will describe both virtues and caveats in the discussion. The authors' prejudices and judgments will no doubt be evident, but we hope advice from our colleagues has tempered the impact of such. The origin of the satellites constrains the origin of the solar system, and we hope this chapter will be a suitable introduction to researchers who seek to understand the origin of our solar system and that of planetary systems in general.

Each system of satellites is unique, and it is impossible to apply the same detailed sequence of events to account for the origin of the different systems. Of all the planetary satellites, our own Moon has generated the most curiosity about its origin and the subsequent tidal evolution that has placed constraints on the theories. The dynamic mechanisms that have been proposed for the formation of the Moon are evaluated by Boss and Peale (1986), and one or another of these has been proposed for other natural satellites. The mechanisms include what have been called rotational fission, precipitation fission, intact capture, disintegrative capture, binary accretion, and formation by giant impact. In rotational fission, favored by Darwin (1879, 1880), the Moon is derived from material shed from a rapidly spinning Earth as a result of a dynamic fission instability. Precipitation fission (Ringwood, 1970, 1972) requires a massive primordial atmosphere sufficiently hot to vaporize silicates. As the atmosphere cools, the silicates condense and precipitate to the Earth's equatorial plane where they can collect into the Moon, while the volatiles in the atmosphere are swept away by a T Tauri solar wind. For intact capture, the Moon is assumed to form from the accretion of planetesimals in heliocentric orbit relatively close to that of the Earth. During a close approach to the Earth, energy must be removed from the Moon to leave it in a bound orbit. Methods proposed for this energy loss include collision with an already existing satellite (Dyczmons, 1978), atmospheric drag (Horedt, 1976), an encounter with another object in heliocentric orbit when both the Moon and the other object are within the Earth's sphere of influence (Ruskol, 1972a), changes in the masses of the Sun (Szebehely and Evans, 1980) or the Earth (Lyttleton, 1967), and the dissipation of tidal energy during the time of close approach (Alfvén and Arrhenius, 1969, 1972, 1976; Conway, 1982; Gerstenkorn, 1955, 1969; Singer, 1968, 1970, 1972; Singer and Bandermann, 1970; Winters and Malcuit, 1977). Disintegrative capture involves the tidal disruption of a proto-Moon during a close encounter with the Earth, where some of the resulting fragments could be more easily captured into bound orbit to later accumulate into the Moon (Alfvén, 1963; Alfvén and Arrhenius, 1969; Öpik, 1969, 1971). In binary accretion, the Moon forms in the Earth's orbit from an accretion disk simultaneously with the formation of the Earth (Harris, 1977, 1978; Harris and Kaula, 1975; Ruskol, 1961, 1963, 1972a,b,c, 1975). A formation by giant impact takes advantage of the fact that the last stages of accretion of the terrestrial planets involved large bodies (Wetherill, 1985). The result of such an impact is likely to leave sufficient material beyond the Roche radius R_R to accumulate into the Moon (Cameron and Ward, 1976; Canup, 2004a,b; Hartmann and

Davis, 1975; Öpik, 1971). Only the giant impact origin of the Moon has survived rather intense scrutiny (see Boss and Peale, 1986 for a detailed rejection of the other schemes). The details of the Moon-forming impact are undergoing considerable study in an attempt to understand the observation that isotope ratios of several elements are identical on Earth and Moon. Whereas a giant impactor would generally have had an isotope distribution quite different from that of the Earth, the current Moon's surface and the Earth's mantle are made of the same stuff.

As formation of satellites in accretion disks is thought to be the dominant process for the regular satellites of the giant planets (regular satellites are those in nearly circular orbits coplanar with the planet's equatorial plane), we include a description of the processes and parameters appropriate for such accretion disks in **Appendix A**. In **Appendix B**, we outline a simple theory of gravitational tides and the dissipation therein that result in orbital and spin evolution. This evolution in many instances constrains the choice of processes and events involved in the origin of particular satellites. We do not include tables of orbital parameters or physical properties of the satellites, but refer the reader to the websites http://ssd.jpl.nasa.gov/?sat_elem and http://ssd.jpl.nasa.gov/?sat_phys_par for frequently updated total number of satellites with their orbital parameters at the first website and their updated physical properties in the second.

In **Section 10.17.2**, we develop the arguments supporting the giant impact origin of the Earth's Moon, which is necessary to account for the large angular momentum of the system along with a volatile and iron-poor moon. But in addition, we must account for the plethora of identical isotope ratios on the Earth and Moon. The equatorial orbits of Mars' satellites require their origin in a dissipative disk of debris, where means of accounting for a suspected grossly different composition of the satellites from Mars itself are discussed in **Section 10.17.3**. We describe recent attempts at understanding the origin of Jupiter's regular satellites by a generalization of binary accretion during the last stages of Jupiter's formation in **Section 10.17.4**. The constraints imposed by information obtained from the Galileo spacecraft mission guide these attempts, but all involve assumptions of various degrees of uncertainty. But considerable progress has been made recently, and a self-consistent and plausible theory of origin of Jupiter's regular satellites within the theory of the accretion of Jupiter itself is emerging.

In many ways, the Saturn system of regular satellites is much more complicated than Jupiter's, where nearly all of the mass in the system is in the single large satellite Titan, and small icy satellites and icy rings appear inside Titan's orbit where we might have expected large rocky satellites as in the Jupiter system. An additional complication is that the fraction of each satellite that is not ice is not a monotonic function of the orbital semimajor axis. The origin of Saturn's satellites is discussed in **Section 10.17.5**, where we indicate that this origin is among the least well understood in the solar system. The Uranian satellites are covered in **Section 10.17.6**, where the regular nature of these satellites in spite of a planetary obliquity of 97° implies that the disk from which these satellites formed was created in the giant impact that led to Uranus' large obliquity perhaps by disrupting an existing satellite system that was reassembled from the resulting equatorial disk. An alternative would be that the Uranian obliquity resulted from adiabatic processes that allowed the equatorial orbits of the satellites to be preserved, although such a process has not been found. Details of formation of the Uranian satellites in the collision scenario have been investigated but without detailed accretion processes. Neptune's satellite system, discussed in **Section 10.17.7**, is perhaps better understood than most. A plausible series of events centered around the essentially intact capture of the large retrograde satellite Triton account well for all of the observational properties of this system. The Pluto–Charon system (**Section 10.17.8**), like the Earth–Moon system, is characterized by a large specific angular momentum, which likely resulted from an oblique giant impact. The picture is complicated by the discovery of four additional small satellites coplanar with Charon's orbit, which are too distant to have been created simultaneously with Charon and their origin remains a mystery.

Minor satellites include the irregular satellites with large semimajor axes, eccentricities, and inclinations that orbit all of the major planets and the small close satellites often associated with rings of small particles. The former are distinguished by a capture origin (**Section 10.17.9**) and the latter by having been broken up and reassembled, probably several times, by collisions among themselves, with comets or with planetesimals passing through the planets' Hill spheres. The disintegrations of these close satellites are associated with supplying the small particles, which make up the observed rings.

Many asteroids and Kuiper Belt objects (KBOs) also have satellites, where the widely separated binaries probably result from capture (Goldreich et al., 2002) and those in close orbits most probably from collisions (Canup, 2005). But some small, close asteroid binaries may form from the rotational fission of a rubble pile, where the rotational acceleration comes from the thermal Yarkovsky-O'Keefe-Radzievskii-Paddock (YORP) effect (Walsh et al., 2008). Finally, Nesvorny et al. (2010) had proposed formation of the wide binaries of comparable mass components in the Kuiper Belt from gravitational collapse of a swarm of particles. The particles can be brought into the unstable swarms perhaps by assembly in turbulent eddies (Cuzzi et al., 2001, 2008; Johansen et al., 2006) or by a streaming instability (Johansen and Youdin, 2007; Johansen et al., 2007, 2009, 2011, 2012; Youdin and Johansen, 2007). We will not discuss the small body satellites beyond these assertions. Rotational fission, precipitation fission, and disintegrative capture among those failed processes offered for the formation of the Moon also fail to find any likely applications to the satellites of Mars, Pluto, and the major planets.

10.17.2 Earth–Moon System

As additional observational constraints are imposed, the ingenious theories of origin and evolution of the Moon become more complicated. Attempts to accommodate the constraints in modifications of the theories, albeit sometimes successful on the surface, introduce uncertainties and leave gaps in the evolution, which leave us without a completely definitive theory of origin. However, all theories keep the giant impact as the most likely beginning of the process leading to our current Earth–Moon configuration, and details described in this section may generate additional ideas.

The Moon's mass is 1.2% of the Earth's mass, which is the largest fractional mass of all the satellites in the solar system

with the exception of that in the Pluto–Charon system (if we ignore asteroid and Kuiper Belt satellites). In addition, the angular momentum of the system of $L_{EM} = 3.5 \times 10^{41}$ g cm^2 s^{-1} would lead to a 4 h rotation period of the Earth if the Moon were incorporated within. This large specific angular momentum is a key constraint on the origin. The expansion of the lunar orbit by tidal interaction with the Earth (Goldreich, 1966; Touma and Wisdom, 1994) is consistent with formation close to the Roche radius $R_R = 2.9R_E$, where R_E is the Earth's radius. Accretion of the Moon inside this distance would be prevented by tidal forces. At a density of 3.34 g cm^{-3}, the Moon is depleted in iron relative to the Earth, and samples of lunar material are depleted in volatiles with vaporization temperatures < 1300 K in solar nebula conditions (e.g., Jones and Palme, 2000). A thick layer of anorthositic crust whose constituents have a positive Eu anomaly is complemented with a Eu deficiency in the mare basalts. The thickness of the anorthositic crust coupled with the complementary Eu anomalies is consistent with the crystallization of the lighter anorthositic material in a few hundred kilometer deep magma ocean with the crystals floating to the top. The floating crystals are enriched in Eu leaving the magma, from which the mare basalts are later derived, deficient in this element (Taylor and Jakes, 1974; Wood, 1972; Wood et al., 1970). Limits on lunar contraction ($\lesssim 1$ km in radius) during cooling have been inferred from the lack of stress features on its surface, which has been interpreted as implying that the interior of the Moon was initially cold beneath the magma ocean (Solomon, 1986). While contraction of an initially hot Moon might be accommodated without the expected surface scarps (see the discussion in the succeeding text), the recent detection of subsurface gravity anomalies by the Gravity Recovery And Interior Laboratory (GRAIL) spacecraft also suggests an initially cool lunar interior (Andrews-Hanna et al., 2013) in contrast to an initially hot moon inferred from the giant impact origin.

With the exception of the volatiles, the lunar material and the Earth's mantle share a number of very close compositional similarities, where isotope ratios for several elements in lunar samples are identical to those on Earth within experimental uncertainty (Lugmair and Shukolyukov, 1998; Touboul et al., 2007; Wiechert et al., 2001; Zhang et al., 2012). The current angular momentum and the Moon's overall depletion in iron are consistent with the formation of the Moon by the impact of a differentiated Mars-sized body with a differentiated Earth (Canup, 2004a), which we shall refer to as the canonical impact. However, it is unlikely that such an impact alone can account for the isotopic similarities between the Moon and the silicate Earth, which has led to a suggestion of mixing of the disk vapor with the Earth's silicate atmosphere after the impact (Pahlevan and Stevenson, 2007) as well as to the recent exploration of alternative impact scenarios (Canup, 2012; Ćuk and Stewart, 2012; Reufer et al., 2012).

The formation of the Moon by giant impact was first published by Hartmann and Davis (1975) with a lunar-sized impactor that could account for the iron and volatile deficits, but Cameron and Ward (1976) realized that the grazing collision of a Mars-sized body could also account for the large angular momentum of the Earth–Moon system. Models of terrestrial planet accretion (e.g., Wetherill, 1985, 1992) showed that the Earth was likely to have undergone such Mars-sized impacts late in its accretion history and it is this scenario that has become the paradigm for the formation of the Moon. (For a delightful account of the development of the idea of giant the impact origin of the Moon by the four authors, see MacKenzie (2003), reviewed by Burns (2003).)

Hafnium–tungsten chronology has been used to estimate the time of the solidification of the lunar magma ocean. Radioactive ^{182}Hf decays to ^{182}W with a half-life $\tau_{1/2} = 9$ million years. Both elements are refractory, so the planets should have the same overall abundances as the solar system as a whole. The most recent analysis was limited to metals in returned lunar samples. This choice avoids augmentation of the ^{182}W from the capture of cosmic ray-generated neutrons by ^{181}Ta, since Ta is excluded from the metals. Any excess ^{182}W in the metals can thereby be attributed solely to production from ^{182}Hf decay. Recent experiments have detected no excess ^{182}W in metallic parts of 18 lunar samples, which implies that Hf was extinct at the time of solidification (Touboul et al., 2007). This result implies that solidification occurred more than 60 million years after the formation of the oldest constituents of meteorites, the calcium–aluminum-rich inclusions (CAIs). This is in contrast with earlier Hf–W chronology, which inferred a solidification age of 30–50 million years (Kleine et al., 2005), which was thought consistent with the timescale within which a giant impact was likely to have occurred. The late solidification of the Moon is supported by ^{207}Pb–^{206}Pb, ^{147}Sm–^{143}Nd, and ^{146}Sm–^{142}Nd chronologies performed on anorthositic material, which are consistent with crystallization as much as 200 million years after the formation of the CAIs (Borg et al., 2011). Since the solidification time of a magma ocean is ~10 million years (Elkins-Tanton et al., 2011), the giant impact may have occurred much later than previously assumed, or a scheme different from crystals of anorthositic material floating to the surface of a magma ocean to account for the anorthositic crust must be invoked. Contradicting the inference of a late formation of the Moon is the work of König et al. (2011), who find evidence for an early formation of the Earth's core associated with an inferred concurrent formation of the Moon. But the Earth's core probably formed long before the impact. Using Lu–Hf chronology, Taylor et al. (2009) argued for a rapid lunar differentiation implying an early formation. Still, Touboul et al. finding no excess ^{182}W in lunar metals is a rather clean result favoring a formation of the Moon after ^{182}Hf is extinct.

The angular momentum relative to the center of mass of the target (mass M_t) delivered by an impactor of mass $M_i = \gamma M_T$, where $M_T = M_t + M_i$ is the total mass, is (Canup, 2004a)

$$L_i = bM_T^{5/3} f(\gamma) \sqrt{\frac{2G}{\left(4\pi\rho_p/3\right)^{1/3}}} \left(\frac{v_i}{v_{esc}}\right) \approx 1.3 L_{EM} b \left(\frac{M_T}{M_E}\right)^{5/3} \left(\frac{\gamma}{0.1}\right) \left(\frac{v_i}{v_{esc}}\right) \quad [1]$$

where $b = \sin\xi$ is the impact parameter divided by $R_t + R_i$, the sum of the target and impactor radii; ξ is the angle between the line connecting the centers of M_t and M_i and the impact trajectory at the time of first contact, such that grazing incidence has $\xi = 90°$ or $b = 1$; G is the gravitational constant; ρ_p is the common density of M_t and M_i; v_i is the velocity of the impactor; $v_{esc} = \sqrt{2GM_T/(R_t + R_i)}$ is the mutual escape velocity, $f(\gamma) = \gamma(1-\gamma)\sqrt{\gamma^{1/3} + (1-\gamma)^{1/3}}$; and M_E is the Earth's mass. The complication of eqn [1] comes from introducing v_{esc} into the equation for angular momentum.

For the simplest case in which a single impact provides all the Earth–Moon system angular momentum, L_i must be comparable to or greater than that in the current Earth and Moon (L_{EM}). Some angular momentum will be lost in escaping material both from the initial impact and during the assembly of the Moon from the impact-generated disk. The magnitude of the former depends primarily on the impact velocity, while models of the Moon's accretion suggest that the latter would have been of order of a few $\times 10^{-2}\ L_{EM}$ (Kokubo et al., 2000; Salmon and Canup, 2012). The Earth–Moon angular momentum would have also been decreased by a few percent by tides raised on the Earth by the Sun that slow the Earth's rotation (e.g., Canup et al., 1999). For a given value of L_i, there is a multidimensional parameter space involving b, M_T, γ, and v_i that must be explored to find successful candidate impacts. Accommodation of values of $L_i \approx 2L_{EM}$ in more energetic impacts (Canup, 2012; Ćuk and Stewart, 2012) will be discussed later.

A successful lunar-forming impact produces a disk capable of later yielding an iron-depleted moon outside the Roche limit. This condition is met either when a lunar mass or more is placed into orbits outside R_R by the impact itself or when the disk has sufficient mass and angular momentum so that viscous spreading after the impact can deliver sufficient mass beyond R_R. Simulations of the disk's evolution typically find that a single moon accretes just outside R_R, with inner disk material driven into the planet and $<5\%$ of the disk's mass escaping from the Earth's orbit (Crida and Charnoz, 2012; Ida et al., 1997; Kokubo et al., 2000). A mass and angular momentum conservation argument can be used to estimate the mass of the moon (M_M) that would accumulate from a disk as a function of the initial disk mass (M_D), the initial disk angular momentum (L_D), the initial position of the moon ($a = \lambda R_R$), and the angular momentum of material that escapes or collides with the Earth. Based on results of disk simulations and with $\lambda = 1.3$, the predicted moon mass is

$$\frac{M_M}{M_D} \approx 1.9\left(\frac{L_D}{M_D\sqrt{GM_E R_R}}\right) - 1.1 - 1.9\left(\frac{M_{esc}}{M_D}\right) \qquad [2]$$

where M_{esc} is the escaping mass (Ida et al., 1997; Kokubo et al., 2000). This equation provides a simple way to determine whether a disk produced by a hydrodynamic simulation could later yield a lunar mass moon. It is physically invalid for cases that would give $M_M/M_D > 1$; these correspond to initial disks with specific angular momenta too high to be consistent with the assumption that the final moon forms at $1.3R_R$.

Smooth particle hydrodynamics (SPH) is the method most used in numerical exploration of the impact parameter space. SPH is a Lagrangian method that describes the colliding objects by a multitude of particles that are evolved due to self-gravity and pressure forces. Over time, the spatial resolution of such calculations has increased from $\sim 10^3$ particle simulations in Benz et al. (1986, 1987) to 10^5–10^6 particle simulations in recent works (e.g., Canup, 2004b, 2008, 2012; Canup and Asphaug, 2001; Ćuk and Stewart, 2012; Reufer et al., 2012). At the same time, there have been algorithm and equation of state (Melosh, 2007; see also the discussion in Canup, 2004b) improvements that have influenced the results. Alternatively, impacts can be modeled with a grid-based, Eulerian hydrocode (Canup et al., 2013; Wada et al., 2006). Simulations with SPH and the grid-code CTH yield broadly similar results, with the predicted protolunar disk mass and its angular momentum converging to typically within about 10% for simulations of very similar impact conditions (Canup et al., 2013).

SPH simulations show that for $L_i \approx L_{EM}$, those impacts that produce a relatively iron-poor disk having M_M (from eqn [2]) of at least a lunar mass typically have $b \sim 0.7$ ($\sim 45°$ impact angle), a low impact velocity $v_i/v_{esc} < 1.1$, and an impactor mass ratio $0.1 < \gamma < 0.15$ (a roughly Mars-sized impactor) for $M_T \sim M_E$ (Canup, 2004a; Canup and Asphaug, 2001). An impact involving a low-velocity, Mars-sized impactor with $L_i \approx L_{EM}$ has generally been considered the 'canonical' impact for forming the Moon, because it accounts for the main dynamical properties of the Earth and Moon and the Moon's relative lack of iron while relying on conditions that are probable during the late stages of terrestrial planet accretion, that is, large, randomly oriented impacts, with 45° being the most probable impact angle (e.g., Agnor et al., 1999). However, because such cases yield a disk formed primarily from material originating from the impactor, the observed identical isotope ratios for lunar and Earth mantle materials cannot prevail.

It has been known for decades that the Earth and Moon share identical oxygen isotope compositions that are distinct from those of most meteorites and Mars (e.g., Wiechert et al., 2001). This would be consistent with the Moon's composition if the Moon formed directly from the Earth's mantle. If instead the disk (and the Moon) formed primarily from impactor material, an impactor with an identical oxygen composition as the Earth would then be required. Because oxygen compositions vary with heliocentric position, it was suggested that this similarity would be expected if the impactor formed near the Earth (e.g., Belbruno and Gott, 2005; Wiechert et al., 2001). This seemed to agree well with the canonical impact, which required a low impact velocity and therefore an orbit close to that of the Earth. However, this explanation was brought into serious question by Pahlevan and Stevenson (2007), who argued that it is very improbable that the impactor and Earth would share the same oxygen composition even if they were in close orbits, given the degree of radial mixing predicted by planet accretion models. Using the impacts predicted in one of Chambers' (2001) terrestrial accretion simulations, together with the assumption that the oxygen composition of planetary embryos varied linearly with initial heliocentric distance, they estimated that the typical difference between the composition of an impactor and its final target planet would have been comparable to the current difference between Earth and Mars, which is about 50 times greater than the allowable difference in the Earth–Moon oxygen compositions. A moon accreted from a disk composed primarily of impactor-derived material would then be expected to have a substantially different oxygen composition than the Earth. Furthermore, the isotopic composition of multiple other elements now also appears identical in the silicate Earth and Moon, including chromium (Lugmair and Shukolyukov, 1998), titanium (Zhang et al., 2012), tungsten (Touboul et al., 2007), and silicon (Georg et al., 2007). Georg et al. pointed out that Si partition into the core is a high-pressure process that depletes the heavy isotopes more than the light ones and that requires at least 0.15 Earth masses to become

effective. That means that even if the oxygen, chromium, and titanium isotopic compositions were identical in the Earth's mantle and the Mars-sized impactor, the silicon composition of the impactor would likely not be because of partitioning of the heavier Si isotopes into the Earth's core. This supports the Pahlevan–Stevenson assertion that Earth and impactor could not have identical isotopic compositions before the impact.

As a solution, Pahlevan and Stevenson (2007) proposed that the vapor components of the disk and the Earth's silicate atmosphere diffusively mixed after the impact via vigorous convection, allowing the disk to compositionally equilibrate with the Earth before the Moon forms. However, as stressed by Melosh (2009), for this to occur, one must assume that the convection mechanism does not also transport angular momentum at the same efficiency, because if it did, the disk would spread into the Earth on a similar timescale and diffusion from the Earth's atmosphere would have to operate upstream against the flow of this incoming material. Still, this may be a valid assumption, since thermal convection is now thought to be inefficient in transporting angular momentum in disks (Stone et al., 2000). Equilibration is estimated to require $\sim 10^2$–10^3 years, so that the Moon's accumulation must be delayed by this amount of time after the impact (Pahlevan and Stevenson, 2007). The mixing must involve the whole of the disk to equalize the planet-disk compositions, which may be difficult if a substantial fraction of the Moon's mass is initially outside the Roche limit (e.g., Salmon and Canup, 2012). It is not clear that vapor equilibrium of refractory elements in a canonical impact (including notably titanium) is possible, although if the disk lasts for $\geq 10^2$ years, there may be sufficient time for even refractory elements in the magma layer to equilibrate with the disk's vapor atmosphere (Zhang et al., 2012). In addition, the titanium isotope composition of Mars appears much closer to the Moon's composition than is true for oxygen. Within current uncertainties, the Mars–Earth Ti difference may only be about a factor of 2 larger than the Moon–Earth difference (e.g., Canup, 2012, supplemental material), so that a disk composed primarily of material from a Mars-composition impactor might not require much equilibration of Ti to be consistent with the current Moon. Thus, titanium does not provide as strong a constraint on equilibration as oxygen, for which the Earth–Mars difference is much larger.

Such issues motivated additional impact studies with L_i close to L_{EM} with varying assumptions to see if a disk with planet like composition could be produced. Comparisons between simulations performed with SPH versus CTH found no systematic influence of simulation method on predicted disk composition (Canup et al., 2013). To quantify the compositional difference between the silicate portions of the disk and planet, one can define a deviation percentage (after Reufer et al., 2012),

$$\delta f_T = \left[\frac{F_{D,tar}}{F_{P,tar} - 1}\right] \times 100 \qquad [3]$$

where $F_{D,tar}$ and $F_{P,tar}$ are the mass fractions of the silicate portions of the disk and the planet derived from the target's mantle. Identical disk-planet compositions have $\delta f_T = 0$, whereas a disk that contains fractionally more (less) impactor-derived silicate than the final planet has $\delta f_T < 0$ ($\delta f_T > 0$). For a Mars-like composition impactor, consistency with the Earth–Moon oxygen composition requires $|\delta f_T|$ less than a few percent (e.g., Canup, 2012).

Prior works had assumed a target and impactor that were not rotating prior to their collision, an almost certainly incorrect assumption. Canup (2008) examined the effect of pre-impact rotation in impacts that leave a planet-disk system with an angular momentum, L, comparable to L_{EM}. She found that a target proto-Earth with a pre-impact retrograde rotation (i.e., in the opposite rotational sense as the impact itself) allowed for somewhat larger impactors and produced disks containing up to 40% target material. Reufer et al. (2012) considered higher-velocity, more head-on impacts in which a substantial fraction of the impact angular momentum escapes, so that L_i may be much greater than L_{EM} and still leave a planet-disk system with $L \sim L_{EM}$. They found that collisions with $1.2 \leq v_i/v_{esc} \leq 1.3$, $0.15 \leq \gamma \leq 0.2$, and $\xi = 30$–$40°$ produced appropriately massive disks that contained up to $\sim$60% target material.

The canonical impacts typically have $-90\% \leq \delta f_T \leq -70\%$, whereas the successful cases (producing a disk leading to a $\sim 1 M_M$ Moon) in Canup (2008) have $\delta f_T \leq -50\%$ and those in Reufer et al. (2012) have $-40\% \leq \delta f_T \leq -30\%$. The more target-rich disks produced by Canup (2008) and Reufer et al. (2012) have values of $|\delta f_T|$ far greater than the required few % that would account for the Earth–Moon oxygen isotope similarity.

These failures to obtain a disk made up almost entirely of Earth mantle material have motivated proposals for additional modifications of the impact scenario, where the angular momentum of the resulting system is no longer constrained to be near L_{EM}. Ćuk and Stewart (2012) chose high-velocity, equatorial plane impacts ($v_i = 15$–25 km s^{-1}, 1.5–3 times v_{esc}) onto rapidly spinning Earth-mass targets ($M_t = M_E$) (periods 2.3–2.7 h corresponding to angular momenta of 1.9–$3.1 L_{EM}$), where $0.026 \leq M_i/M_t \leq 0.1$. The requirement of a near-fission rotation rate of the Earth prior to impact may be quite restrictive. Rapidly rotating planets are seen in N-body simulations of late-stage accretion (e.g., Agnor et al., 1999). However, such models tend to overestimate planetary rotation rates because they assume pure mergers and ignore the possible ejection of mass and angular momentum during large impacts. The most successful outcomes in the Ćuk–Stewart simulations, where the disk was sufficiently Earth mantle-dominated to satisfy the isotopic constraints (with $|\delta f_T|$ $\sim$several percent) and the predicted mass of the accreted satellite was near M_M, occurred for head-on or slightly retrograde impacts onto the higher angular momentum initial targets with impact velocities ~ 1.5–$2.5 v_{esc}$. In the successful Ćuk–Stewart impacts, the Earth rotation period is reduced, but the total remaining angular momentum is still $\gtrsim 2 L_{EM}$.

Canup (2012) reported simulations successful in producing a disk with the same composition of the Earth's mantle by colliding nonrotating targets and impactors of similar mass ($M_i/M_T \geq 0.4$) at low velocity. Here, the impact parameter was varied over a wide range yielding $0.35 \leq b \leq 0.7$, which determined the angular momentum of the Earth + disk and yielded a disk of sufficient mass to produce a Moon mass satellite. The silicate mantles of target and impactor were well mixed by the impact, so the resulting Earth mantle and disk had essentially the same silicate composition to satisfy the isotope constraints

(Nakajima and Stevenson, 2013). The most successful Canup examples yielded $\delta f_T = -0.8\%$ and -0.3%, predicted satellite masses of 1.64 and $1.09 M_M$, but left the Earth spinning with period of about 2 h with total angular momenta of 2.45 and $2.22 L_{EM}$.

The kinetic energy of both the new impact scenarios is comparable (although the Canup model involves a much larger impactor, the Cuk and Stewart model involves a higher impact velocity) and is about a factor of three larger than that of the canonical impacts. Such violent events may have difficulty explaining the recent inference that the Earth's mantle may not have been thoroughly mixed (Touboul et al., 2012), although Ćuk and Stewart (2012) argued that at least in the case of their impacts, this may result from nonuniform heating during the collision. In general, relaxing the angular momentum constraint in two different giant impact scenarios has allowed disk and Earth mantle to have compositions that are sufficiently alike in both the Ćuk and Stewart (2012) analysis and that of Canup (2012) to satisfy the isotope constraints in oxygen, titanium, and chromium (see succeeding text for the discussion on tungsten and silicon), but both leave the system with excess angular momentum that must be eliminated.

Ćuk and Stewart (2012) offered an ingenious scheme for reducing the system angular momentum. As the Moon recedes from the Earth due to torques from tides raised on the Earth, it is captured into the evection resonance with the Sun. The evection resonance occurs when the precession period of the Moon's perigee is commensurate with the Earth's orbital period about the Sun. For an Earth–Moon system with an angular momentum $\sim L_{EM}$, the resonance occurs when the Moon's semimajor axis is $a \approx 4.6$ Earth radii. This resonance had been previously investigated by Touma and Wisdom (1998), who found that it could play a key role in setting up capture into a resonance involving the lunar inclination that could explain the Moon's initial orbital inclination (see succeeding text). For the more rapidly spinning Earth (~ 2.5 h day), corresponding to a system angular momentum ~ 2–$2.5 L_{EM}$, the Earth's increased oblateness causes the location of the resonance to shift outward to $a \approx 7$ Earth radii. At this larger distance, the rate of the Moon's orbital expansion due to tidal interaction with the Earth is slower, which increases the likelihood of capture into evection. In the evection resonance, the line of apsides of the lunar orbit remains perpendicular to Earth–Sun direction. Angular momentum is tidally transferred to the Moon orbit from the Earth and from there to the Earth–Moon orbit about the Sun because of resonance. The orbital eccentricity increases to a value near 0.6 for $A_Q \approx 1$ (see eqn. 4) as the Moon's orbit expands until the expansion of the Moon's orbit stalls due to a balance between Earth tides (which cause a to expand) and satellite tides (which cause a to contract for high-eccentricity orbits). As long as the evection resonance is maintained, angular momentum of the Earth–Moon system is being reduced, and in the Ćuk and Stewart simulations, the Moon's prolonged residency in the resonance removes the excess angular momentum until the resonance is broken and the Moon commences its tidal evolution to its current distance from the Earth. However, there are some caveats in this scheme for removing the excess angular momentum.

A measure of the relative tidal dissipation in the Moon and Earth is given by the ratio

$$A_Q = \frac{k_{2M}}{k_{2E}} \frac{Q_E}{Q_M} \frac{M_E^2}{M_M^2} \frac{R_M^5}{R_E^5} \qquad [4]$$

where the subscript Q indicates the constant Q tidal model. The successful cases of Ćuk and Stewart, where systems with $L \approx L_{EM}$ were obtained, occurred only for a very narrow range of A_Q near 1. If lunar tides are too strong relative to Earth tides, the system leaves the resonance before sufficient angular momentum is removed, whereas if the lunar tides are too weak compared to the Earth tides, the lunar orbital eccentricity reaches overly high values that destabilize the resonance (Ćuk and Stewart, 2012). Both the Earth and Moon are likely to be nearly all molten initially with values of k_2 close to the fluid values, and $A \sim 1$ implies $Q_M \approx 10 Q_E$ (little dissipation in the Moon) from eqn [4]. There is no reason for Q_M to be so much larger than Q_E, but see the succeeding text.

The reader should be warned that the results of the calculations depend on the tidal model. Ward and Canup (2013), using the constant Δt ($Q \propto 1/\omega$) described in **Appendix B**, were also in some cases able to remove all the excess angular momentum while the Moon is trapped in the evection resonance. In their case, the measure of dissipation in the Moon to that in the Earth is given by

$$A_{\Delta t} = \frac{k_{2M}}{k_{2E}} \frac{\Delta t_M}{\Delta t_E} \left(\frac{M_E}{M_M}\right)^2 \left(\frac{R_M}{R_E}\right)^5 \qquad [5]$$

and a value of $A_{\Delta t} \approx 9$ is used in a successful case that removes nearly all of the excess angular momentum. Recall for this tidal model that $Q = 1/\omega \Delta t$ (**Appendix B**), so we could replace $k_2 \Delta t$ in eqn [5] with $k_2/Q\omega$, where Q is now that value appropriate for the frequency ω. The dominant tidal frequency in the Moon is close to the mean orbital motion n, whereas that in the Earth is the much larger $\dot{\psi} - n$, where $\dot{\psi}$ is the angular velocity of the Earth. Then, $k_{2M}\Delta t_M/(k_{2E}\Delta t_E) = (k_{2M}/k_{2E})(Q_E/Q_M)\left(\left(\dot{\psi} - n\right)/n\right)$, where again the Qs are those appropriate for the frequencies they multiply. But for constant Δt, $Q_E(\omega) = Q_E(n)(n/\omega)$, so $A_{\Delta t} \approx 10 Q_E(n)/Q_M(n)$ if the k_2s are comparable. The Ward–Canup result with $A = 9$ would then require the Qs for the Moon and Earth evaluated at the frequency n to be comparable, which contrasts with the constant Q model. Another reservation is that the large increase in the eccentricity during the angular momentum transfer could lead to a drastic increase in the lunar dissipation and the value of A_Q would drift far outside the narrow range for stability of the evection resonance (Wisdom, private communication). There may be a similar restriction on $A_{\Delta t}$. We should therefore regard both the Ćuk–Stewart and the Ward–Canup results as indicative that removal of the angular momentum in the evection resonance could be possible with the reservation that at least the constant Q results have to be relatively finely tuned, in which tuning might be frustrated by the increased dissipation in the Moon during the high-eccentricity phase, and that neither tidal model represents the behavior of real materials (e.g., Castillo-Rogez et al., 2011).

There are thus two viable schemes for creating a moon with identical isotopes to those of the Earth's mantle that are consistent with a giant impact origin of the Moon (Canup, 2012; Ćuk and Stewart, 2012) without requiring postimpact equilibration. Although both require a system angular momentum close to twice L_{EM}, at least a process has been demonstrated that could reduce the angular momentum to a value close to

L_{EM}, but not without important caveats. What is less clear is whether these models can account for the Earth–Moon similarities involving elements that partition strongly into metals and therefore can be affected by core formation, including tungsten and silicon. Whether the disk is formed from the target's mantle (as in the Ćuk and Stewart impacts) or from an approximately equal mix of target and impactor mantles (as in the Canup impacts), the core of the impactor is absorbed by the planet, while the disk contains little iron. Mixing and equilibration of the impactor's core with the target's mantle would tend to alter the planet's tungsten and silicon compositions relative to that of the disk (and the resulting Moon). However, it is possible that rapid merging of the impactor's large core with the Earth's core precludes efficient silicate–metal equilibration, because the latter requires emulsification down to centimeter scales (Dahl and Stevenson, 2010; Rubie et al., 2003).

Although the overall compositional and dynamical properties of the current Earth–Moon system appear consistent with these latest versions of giant impact origin, the transition from the distribution of material following the impact to the accreted Moon a little outside the Roche radius R_R that is also consistent with current observations remains less well understood. An impact-produced disk contains silicate magma and vapor, with initially 10–30% vapor by mass for canonical impacts and up to 90% vapor by mass for the high angular momentum impacts. Much or perhaps most of the disk mass initially orbits within the Roche limit. Interior to R_R, clumps among the magma formed by local gravitational instability are sheared apart by planetary tidal forces (Ward and Cameron, 1978). This generates a large viscosity that dissipates heat and causes the Roche interior disk to spread inward onto the planet and outward past R_R on a timescale τ_v. Material from the inner disk that spreads beyond R_R, together with material that was placed into orbits outside R_R by the impact itself, provides the material that can accrete into the Moon.

Early estimates that assumed a pure magma disk (no vapor) suggested $\tau_v \sim O(1)$ year (Ward and Cameron, 1978). This timescale is consistent with that seen in N-body lunar accretion simulations of a vapor-free disk of particles that find that the Moon accretes in less than a year (Crida and Charnoz, 2012; Ida et al., 1997; Kokubo et al., 2000). However, there is an inconsistency in modeling the protolunar disk as vapor-free, because the energy dissipated as a disk of molten or solid particles viscously spreads is sufficient to vaporize the disk. Vaporization renders the disk gravitationally stable unless the energy is radiated away. Silicate vapor and liquid phases coexist when the disk's photospheric temperature is of order ~2000 K. If the phases are vertically well mixed, the radiation rate of the disk at this temperature can limit the disk's spreading to a much longer timescale, $\tau_{rad} \sim O(10^2)$ years (Thompson and Stevenson, 1988). Thompson and Stevenson (1988) suggested that a lower viscosity consistent with this timescale could result as the disk hovers on the brink of local gravitational instability with a sound speed just below the critical value for marginal stability. The latter can occur in a two-phase disk if the gas mass fraction is very low – only a few percent – with the bulk of the material comprised of liquid droplets that are vertically well mixed with the vapor. An alternative, stratified disk structure can result if the liquid instead settles, forming a midplane magma layer surrounded by a vapor disk atmosphere (Ward, 2012). In either case, the lifetime of the Roche interior disk is $\geq 10^2$ years.

The $\leq$1-year accretion timescale predicted by N-body lunar accretion models is at odds with these much longer disk lifetimes. More recent simulations that pair an N-body model for material outside the Roche limit with a fluid model for an inner disk that persists for $\sim 10^2$ years find that the Moon takes $\sim 10^2$ years to complete its accretion (Salmon and Canup, 2012), which may provide sufficient time for the equilibration of oxygen (Pahlevan and Stevenson, 2007). Accretion of the Moon in $\leq$1 year implies a fully molten Moon, whereas accretion over 10^2 years may allow for partial cooling for favorably chosen conditions (e.g., Pritchard and Stevenson, 2000). A molten Moon is not consistent with the most straightforward interpretation of the lack of global-scale thrust faults on the Moon, which implies limited contraction and an initially cool interior (Solomon, 1986). There are uncertainties in the properties of the lunar crust and in the thermal history that seem to allow ranges of parameters and processes that could accommodate an initially molten Moon in spite of the lack of observable indications of a significant radius change (Pritchard and Stevenson, 2000). But recently, the GRAIL spacecraft has identified a system of subsurface gravity anomalies hundreds of kilometers in length that are interpreted as dikes formed during the expansion of the early lithosphere (Andrews-Hanna et al., 2013). Such an early period of expansion is predicted for an initial Moon with a cool interior and an overlying magma ocean as the interior warms during the Moon's first billion years (Solomon, 1977). The GRAIL data thus provide additional evidence for an initially cool lunar interior. Any surface indication of the expansion could have been erased by the late heavy bombardment (LHB) on the Moon, where the existence of the dikes seems to imply that the LHB was not so intense as to create a second magma ocean. But an initially cold Moon is not consistent with the results of the giant impact.

The most likely consequence of the accretion of the Moon from a disk of material generated by a giant impact is a hot, at least partially molten Moon orbiting just outside R_R in the Earth's equatorial plane. Before we leave the Earth–Moon system, we must then account for the Moon's current orbital properties under the assumption that the semimajor axis of the Moon's orbit was increased from its initial to the current value by tidal torques. By integrating backward in time from the current state, Goldreich (1966) found that the Moon's orbit had an inclination to the Earth's equator of about 10° when the lunar semimajor axis was approximately $10R_E$. This result was confirmed by Touma and Wisdom (1994). The 10° inclination is not consistent with the Moon having formed in the Earth's equatorial plane from the debris generated by a giant impact. Moving the Moon from an equatorial orbit to one inclined by 10° is called the 'inclination problem.'

There are four proposals for accomplishing this bit of dynamics. If the Earth had a significant spin before impact like the Ćuk and Stewart initial condition, and a substantial fraction of the Moon remained in a coherent clump after the impact, the latter's orbit could have been inclined to the equatorial plane and subsequent accretion of the remaining lunar mass could leave it inclined (Canup, 2004a). But the equilibration of the isotope ratios would have been frustrated, even if the unlikely event occurred. Alternatively, an additional impact

on the Earth after the Moon-forming event could have altered the alignment of the Earth's spin. But this event would have had to have occurred while the Moon was very close (Ward, 2002), and it is not clear how the Moon would not have been contaminated with additional material with different isotope ratios – even if the first impact established equal ratios. The remaining two hypotheses do not obviously frustrate the identical isotope condition, but both still have caveats. They both involve resonant interactions to increase the initial Moon's orbital inclination – one with orbital resonances between the Moon's motion and the Sun (Touma and Wisdom, 1998) and the other with resonances between the Moon's motion and a remnant disk inside R_R (Ward and Canup, 2000).

In an integration that produces the current configuration when the Moon has reached its current distance from the Earth, Touma and Wisdom (1998) started the Moon in the equatorial plane of the Earth at a separation of $3.5R_E$ with an eccentricity of 0.01. The initial obliquity of the Earth is 10° and the initial Earth rotation period is 5 h. There is no circumplanetary disk present. Realistic rates of tidal evolution are used in the symplectic integrations that include the entire chaotic solar system, and dissipation in the Moon is included at a variety of dissipation rates. A tidal model was used employing the constant time lag as discussed in **Appendix B** but with the Mignard (1981a) formulation. The evection resonance is encountered when the Moon is at about $4.6R_E$, where the period of the periapse motion of the lunar orbit relative to an inertial reference is near one year. This resonance is called the evection resonance because the same term in the disturbing function gives rise to the 1.3° amplitude, 31.8 day periodic variation in the Moon's mean longitude called the evection. Capture into the evection resonance is certain if the eccentricity is below about 0.07 as the resonance is approached and if the rate of tidal evolution is sufficiently slow. With the assumed parameters, capture occurs and the eccentricity grows rapidly to large values, where the maximum value reached before the system escapes the resonance is determined by the value of $A_{\Delta t}$ defined by eqn [5]. For $A_{\Delta t}=0$ (no dissipation in the Moon), the maximum eccentricity is about 0.5 before escape and the eccentricity continues to climb after escape from the resonance because of tides raised on Earth and no dissipation in the Moon (Goldreich, 1963). For $A_{\Delta t}=10$ (high dissipation in the Moon), the maximum eccentricity is only about 0.15. For $1 \le A_{\Delta t} \le 10$, the energy dissipated in the Moon in about 8000 years is in the range $\sim 2\times10^{35}$–1.5×10^{36} ergs, which could lead to substantial melting (Touma and Wisdom, 1998).

After escape from the evection resonance, the continued expansion of the orbit further decreases the prograde motion of the orbit periapse and twice the time derivative of the evection resonance variable plus the retrograde motion of the lunar orbit node approaches zero near $6R_E$. The term in the Hamiltonian corresponding to this resonance has $e_M^2 i_M$ in the coefficient, but this resonance affects the inclination more than the eccentricity. Touma and Wisdom named this resonance the eviction – changing the e in evection to i to emphasize the inclination and noting that this resonance 'evicts' the Moon from an equatorial orbit. If A is not too large, the eviction resonance is approached with high eccentricity in the wrong direction for capture. Passage through the resonance leaves the eccentricity large and excites an inclination of 2°–3°. If A were now to increase drastically – perhaps because the continued high eccentricity has partially melted the interior – the dissipation in the Moon becomes so high that the semimajor axis is decreased as the eccentricity is reduced. This takes the system through the eviction resonance from the other direction where capture and subsequent evolution force the inclination to values between 9° and 13°. Escape from the resonance is effected because of the continued decrease in e_M, but the remnant inclination is preserved. Subsequent evolution brings the Moon to the current configuration. The Touma and Wisdom analysis was the first that allowed the Moon to evolve from an equatorial orbit to its current configuration from the effects of tidal dissipation alone.

An important constraint on the Touma–Wisdom model is that the Moon needs to begin its tidal evolution cold, which is contrary to our conclusion earlier that the Moon most likely started hot in at least a partially molten state (e.g., Pritchard and Stevenson, 2000). In addition, a more rapidly rotating initial Earth as advocated in Ćuk and Stewart (2012) moves the position of the evection outward, so that it takes longer for the Moon to encounter the resonance. However, from the expression for the tidal variation in the mean motion (Peale, 1988)

$$\frac{dn}{dt} = -\frac{9}{2}k_2\frac{M_M}{M_E}\frac{R_E^5 n^{16/3}}{(GM_E)^{5/3}}\frac{1}{Q_E} \qquad [6]$$

the timescale for expanding the lunar orbit from $3R_E$ to $7R_E$ is only $\sim 32Q_E$ years, where Q_E is likely to be < 10 for a partially molten Earth. The timescale for solidifying a magma ocean on the Moon is 1000 years for the first 80%, appropriate to maintaining melt on the surface from foundering of the cooled material, and 10 million years for the remainder appropriate for the conductive timescale of an anorthositic stagnant lid (Elkins-Tanton et al., 2011). The further distance of the evection resonance for the rapidly spinning Earth does not allow sufficient time for significant cooling of the Moon. The probable hot Moon remains a caveat in the Touma–Wisdom solution to the inclination problem. But if the inference from the GRAIL data that the Moon was initially cold can be supported by a believable evolution of the system, perhaps the Touma–Wisdom ideas can gain credibility.

The scheme involving disk interactions to change the Moon's inclination (Ward and Canup, 2000) depends on the coexistence of the Moon with a 0.5–1 lunar mass Roche interior disk for 10–100 years. Waves in the disk are generated at locations where the ratio of the local mean motion to that of the Moon involves two small integers. Torques that result from the gravitational interaction of the Moon with the distribution of mass in the wave structures can affect the lunar orbit. Such mean motion resonances (MMRs) from planar interactions are called Lindblad resonances, and they generate spiral density waves. Spiral bending waves are associated with the inclination of the Moon's orbit, where material in the disk is lifted out of the plane (e.g., Shu, 1984). When the Moon is just outside R_R, there are many MMRs in a disk that extends nearly to R_R. Torques from the waves generated in the disk force the Moon to larger semimajor axes, while the back reaction reduces the angular momentum contained in the disk. The resonances thereby move out through the disk and eventually leave its outer edge until the last strong one to leave the disk is the 3:1 inner vertical resonance (IVR) when the Moon's semimajor axis is a little over twice the disk radius.

The effect of the torque $T_{IVR} \propto \sigma_g \sin^2 I$ from the so-called bending waves, where I is the orbital inclination for the Moon and σ_g is the surface mass density of the inner disk, in addition to contributing to the growth of the semimajor axis a of the Moon's orbit, is an increase in the inclination at the rate (Ward and Canup, 2000)

$$\frac{dI}{dt} = \frac{T_{IVR}}{M_M a^2 \Omega_K \sin I}\left(\frac{3}{2}\cos I - 1\right) \quad [7]$$

where M_M is the lunar mass and Ω_K is the Kepler mean motion. With a disk mass of $0.75 M_M$ and an initial $I = 1°$, inclinations reached 12.3° and 14.5° as the Moon nears $6R_E$ for initial disk spreading times of 37 and 50 years, respectively (Ward and Canup, 2000). The growth of I stops if either the resonance moves outside the disk or the disk is depleted. The disk interaction mechanism requires control of the evolution by the 3:1 vertical resonance. Other resonances, if still present, can lead to inclination damping (e.g., Borderies et al., 1984; Ward and Hahn, 1994). However, the Lindblad resonances invoked by Borderies et al. to damp the inclination are out of the disk when the 3:1 vertical resonance is near the disk edge, and the co-orbiting vertical resonances used by Ward and Hahn are at the position of the Moon, which is outside of the disk. Once the inclination is at 10° near the Earth, tidal evolution can carry the Moon to the current distance with the orbit inclined by about the observed 5° relative to the ecliptic. Whether the Ward–Canup scheme would be as effective in a full model of the Moon's accretion has not yet been assessed. For example, it is not clear that a disk of sufficient mass could even exist after the Moon was formed or could persist long enough to increase the lunar inclination to the necessary value given the very high efficiency of accretion. Ward and Canup considered the IVR torque due to the total inner disk surface density in their analysis. This inherently assumes that the waves in both the disk's gas and magma layers damp sufficiently. If the gas waves do not damp sufficiently, then the torque could be dominated by that of the magma layer, an issue that should be addressed by future models. The Moon's resonant interactions with a Roche interior disk would generally predate its encounter with the evection resonance. An inner disk contributes to the lunar perigee precession, shifting the location of evection outward. The disk mass must be reduced to $< 0.1 M_M$ before the evection resonance moves inside $10R_E$ where it can encounter the Moon (Canup, 2004a), thereby making the Ward–Canup and Touma–Wisdom schemes mutually exclusive.

If the Moon is partially molten in the Ward–Canup scenario, the high dissipation limits the eccentricity growth in a subsequent passage through the evection resonance as the disk is dissipated and the lunar orbit continues to expand, even if trapped for a time (Touma and Wisdom, 1998). The passage through the eviction resonance is in the wrong direction for capture so the inclination will not change significantly after the Ward–Canup mechanism has brought it above 10°.

The major recent change in the giant impact paradigm has been the accommodation of the identical isotope ratios in Earth and Moon. Two successful modifications of the giant impact scenario involving an initial value of system angular momentum $\sim 2L_{EM}$ have been proposed, and there may be a way to remove the excess angular momentum. But getting from the disk of essentially identical isotope composition as the Earth's mantle to the Moon at $\sim 10R_E$ with orbit inclined 10° to the equator has many uncertain steps and generally has a deficiency of investigations. The reader can identify several processes needing more thorough investigation, and even those processes that are reasonably well understood have uncertainties that remain to be resolved. For example, how can we reconcile the initially hot Moon inferred from the giant impact origin and rapid accretion with those observations consistent with an initially cold moon? We are sure that imaginative minds will develop new ideas perhaps motivated or constrained by new data on the properties of the Moon that must be produced in a complete theory of origin.

10.17.3 Mars System

Mars' inner satellite Phobos is located at a distance of 2.77 Mars radii (R_M) from the center of Mars, which is well inside the corotation radius of $\sim 6.0 R_M$, and the outer satellite, Deimos, is just outside the corotation radius at $6.91 R_M$. The tides raised on Mars thus cause Phobos to be spiraling toward Mars and Deimos to be spiraling away. In fact, Phobos is inside the Roche radius for a density of 1.9 g cm^{-3} and would be torn apart by tidal forces if it were a fluid. It needs shear strength of only 10^5 dynes cm^{-2} to resist disruption (Yoder, 1982) – a loose rubble pile would survive (Dobrovolskis, 1982; Soter and Harris, 1977).

Determinations of the dissipation function Q (**Appendix B**) of Mars are $O(100)$ (Bills et al., 2005; Duxbury and Callahan, 1981; Shor, 1975; Sinclair, 1978) from observations of the secular acceleration of Phobos' orbital mean motion. If we choose a constant value of $Q_M = 100$ with Love number $k_M = 0.16$ (Bills et al., 2005), Deimos' orbit could have expanded by < 200 km in 4.6×10^9 years. Phobos' initial semimajor axis would have been near $5.6 R_M$ under the same assumptions. The rotation period of Mars has been essentially unaffected by the exchange of angular momentum with the satellites and would have been increased by only about 10 min due to solar tides. Deimos has essentially its initial orbit, and Phobos having started inside the corotation radius is consistent with the measured current value of $Q_M \approx 100$.

Both Phobos and Deimos are synchronously rotating; Deimos would have reached this state in $< 10^8$ years from an unlikely small initial spin period of 4 h, where a rigidity of 5×10^{11} dynes cm^{-2} and $Q = 100$ were assumed. Under the same assumptions, Phobos would have reached this state in $< 10^5$ years at its current separation from Mars and in $< 10^7$ years at its likely initial separation near the corotation radius. (See Peale (1977) for a detailed discussion of the rotation histories of all of the satellites known at that time.)

The two satellites of Mars are in nearly circular equatorial orbits and this argues for their accretion in situ from a debris disk in the equatorial plane – like the regular satellites of the major planets. However, the density of Phobos of 1.88 ± 0.07 g cm^{-3} determined from the 5-day rendezvous by Soviet spacecraft Phobos 2 with $GM_P = 7.22 \pm 0.05 \times 10^{-4}$ km^3 s^{-2} (Kolyuka et al., 1990) coupled with the volume of 5748 ± 190 km^3 from Thomas (1993) has been verified by the analysis of the flybys of the Mars Express spacecraft (1.876 ± 0.020 g cm^{-3}) (Andert et al., 2010). The density of Deimos is 1.48 ± 0.22 g cm^{-3} (Rosenblatt, 2011). Early evaluations of albedos near 5% and the reflection spectra are consistent with carbonaceous chondritic material (Pang et al.,

1978; Pollack et al., 1978). But this interpretation has been challenged by Rosenblatt (2011), who finds the spectra to be inconsistent with meteoritic material, whereas the thermal IR is consistent with silicate material. Nevertheless, these early interpretations of the spectra and the fact that the densities are much less than the mean density of Mars of 3.9 g cm^{-2} lend support to the suggestion that the satellites are composed of material that did not originate in the vicinity of Mars, although porosity is another means of reducing the density (25–45% for Phobos, 40–60% for Deimos, Rosenblatt, 2011). This interpretation inspired the consideration of intact capture (Mignard, 1981b; Pollack and Burns, 1977), but Szeto (1983) showed several seemingly insurmountable inconsistencies with the capture hypothesis independent of the impossibility of relaxing the captured satellites into the circular equatorial orbits where they are found. If the debris were indeed carbonaceous chondritic, which is not at all certain, one possible way it could have gotten into orbit about Mars would be the shattering of a planetesimal that was formed in the asteroid belt region of the nebula when it collided with a denser object already in orbit about Mars. Samples of both Phobos and Deimos would tell us if such a contrived origin were necessary. Alternatively, a giant impact on Mars could have launched a disk of material that would settle to the equatorial plane (Craddock, 2011). Craddock pointed out basins on Mars that could be the signature of such an impact. Whether an impact consistent with such basins could have produced a sufficiently extended disk to produce Phobos and Deimos at their initial locations close to the current corotation radius has not been determined. If an accretion disk is indeed the birthplace of Phobos and Deimos, many Phobos-like objects may have impacted Mars, leaving a distribution of craters with asymmetrical or elongate ejecta (Schultz and Lutz-Garihan, 1982), and we are seeing only the surviving members of the swarm. Rosenblatt and Charnoz (2012) had demonstrated the feasibility of accreting Phobos and Deimos near the corotation resonance. Any scheme to capture these satellites intact and bring them into their current orbits cannot survive close inspection of the assumptions involved.

The hypothesis that Phobos and Deimos are remnants of material in a dissipative disk, whatever the disk's origin, is not compromised by the inferred orbital history of the satellites. The initial equatorial orbits remain equatorial in spite of the chaotic, large amplitude variations in the obliquity of Mars (Laskar and Robutel, 1993; Touma and Wisdom, 1993; Ward, 1979) and despite the precession of the spin axis of Mars (Goldreich, 1965). The solid angle described by the orbit normal as the satellite orbit precesses due to Mars' oblateness is an adiabatic invariant (Goldreich, 1965), as the precession rates for the Martian satellites (periods of 2.3 and 57 years for Phobos and Deimos, respectively; Peale, 1977) are fast compared with rates of change of Mars' spin axis direction relative to inertial space (timescales $O(10^5)$ years; Folkner et al., 1997; Touma and Wisdom, 1993).

If we insist that both satellites started with nearly circular orbits, how then can we explain the current eccentricity of Phobos' orbit $e_P = 0.0151$? Both the tidal dissipation in Phobos and that in Mars due to tides raised by Phobos damp the eccentricity (see eqn [B.28]). If the orbital motion is integrated backward in time, this eccentricity grows to large values and collisions with Deimos would have been likely (Szeto, 1983; Yoder, 1982), even if there were no tidal dissipation in Phobos. Significant dissipation in Phobos reduces the timescale for a crossing orbit with Deimos to $< 10^9$ years in the past (Yoder, 1982). The current eccentricity cannot therefore be a remnant eccentricity from tidal decay beginning 4.6×10^9 years ago. Yoder (1982) had identified three commensurabilities (defined when two characteristic periods in the description of the motion are in the ratio of small whole numbers) that Phobos has passed through within the past 10^9 years that provide likely gravitational excitations of Phobos' eccentricity during its inward spiral. The commensurabilities are encountered at semimajor axis $a = 3.8$, 3.2, and $2.9R_M$, where the earliest resonance was encountered only 5×10^8 years ago. The first and third are 2:1 and 3:1 commensurabilities between the rotation of Mars and the orbital mean motion, where the resonant interaction is with Mars' axial asymmetry. At $3.2R_M$, the 2:1 commensurability is between the apparent mean motion of the Sun and the periapse motion of Phobos' orbit, where the latter's secular motion is due to the oblate figure of Mars. This resonance is like the evection resonance for the Moon. There is also a 3:2 spin-orbit resonance excitation of the eccentricity when $a = 4.6R_M$, but this excitation happened so long ago that there would be no contribution to the current eccentricity. The eccentricity would have decayed after each excitation and plausibly arrives at the current eccentricity after the series of kicks and subsequent decays (Yoder, 1982). Orbital inclination can also be excited, and even though the resonance interaction is not as strong as it is for the eccentricities, the excited inclinations do not decay. Still, the current inclinations of the orbits are consistent with the resonance passages (Yoder, 1982).

There is a condition on the dissipation in Phobos for this scenario to work. Yoder (1982) had calculated the dissipation in the satellite accounting for the tidal dissipation both due to eccentric orbit as discussed earlier and due to the forced libration of the very asymmetrical satellite. This libration was thought to have an amplitude of 3.9° (Duxbury and Callahan, 1981; Yoder, 1982) at the time and would cause twice the tidal dissipation in Phobos that would occur if Phobos were nearly axially symmetrical in the same eccentric orbit (Yoder, 1982). Recall that dissipation in Phobos and that in Mars due to tides raised by Phobos both damp the eccentricity (eqn [B.28]). There cannot be too much damping since the series of eccentricity excitations or the current eccentricity would be less than that observed. Since the dissipation in Mars can be presumed known from the measurement of Q_M, and the magnitude of the probable excitations can be reasonably estimated from the resonance passage analysis, the current value of e_P limits the contribution by Phobos. Yoder finds that $\mu_P Q_P > 3$–6×10^{12} dynes cm^{-2} or, if $Q_P \sim 100$, $\mu_P \gtrsim 3$ to 6×10^{10} dynes cm^{-2}, which is about that of ice. However, subsequent determinations of the amplitude of physical libration for Phobos are near 1° (Borderies and Yoder, 1990; Duxbury and Callahan, 1989; Jacobson, 2010; Willner et al., 2010). This reduces the dissipation by about a factor of two from what Yoder assumed, thereby relaxing the constraint on the rigidity by about a factor of 2. The properties of Phobos are not sufficiently well known to be sure that the rigidity could satisfy this new constraint, but $\mu \gtrsim 6 \times 10^{10}$ to 1.2×10^{11} is not unreasonable.

During Phobos' spiral toward Mars, it is likely that it passed through the 2:1 orbital mean motion commensurability with

Deimos. Such a passage would excite an eccentricity of about 0.002 in Deimos orbit if the eccentricity of Deimos were much smaller than this before resonance passage (Yoder, 1982). The time of this commensurability is known if the current dissipative properties of Mars have not changed substantially since the resonance encounter. This places a lower bound on the dissipation in Deimos if the current eccentricity (0.0002) is the tidal remnant from an initial value of 0.002 excited by the resonance passage. Yoder (1982) found $\mu_D Q_D(1-\alpha_D)^2/\alpha_D^2 \lesssim 10^{10}$ dynes cm^{-2}, where $\alpha_D = 3(B-A)/C$ with $A<B<C$ being the principal moments of inertia of Deimos. This limit may be unreasonably low, but the dissipation in Deimos may be increased if the forced libration is nearly resonant with the free libration. The enhanced amplitude of libration would lead to higher dissipation and relax the constraint on $\mu_D Q_D$. The free libration period could be better constrained by an estimate of α_D from a more accurate determination of Deimos' shape along with an accurate measure of its physical libration amplitude. With semi-axes of 7.5, 6.2, and 5.4 km for Deimos (Duxbury and Callahan, 1989) and a mean density of 1.5 g cm^{-3} (Rosenblatt, 2011), $\alpha_D = 0.354$ and $\mu_D Q_D \lesssim 3.3 \times 10^{10}$ dynes cm^{-2}. A homogeneous Deimos modeled as a triaxial ellipsoid would have a free libration period about 1.3 times the orbital period, which is not sufficiently close to resonance to enhance the forced libration significantly, but the fact that Deimos is a porous rubble pile may enhance the dissipation above that for a less rigid solid body.

In any case, Yoder's hypothesis that the satellite orbits have always been regular and current properties of the system then attributed to the effects of resonance passages by Phobos is reasonably well supported. This is consistent with our presumed origin from a dissipative disk of small particles, although the details of the origin of the disk have yet to be constrained.

10.17.4 Jupiter System

The Galilean satellites of the Jupiter system and those small satellites inside Io's orbit are nearly coplanar with Jupiter's equator implying their formation in a dissipative disk (**Appendix A**). Additional constraints on the formation of the Galilean satellites of Jupiter have been established by theoretical analysis and the Galileo spacecraft observations. The mean densities of Io, Europa, Ganymede, and Callisto are, respectively, 3.53, 3.01, 1.94, and 1.83 g cm^{-3}. Ganymede and Callisto are about 40% ice and 60% rock by mass (Sohl et al., 2002). Europa has a layer of water and ice 80–170 km thick (Anderson et al., 1998b). CO_2 has been detected on the surfaces of Ganymede and Callisto (Hibbitts et al., 2000, 2002, 2003; McCord et al., 1998) and in the atmosphere of Callisto (Carlson, 1999). The discovery of an intrinsic dipole magnetic field on Ganymede and the low amplitude of higher-order multipoles in the field implies generation of the field deep within the satellite probably by dynamo action in a molten metallic core (Kivelson et al., 1997, 1999, 2002). Induced fields in Europa and Callisto and possibly Ganymede from the variation in the external field due to Jupiter's rotation are consistent with induced fields expected from a conducting liquid water layer at rather shallow depths (Kivelson et al., 2002). It has been speculated that NH_3 is sufficiently abundant on Ganymede and Callisto to lower the solidus temperature of an NH_3–H_2O mixture so that such a liquid layer could be maintained over the age of the solar system (Mousis et al., 2002; Spohn and Schubert, 2003). However, there has been no NH_3 nor N_2 detected on any of the Galilean satellites, but McKinnon (2006) argued that halides in solution may depress the solidus temperature sufficiently to preserve the liquid layers.

The large amount of relatively volatile material in Ganymede and Callisto implies that the disk temperature remained low enough during the accretion process that icy particles could persist. Callisto may not be fully differentiated (Anderson et al., 1998a, 2001; Nagel et al., 2004), and an accretion timescale $\geq 6 \times 10^5$ years is required to keep ice in its interior from melting (Barr and Canup, 2008). The change in composition from rocky to icy from Io to Callisto is consistent with an expected radial temperature gradient in the disk at the time of satellite accretion, but note the existence of the icy satellite Amalthea inside Io's orbit. It is possible that Europa lost initial volatiles due to tidal heating (**Appendix B**). Given its current tidal dissipation rate, a very efficient conversion of tidal heating into vaporization of ice is required over the satellite's entire lifetime in order for Europa to have started as ice-rich as Ganymede and Callisto (e.g., Canup and Ward, 2009). If Europa's ice depletion is primordial, then Io's likely is as well, since by virtue of being interior to Europa, it may have formed in a higher-temperature environment.

The theories for the formation of the Galilean satellites are guided by numerical hydrodynamic calculations – first in two dimensions (2-D) (e.g., Lubow et al., 1999) and later in 3-D (e.g., Bate et al., 2003; d'Angelo et al., 2003; Machida et al., 2008; Tanigawa et al., 2012), where the flows near the Hill sphere are strikingly different in the two types of calculations. It is clear that 3-D calculations are required to constrain the conditions of satellite formation in planetary accretion disks, but the incompleteness of these calculations (e.g., there are no numerical calculations that follow the development of the disk from the collapse phase of Jupiter's atmosphere to the satellite formation stage) has led to a variety of models involving speculation of the disk properties and the dominant processes therein.

The formation of the regular Jovian satellites must necessarily occur late in Jupiter's accretion to allow the hot inflated protoplanet to cool and contract to a radius less than that of the closer satellites. This can plausibly occur by the time the planet is accreting the last few tens of percent of its mass, depending primarily on the planet's opacity (Ward and Canup, 2010). Minimum mass disk models (called minimum mass sub nebula (MMSN) models) for the formation of the satellites require sufficient mass of condensable material to form the satellites augmented with gas to reach solar composition in the initial disk (e.g., Lunine and Stevenson, 1982), where no mass is added to the disk during the satellite accretion process. Mosqueira and Estrada (2003a,b) modified the MMSN model by enhancing the fraction of solid material in the disk (solids-enhanced minimum mass), so there is less gas than in the traditional MMSN models. Various theoretical considerations of disk processes and histories (**Appendix B**) will lead us to favor models (with some caveats) where the current satellites form during the very last stages of Jupiter's

accretion when the accretion disk was 'starved' of gas input (Alibert et al., 2005a,b; Canup and Ward, 2001, 2002, 2006, 2009; Mousis and Alibert, 2006; Ogihara and Ida, 2012; Sasaki et al., 2010; Stevenson, 2001a,b; Ward and Canup, 2010). In these latter models, considerably more condensable mass passes through the disk than is contained in the current satellites, and these objects form in a disk with several orders of magnitude less gas than in an MMSN.

The shocks near the L_1 and L_2 Lagrange points, after a gap is formed in the solar nebula, which are found in the 2-D calculations of Bryden et al. (1999), Kley (1999), and Lubow et al. (1999), are modified considerably in the higher-resolution 3-D calculations of Machida et al. (2008). For a 1 Jupiter mass protoplanet, the shocks are displaced about 45° from the Sun–Jupiter line and stand off from the Hill sphere by about 20% of R_H. A reservation about this comparison is that the calculations correspond to a full density solar nebula and are local. The local nature of the Machida et al. calculations means the creation of a deep gap in the disk as Jupiter's mass grows cannot be treated (Machida et al., 2010). In the final stages of accretion, the circumplanetary disk is more likely to behave like a standard accretion disk rather than being subject to the shock-driven accretion found in the 2-D calculations (Bate et al., 2003). In both 2-D and 3-D calculations, a prograde accretion disk is formed, which is the basis for the formation of a coplanar set of satellites in nearly circular orbits.

In spite of Jupiter having likely opened a gap (**Appendix A**) in the solar nebula when its mass exceeded approximately 1/3 of its current value (e.g., Bryden et al., 1999; Ward and Hahn, 2000), 3-D numerical simulations (e.g., Kley et al., 2001) find continuing accretion onto Jupiter at a rate of 10^{-4}–$10^{-2}\,M_E$ year^{-1}, depending on the assumed nebular viscosity, surface mass density, and scale height. Bate et al. (2003), in a 3-D hydrodynamic simulation, found an accretion rate close to $10^{-4}\,M_J$ year^{-1} ($3\times10^{-2}\,M_E$ year^{-1}) as Jupiter approaches its final mass, M_J. The latter authors find that accretion only stops when the planet at 5.2 AU reaches about $10M_J$, with an undepleted solar nebula. The accretion of Jupiter was therefore most likely protracted, with the rate of accretion tailing off as the solar nebula is depleted. A striking conclusion from the 3-D calculations (Bate et al., 2003; Machida et al., 2008; Tanigawa et al., 2012) is that relatively little material from the midplane of the solar nebula is accreted onto the disk. Most of the material rains down on the disk from above and below the midplane. This phenomenon is incorporated into starved disk models discussed in the succeeding text, but first, we describe a recently developed solids-enhanced minimum mass (SEMM) model (Estrada et al., 2009; Mosqueira and Estrada, 2003a,b) and a gas-free accumulation of the satellites from planetesimals captured from the heliocentric swarm (Mosqueira and Estrada, 2006).

In the following discussions of gaseous disk models, we will use the turbulent viscosity parameter α, defined by $\nu_t=\alpha c_s$, where ν_t is a characteristic velocity of a turbulent eddy and c_s is the speed of sound in the gas (**Section A.2**). The value of α is very uncertain, but typical values are chosen near 10^{-3}. Sources of turbulence in the circumplanetary disks include the influx of material onto the disk (e.g., Cassen and Moosman, 1981) and/or turbulence generated by the Magnetohydrodynamic (MHD) instability (Turner et al., 2014). The latter source requires a certain degree of ionization of the disk material that may be difficult to attain in the environments of most planetary accretion disks. See Turner et al. (2014) for a thorough discussion of the conditions where MHD turbulence may be effective in generating a viscous evolution of a disk and Lubow and Martin (2013) who consider the possibility of a layered disk in which the disk's midplane is nonturbulent, while the outer layers are MHD-active.

10.17.4.1 SEMM Model

We first outline the motivation for the initial conditions in the Mosqueira–Estrada (2003a,b) model. The angular momentum of a planetesimal (or a small volume of gas) relative to the Jupiter embryo is $\mathbf{L}=m\mathbf{r}\times\mathbf{v}$, where m, $\mathbf{r}$, and $\mathbf{v}$ are mass, position, and velocity relative to a frame centered on Jupiter but not rotating. If we write $\mathbf{v}=\mathbf{v}_{rel}+\mathbf{n}_J\times\mathbf{r}$, where $\mathbf{v}_{rel}$ is the velocity of the particle relative to a frame centered on Jupiter and rotating with the mean orbital angular velocity $\mathbf{n}_J=\sqrt{GM_\odot/a_J^3}\,\boldsymbol{e}_z$ with G, $M_\odot$, a_J, $\boldsymbol{e}_z$ being the gravitational constant, solar mass, semimajor axis of Jupiter's orbit, and normal to the orbital plane, respectively, $\mathbf{L}=m\mathbf{r}\times(\mathbf{v}_{rel}+\mathbf{n}_J\times\mathbf{r})=m\mathbf{r}\times\mathbf{v}_{rel}+mr^2\mathbf{n}_J$, where the second form is for the assumption that $\mathbf{r}$ is in the plane of the disk and thereby perpendicular to $\mathbf{n}_J$ along the orbit normal. The specific angular momentum is

$$\ell=\mathbf{r}\times\mathbf{v}_{rel}+r^2\mathbf{n}_J \qquad [8]$$

where the first term is the specific angular momentum relative to the rotating system and the second is the correction for inertial space representation.

Before the creation of a gap in the heliocentric nebula, ($M\ll M_J$), it is assumed that all of the flux encountering the Hill sphere of radius $R_H=(M/3M_\odot)^{1/3}a$ is captured by the proto-Jupiter. Lissauer and Kary (1991) found for the sum of all the specific angular momenta

$$\ell=n_J\frac{\int_0^{R_H}-1.5x^3\,dx}{\int_0^{R_H}x\,dx}+n_JR_H^2=\frac{1}{4}n_JR_H^2 \qquad [9]$$

where x is the difference in the semimajor axes of the particle and Jupiter, where we have dropped the vector notation, since it is assumed that all contributions to the specific angular momentum of accreted material are perpendicular to the disk. With conservation of angular momentum, the centrifugal radius is defined by $r_c=\ell^2/GM=R_H/48\approx15R_J$ for the value of ℓ given in eqn [9] and for R_H determined for $M=M_J$, where R_J is Jupiter's current radius. The centrifugal radius r_c is interpreted as the disk size. For $M\ll M_J$ appropriate for eqn [9], the disk before gap opening is quite compact.

After the gap in the heliocentric disk becomes large compared to R_H, material enters the Hill sphere near the Lagrange points in the 2-D calculations of Artymowicz and Lubow (1996) and Lubow et al. (1999). In the 3-D calculations of Machida et al. (2008), material enters the Hill sphere, after passing through the shocks, in the first and third quadrants projected onto the $z=0$ plane with the x-axis pointing away from the Sun. Nearly all of the 3-D calculations show material falling vertically onto the disk (d'Angelo et al., 2003; Machida,

2009; Machida et al., 2008, 2010; Tanigawa et al., 2012). After gap opening, Mosqueira and Estrada (Estrada et al., 2009) assumed that gas enters the Hill sphere at very small relative velocity. The first term in eqn [9] thereby vanishes and the specific angular momentum becomes $R_H^2 n_J$ and $r_c = R_H/3 \sim 250 R_J$.

Based on this, Mosqueira and Estrada (2003a,b) proposed a two-component disk: a massive disk for ($r \lesssim 15 R_J$) that persists before gap opening surrounded by an extensive outer disk ($r \sim 150 R_J$) of much lower surface mass density, emplaced after a large gap has formed. The sparseness of the outer disk follows from the much reduced gas flow into the Hill sphere after the gap approaches its maximum extent, and the large radius of the disk follows from the higher specific angular momentum of the material entering the Hill sphere at the Lagrange points as discussed earlier. The gas influx rapidly goes to zero due to gap opening, but solid material continues to be added to the disk through ablation of fragmented planetesimals passing through the disk (e.g., Mosqueira et al., 2010) or collisions of such fragments with existing solid satellitesimals already in the disk (e.g., Estrada and Mosqueira, 2006, see succeeding text).

The gas flow is assumed to wane on the same timescale as the gap opening timescale of $\sim 10^3$ years for a weakly turbulent heliocentric disk (Bryden et al., 1999, 2000; Morbidelli and Crida, 2007). The cessation of the gas flow onto the disk means the presumed chief source of turbulence in the disk is eliminated and the disk viscosity and temperature plummet. Note that the gas flow ends when $M \approx M_J$, which is contrary to the conclusion of Bate et al. (2003), where accretion stops only when $M \approx 10 M_J$, although the latter is for an undepleted solar nebula.

The postaccretion low disk viscosity and low temperature are involved in various schemes for avoiding the short timescales for the important processes in the disk discussed in **Appendix A**. The system is closed, since continuing accretion is omitted, where the minimum mass tag implies there is only sufficient solid material to make the satellites, but the gas content of the disk is down from a solar composition by a factor of 10 (Estrada et al., 2009). A $1/r$ temperature distribution is assumed with $T = 250$ K at Ganymede's distance in order to accommodate the stability of icy particles at greater distances. A feature of the model is a surface density distribution ($\sigma_g \propto 1/r$) with sufficient solids to make Io, Europa, and Ganymede inside $\sim 15 R_J$, leading to an optically thick, massive inner disk. Mosqueira and Estrada set the value of the gas surface density to $\sigma_g \sim 3 \times 10^4$ to 3×10^5 g cm^{-2}, with the lower end of the range indicating a disk enhanced in solids compared to the standard MMSN disk. But the surface density falls drastically beyond about $15 R_J$ to a value determined by spreading Callisto's mass in the outer disk out to $r \sim 150 R_J$. With an opacity due only to the gas (i.e., without dust grains), an optically thin outer disk results from which it is argued that Callisto is accreted slowly ($\sigma_g \sim 1/r$ for $r > 26 R_J$). The $1/r$ temperature dependence in the inner disk goes to a constant temperature in the outer disk of 130 K, like that of the solar nebula. A controversial assumption in the model is that the sharp gradient in the surface density between the inner and outer disks is maintained throughout the accretion timescale of Callisto, which they estimate to be $O(10^5$–10^6 years).

The steep surface density gradient between the inner and outer disks is maintained by assuming that turbulence has been nearly completely damped leading to $\alpha \sim 10^{-5}$–10^{-6} in both the inner and outer disks. Such low values of α might not be definitely ruled out, since there is no continuing accretion to stir the disk. Small but decoupled objects are rapidly lost to Jupiter through gas drag. But the accumulation of dust and rubble into larger objects is more rapid than the decay of these objects by gas drag. The small particles are assumed entrained in the gas and encounter larger particles that are at Kepler velocities. The growth timescale is $M/\dot{M} = 4\rho_p R(3\rho_s \Delta v)$, where Δv is the difference between the Kepler and gas velocities. Sweepup time is smaller than gas drag time for $r < 38 R_J$ independent of particle size or distance range where $T \propto 1/r$, such that satellite formation is favored. Then, the timescale for accretion is determined by the rate at which gas drag can bring say 100 m or larger objects to the protosatellite. Accretion times for Ganymede under these assumptions are $O(10^3$–$10^4)$ years. Since they have little or no ice, Io and Europa can accrete more rapidly than Ganymede.

The short migration timescales indicated in **Appendix A** are frustrated by the assumption that the inner three Galilean satellites open gaps in the disk and change from type I to type II migration. The latter is on the viscous timescale, which exceeds the supposed timescale for elimination of the gas disk by photoevaporation (Hollenbach et al., 2000; Shu et al., 1993), because the turbulent viscosity characterized by $\alpha = O(10^{-6})$ is so small. The steep gradient in the surface mass density between about 20 and $26 R_J$ causes type I drift to reverse sign in this region so that a satellite would spiral out instead of in. Callisto is hypothesized to have ended up where the type I drift vanishes at the value of the density gradient where torques from the inner Lindblad resonances balance those from the outer ones. The steep gradient in σ_g between the inner and outer disks must be maintained not only through the accretion phase but also throughout the dissipation of the disk. Alternatively, Callisto could open a gap, shift from type I to type II drift and thereby end up where it is because of the low viscosity assumed. But why did it wait until $r = 26 R_J$ to open the gap?

The SEMM model remains at this point a conceptual framework for satellite formation; there have been no explicit, time-dependent models demonstrating either the formation of the assumed SEMM initial conditions or that the proposed SEMM disk would ultimately accrete into a system of four Galilean-like satellites. Many of the subjective criticisms of the Mosqueira–Estrada model, such as the very low values of α assumed from the outset to preserve the steep surface density gradient between the inner and outer disks, are muted by uncertainties about which processes are ongoing and on the values of various parameters therein. However, many aspects of the model are ad hoc, such as the $1/r$ temperature distribution normalized to allow ice to condense just beyond Ganymede's orbit, the low viscosity (and maintenance of the steep surface density gradient between the inner and outer disks), and the assumption of the existence of a minimum mass, closed disk in the first place. The latter assumption ignores the history of the disk during the long period of waning gas accretion. How could the massive inner disk resist viscous

spreading during this period when accretion still generated a reasonable turbulent viscosity?

The SEMM model, as well as the model of Sasaki et al. (2010) discussed in the succeeding text, is not consistent with recent results from increasingly sophisticated numerical simulations of planetary accretion (e.g., Bate et al., 2003; Machida et al., 2008), which show the protracted nature and persistence of the accretion process as the solar nebula is dissipated. These latter results confirm intuitive conclusions about the accretion histories of the giant planets. The neglect of this history and the added criticisms in the preceding text mean that the SEMM and MMSN models in general are not likely to represent the actual sequence of events that led to the formation of the regular natural satellites around the giant planets. In spite of these criticisms, we note that the Mosqueira–Estrada papers contain discussions of many, if not most, of the processes that occur in disks that effect the satellite development. These processes should be studied in the development of a comprehensive model of origin of the regular satellites.

10.17.4.2 Planetesimal Capture Model

In a rather detailed and careful analysis, Estrada and Mosquiera (2006) reexamined the hypothesis that collisions of planetesimals within Jupiter's Hill sphere in a gas-free environment led to a buildup of captured orbiting material that settles to an equatorial disk through mutual collisions where they could have accumulated into the satellites (e.g., Safronov et al., 1986). Constraints are placed on numerous parameters and assumptions that could allow such a scenario to produce the observed masses and angular momentum distributions, but the authors note that whether or not the parameter values and assumptions are likely to obtain is very uncertain. Perhaps the greatest value of this paper is to show how difficult it is to make a gas-free planetesimal capture scenario a viable alternative for satellite formation. Major caveats are the difficulty in producing the composition gradient in such a scenario (unless later Roche lobe interlopers or tidal dissipation preferentially removes volatiles from the inner satellites), keeping a size distribution of planetesimals that favors collisional capture, and maintaining the supply of planetesimals within Jupiter's feeding zone over the 10^5–10^6-year timescale of the satellite accumulation. It is not clear that a sufficient gas density in the solar nebula to allow a gas drag replenishment of planetesimals in Jupiter's feeding zone would not also keep a gas accretion disk replenished by streaming across the gap. A problem with planetesimals later colliding with the accreted satellites to preferentially remove volatiles from the inner satellites is attaining a sufficient flux of such planetesimals from the depleted zone around Jupiter.

Another problem that is not addressed is the reduction of the optical depth in the circumplanetary disk as the satellitesimals accumulate into larger objects on short timescales, thereby reducing the collisional capture probability of additional mass. In addition, the scenario is not placed in the context of the formation of Jupiter that yields a plausible route to the assumed gas-free initial conditions where Jupiter has no satellites. Presumably, Jupiter has already gone through the last stages of gas accretion through streams of material across a gap in the solar nebula, and we shall see later that it should have acquired a stable satellite system already during that process. With the caveats pointed out by Estrada and Mosqueira and the additional ones we have mentioned here, it seems unlikely that the satellites formed solely from collisionally captured planetesimals in a nearly gas-free environment.

10.17.4.3 Starved Accretion Disk Model

Accumulation of the satellites of Jupiter in an actively supplied, gas-starved accretion disk instead of a MMSN was proposed by Canup and Ward (2001) and separately by Stevenson (2001a) at the Jupiter conference in Boulder, Colorado, in June 2001 (http://lasp.colorado.edu/jupiter/index.html). In this construct, the planet contracts to a size smaller than the satellite region before the nebula dissipates, with subsequent inflow producing a circumplanetary accretion disk (e.g., Ward and Canup, 2010). The satellites form in the disk as the inflow is ongoing, rather than after the inflow has stopped (as in the MMSN and SEMM models). As the planet nears its final mass and the inflow wanes, the disk becomes increasingly gas-starved. Motivations for the starved disk model include a more consistent treatment of the conditions of satellite formation based on planet formation models, the necessity of disk temperatures low enough to allow water ice to condense, and a sufficiently slow accretion of Callisto to allow possibly incomplete differentiation (e.g., Anderson et al., 2001; Kuskov and Kronrod, 2005; McKinnon, 1997; Schubert et al., 2004). Stevenson (2001b) summarized remarks at the conference, whereas Canup and Ward (2002) developed a detailed steady-state model based on their conference paper. Their model was extended by Alibert et al. (2005a,b) who accounted for the time variation of disk properties as accretion wanes. Major features in the Alibert et al. approach are that material from the solar nebula is deposited at the outer edge of the disk with a mass flux through the disk that is in quasi-steady state and that the last part of the satellite formation occurs in a closed disk after accretion has ended. Canup and Ward (2002) had the mass raining down onto the disk consistent with a major finding of the 3-D calculations of Bate et al. (2003), Machida et al. (2008), and Tanigawa et al. (2012) showing the vertical deposition. Canup and Ward (2006) extended their model to include an exponential decrease in the accretion rate with time and a direct model of satellite growth, in which many of the accreted satellites are lost to Jupiter from migration and only the last set formed near the end of accretion remain. Ward and Canup (2010) considered the formation of a disk around a growing gas giant planet, including the energy and angular momentum budget of the inflowing material and the coupled thermodynamic evolution of the planet itself. They found that by the time the planet accretes the final ~10% of its mass, an accretion disk with low gas surface densities and properties broadly similar to those considered in Canup and Ward (2002, 2006) has formed. Sasaki et al. (2010) and Ogihara and Ida (2012) considered two variations on the Canup–Ward model: an inflow that ends abruptly rather than exponentially due to gap opening (and in this these two works share a common element with the SEMM model) and a disk with a magnetically sustained inner cavity. It is the Canup–Ward (2002, 2006, 2009) model that we now describe.

Ward and Canup (2010) argued that the vertical deposition of material onto the disk and planet falls in the range $r_c/4 < r < 9r_c/4$, where the upper bound is close to the $30R_J$ used in their 2002 model. For accretion during gas inflow, the steady-state disk with uniform deposition inside a radius of $30R_J$ treated in 2002 is generalized in 2006 to have a time-dependent influx density of

$$F_{in} \propto \left(\frac{1}{r}\right)^{\gamma_{in}} \exp\left(-\frac{t}{\tau_{in}}\right) \quad [10]$$

where F_{in} is the vertical flux density onto the disk's upper and lower surfaces, r is the radial distance from the center of Jupiter, τ_{in} is the time constant for exponential decay of the influx rate, and γ_{in} is an adjustable constant parameterizing the radial variation in the flux density over the disk inside the outer bounding radius. The radius r_c is a free parameter constrained by the specific angular momentum of inflowing material. A range of 16–46 planetary radii for Jupiter, Saturn, and Uranus is consistent with Lissauer's (1995) 3-D calculation (with 16 being the value for Jupiter in particular). The disk outer boundary is set to $r_d \approx 150R_J$. If the viscous timescale $\tau_\nu \approx r^2/\nu$, with $\nu = \alpha c_s H$ (c_s = midplane sound speed and H = gas scale height, **Appendix A**), is much smaller than τ_{in}, the gas surface density σ_g maintains a quasi-steady state like that assumed in Canup and Ward (2002). For $\tau_{in} \sim 10^6$ years, this condition is valid for $\alpha \geq 10^{-4}$.

Solids smaller than ~1 m are entrained in the gas and, for a planet that has not opened a gap, will be delivered with it to the disk from heliocentric orbit. The delivery of small particles to the disk is more complex once the planet opens a gap. At the outer gap edge, the gas disk's rotation is super-Keplerian because the local gas surface density increases with orbital radius, thereby reversing the radial pressure gradient. The gas drag that caused the inward migration of small particles is reversed, causing them to stall and build up at the outer gap edge (Paardekooper and Mellema, 2006a,b). However, this buildup cannot proceed indefinitely, because once the surface density of small particles becomes comparable to that of the local gas, the back reaction of the particles on the gas causes its motion to become more Keplerian and particles begin to flow into the gap (Ward, 2009). A simple model accounting for this effect suggests that particles mm-sized and smaller could enter the gap and be delivered to the disk (Ward, 2009), although this issue merits further investigation for larger particles.

It has traditionally been thought that most solids in the heliocentric disk would be in large planetesimals by the time of Jupiter's formation, although these would probably be diminished in size through fragmentary collisions after Jupiter had gained most of its mass. However, recent works argue that a large fraction of the disk's solid mass was contained in millimeter- to centimeter-sized 'pebbles,' based both on observations of extrasolar disks (e.g., Testi et al., 2003; Wilner et al., 2005) and on dynamic models (e.g., Lambrechts and Johansen, 2012). The latter found that pebble accretion can lead to formation of the gas giant cores in a time shorter than the nebular lifetime. Such conditions would also imply a substantial population of pebble- and grain-sized particles that could be delivered to the circumplanetary disk by the gas inflow.

It may also be the case that an alternative delivery of solids to the disk may be viable. Once in the disk, the solids are assumed to accrete rapidly enough to decouple from the gas before they can spiral into Jupiter from gas drag. In an inflow-supplied disk, the accretion timescale for a satellite of mass m_s is $\tau_{acc} \approx f m_s/(2\pi r \Delta r F_{in})$, where $f \approx 100$ is the gas to solid ratio for the influx and Δr is the width of the annulus over which the satellite accumulates material. With $\Delta r/r \approx 2e$, where $e \approx (H/r)(m_s/4\pi r H \sigma_g)^{1/3}$ is the maximum eccentricity obtained by m_s from a balance between eccentricity damping by density waves and excitation by scattering from similarly sized objects (Ward, 1993), the accretion timescale for a uniform inflow varies with orbital radius as $\tau_{acc} \propto 1/r^{4/5}$ (Canup and Ward, 2006). The inverse dependence on r is because accretion is being regulated by the rate of the inflow, rather than by the orbital frequency as is the case in disks with a fixed total mass. For a uniform inflow per area, mass is added more quickly to an outer satellite's feeding zone due to its much larger surface area, so that objects in the outer disk grow more quickly than those in the inner disk.

Satellite growth continues, while each satellite spirals toward Jupiter from type I drift (**Appendix A**). The rate of type I drift is proportional to the satellite mass and to the gas surface density in the disk (**Appendix A**), and the satellites tend to accelerate as they drift toward Jupiter due to their accretion of some additional inner disk material. The timescales for type I drift (**Appendix A**) are generally shorter than τ_{in} in eqn [10], so that many satellites are lost to Jupiter as the influx winds down. But as the inflow wanes, the gas surface density drops and the type I timescale lengthens; the last surviving satellites are then those for which $\tau_1 \sim \tau_{in}$. Each satellite reaches a critical mass m_{crit} where the timescale τ_{acc} for further growth is comparable to its type I orbital decay timescale after which further growth is limited before the satellite is lost to Jupiter.

The model includes disk heating and cooling, where the heating comes from the gravitational energy lost by the incoming material, viscous dissipation within the disk, and even radiation from a still warm Jupiter with only radiative cooling to keep the disk temperature below the ice point at least in the outer regions. Disk temperature distributions and surface densities are constrained by assumptions about the disk opacities and the viscosity parameter α defined in **Appendix A**. The timescale for type I drift depends on the scale height, which depends on the temperature of the disk, and that temperature distribution depends on the opacity of the solids–gas mixture in the disk, which itself is a function of temperature (Pollack et al., 1994; **Appendix A**). Higher opacities lead to slower required inflow rates for similar temperatures. Opacity is then important in determining both the disk structure and the manner in which the migration rate changes with r. Unfortunately, the opacity and its dependence on radial distance from Jupiter are highly uncertain, since it depends on the amount, composition, and size distribution of the dust in the nebula. Canup and Ward (2002, 2006) used a constant opacity in their model, and it would be of interest to determine the effect of other assumptions about the opacity distribution and the general thermal properties of the disk on their conclusions.

For the case where $\gamma_{in} = 0$ in eqn [10] (uniform deposition inside r_c) Canup and Ward (2006) find in their eqn [2],

$$\frac{m_{\rm crit}}{M_{\rm J}} \approx 5.4\left(\frac{\pi}{C_{\rm a}}\right)^{5/9}\left(\frac{H}{r}\right)^{26/9}\left(\frac{r}{r_{\rm c}}\right)^{10/9}\left(\frac{\alpha}{f}\right)^{2/3}(\Omega_{\rm K}\tau_{\rm G}f)^{1/9}$$
$$\approx 5.6\times10^{-5}\chi\left(\frac{3.5}{C_{\rm a}}\right)^{5/9}\left(\frac{H/r}{0.1}\right)^{26/9}\left(\frac{r/r_{\rm c}}{0.5}\right)^{10/9}\left(\frac{\alpha/f}{3\times10^{-5}}\right)^{2/3} \quad [11]$$

where $\chi=[(1\ \text{week}/\{2\pi/\Omega_{\rm K}\})(\tau_{\rm G}/10^7\ \text{years})]^{1/9}$ and $\tau_{\rm G}=M_{\rm J}/(dM_{\rm J}/dt)$ is the timescale for the growth of $M_{\rm J}$. Because the ratio $m_{\rm crit}/M_{\rm J}$ depends so weakly on the inflow rate ($\tau_{\rm G}^{1/9}$), a similar maximum satellite mass results for a wide range of inflow rates. Next, the dependence of $m_{\rm crit}/M_{\rm J}$ on α/f for a given inflow rate can be understood from the following. A larger α leads to a lower surface mass density and hence slower migration, which allows the satellite mass to grow more before it is lost, and a smaller f means more solids are delivered also resulting in an increased satellite mass.

Canup and Ward (2002, 2006) used a type I timescale appropriate for optically thin, isothermal disks (Tanaka et al., 2002), with $C_{\rm a}=2.7+1.1\zeta$, where ζ is the exponent for the radial surface mass distribution as in $\sigma_{\rm g}\propto 1/r^{\zeta}$. $C_{\rm a}=3.5$ for a disk with $\zeta=3/4$ (Canup and Ward, 2002). It is possible that even a gas-starved disk can be optically thick, depending on the abundance and size of dust in the disk. Recent works have shown that type I migration is altered in optically thick, adiabatic disks due to opposing effects of corotation torques (e.g., Kley and Crida, 2008; Paardekooper and Mellema, 2006a,b). Paardekooper et al. (2010) provided a revised $C_{\rm a}$ accounting for such effects, where

$$C_{\rm a}=-\frac{2}{\gamma_{\rm a}}\left[-2.5-1.7\beta+0.1\zeta+1.1\left(\frac{3}{2}-\zeta\right)+7.9\frac{\beta-(\gamma_{\rm a}-1)\zeta}{\gamma_{\rm a}}\right]$$

where $\gamma_{\rm a}$ is the adiabatic index (1.4 for diatomic hydrogen), β is the exponent in the disk temperature profile $T_{\rm d}\propto 1/r^{\beta}$, and $C_{\rm a}>0$ (<0) is inward (outward) migration. For values appropriate for an optically thick inflow-supplied disk, $C_{\rm a}=0.5$, indicating inward type I migration that is about seven times slower than that estimated by Tanaka et al. (2002) for optically thin, isothermal disks. Because the satellite mass is set by a balance between satellite growth and type I loss, a reduction in $C_{\rm a}$ to 0.5 in eqn [11] would produce a comparable critical satellite mass for an α/f ratio that is a factor of 5 smaller, reducing, for example, the needed level of viscosity to achieve a desired satellite mass.

In these analytic approximations, each satellite grows to mass $m_{\rm crit}(r)$ within an annulus of width Δr, after which it is rapidly lost from type I migration. But in the time to migrate into Jupiter, another $m_{\rm crit}$ accumulates. So, the total mass $M_{\rm T}$ in satellites at any time is given by eqn [4] of Canup and Ward (2006),

$$\frac{M_{\rm T}}{M_{\rm J}}=\int_{R_{\rm J}}^{r_{\rm c}}\frac{m_{\rm crit}/M_{\rm J}}{\Delta r}dr$$
$$\approx 2.1\left(\frac{\pi}{C_{\rm a}}\right)^{4/9}\left(\frac{H}{r}\right)^{10/9}\left(\frac{\alpha}{f}\right)^{1/3}\frac{1}{(\Omega_{\rm K}\tau_{\rm G}f)^{1/9}} \quad [12]$$
$$\approx 2.5\times10^{-4}\frac{1}{\chi}\left(\frac{3.5}{C_{\rm a}}\right)^{4/9}\left(\frac{H/r}{0.1}\right)^{10/9}\left(\frac{\alpha/f}{3\times10^{-5}}\right)^{1/3}$$

where it is assumed that H/r and f are approximately constant across the disk and that $R_{\rm J}\ll r_{\rm c}$. An important characteristic of eqn [12] is that $M_{\rm T}/M_{\rm J}$ is comparable to the observed satellite–planet mass ratios for Jupiter with plausible choices for the parameters, and by replacing $M_{\rm J}$ by $M_{\rm S}$ or $M_{\rm U}$, the same applies to Saturn and Uranus. Notably, $M_{\rm T}/M_{\rm J}$ is insensitive to the inflow rate through χ, lacks a dependence on $r_{\rm c}$, and depends only weakly on α/f.

Perhaps the most notable result of this model is the prediction that all the major planets should have values of $M_{\rm T}/M_{\rm P}\approx10^{-4}$, which is what is observed. The value of $M_{\rm T}/M_{\rm P}$ is determined primarily by the value of α/f, and the weak dependence of the mass fraction on this ratio ($(\alpha/f)^{1/3}$) means that systems comparable to those of Jupiter, Saturn, and Uranus result for $10^{-6}<\alpha/f<5\times10^{-4}$. Neptune is excluded because the capture of the large satellite Triton disrupted the original system. The application of the theory to Uranus requires additional processes that lead to the large obliquity after the satellite system was formed. An impact that tilted Uranus would disrupt the Canup and Ward-formed satellite system leading to mutual collisions among the satellites and reassembly in the new equatorial plane, or if an adiabatic process can be found to tilt Uranus, the satellite system would remain equatorial during the process (see **Section 10.17.6**). Both α and f are most likely to vary both in time and from planet to planet given the difference in the planet compositions and the likely decrease in f from solar composition as the solar nebula is evaporated. Whether or not the given influx of material can cause enough turbulence for values of α/f within this range has not been ascertained. Magnetorotational instability is another potential source of turbulence, but its effectiveness is greatly diminished by the likely presence of dust grains and likely insufficient ionization (e.g., Fujii et al., 2011).

To check these conclusions, satellite formation is simulated in Canup and Ward (2006) by the N-body SyMBA code (Duncan et al., 1998) based on the algebraic mapping integration scheme of Wisdom and Holman (1991), modified to include the interaction of the masses with the gas disk and ongoing mass inflow (Canup and Ward, 2006). The satellites interact gravitationally with Jupiter and with each other. The background disk is treated analytically and interactions of the satellites with it are treated as small perturbations of the orbits. The radial surface density profile is approximated by $\sigma_{\rm g}(r)=\sigma_0(R_{\rm J}/r)^{\gamma_{\rm g}}$, and $H/r=c_{\rm s}/r\Omega_{\rm K}=h_0(r/R_{\rm J})^{\gamma_{\rm c}}$ gives the radial variation of the scale height. The scale height depends on the radial temperature distribution determined by the opacity. Values of $\gamma_{\rm g}=0.75$, $\gamma_{\rm c}=0.13$, and $h_0=0.07$ are estimated from the steady-state disk model of Canup and Ward (2002) with a constant opacity (see **Appendix A**). Satellites experience a drag force because the gas is partially supported by the radial pressure gradient discussed in **Appendix A**, where the satellites are given kicks at each time step proportional to the area to mass ratio in a direction opposite to the relative velocity between the satellite and the gas. The gas drag is only important while the satellites are small, where type I interactions dominate the reduction in eccentricity, orbital inclinations, and semimajor axis for larger satellites. After Papaloizou and Larwood (2000), type I interactions are simulated with added accelerations $\vec{a}_{\rm I}=-\vec{v}/\tau_{\rm I}$, and $\vec{a}_{\rm damp}=-2\left(\vec{v}\cdot\vec{r}\right)\vec{r}/(r^2\tau_{\rm e})-2\left(\vec{v}\cdot\hat{k}\right)\hat{k}/(r^2\tau_{\rm i})$, where $\hat{k}$ is a unit vector perpendicular to the plane of the disk and $\vec{v}$ is the satellite velocity. The timescale $\tau_{\rm I}$ for type I reduction of the semimajor axis is related to the timescale $\tau_{\rm e}\approx1.4\tau_{\rm i}$ for the damping of the eccentricity and inclination by (Tanaka and Ward, 2004)

$$\tau_I = \frac{1}{C_a \Omega_K}\left(\frac{M_J}{m_s}\right)\left(\frac{M_J}{r^2\sigma_g}\right)\left(\frac{H}{r}\right)^2 = \frac{C_e}{C_a}\frac{\tau_e}{(H/r)^2} \qquad [13]$$

where C_a and C_e are constants of order unity.

The solid inflow is represented by adding orbiting masses with random positions for $r < r_c$ at a rate proportional to F_{in}/f. Constraints on CPU time for the calculations forced the added objects to be 50–600 km in radius – far larger than the small objects expected to follow the gas during the inflow. But once in orbit, the rapid accretion times imply that the particles would coagulate into sizes that are decoupled from the gas in times less than the viscous spreading time of the gas and to accumulate into larger objects on timescales short compared to gas drag timescale τ_{GD}. If these assumptions are valid, starting with 50–600 km objects to accommodate the computational constraints should have little effect on the outcomes for satellites much larger than these sizes. Collisions within the disk are treated as inelastic mergers.

Since the satellites continue to accrete objects after they reach mass m_{crit}, their migration into Jupiter is hastened, and the value of M_T/M_J given by eqn [12] is an upper bound. This is illustrated in **Figure 1** for a constant and uniform flux density F_{in} ($\gamma_{in} = 0$), $\tau_G = 5 \times 10^6$ years, $r_c = 30R_J$, and $\alpha/f = 10^{-6}$, 5×10^{-5}, 5×10^{-4}. The solid lines indicate the oscillating values of M_T/M_J resulting from the occasional loss of a satellite into Jupiter as a function of time normalized by the accretion timescale, and the dotted lines are the values of M_T/M_J from eqn [12], both for the indicated values of α/f. Generally, the total mass of solids delivered to the disk will exceed M_T, so that several satellite systems with $M_T/M_J = 2 \times 10^{-4}$ would be provided with the earlier ones being lost to Jupiter.

Figure 2 shows that for time-dependent influx rates with $\tau_{in} \sim 1.5 \times 10^6$ years, outer radius for flow deposition $r_o = 30R_P$,

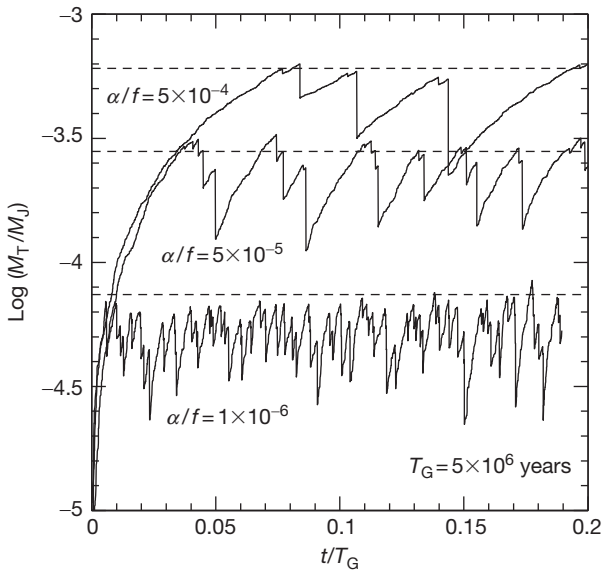

Figure 1 Total mass of satellites as a function of time for a constant rate of inflow for three values of α/f. Modified from Canup R and Ward WR (2006) A common mass scaling for satellite systems of gaseous planets. *Nature* 441, 834–839, with permission.

$\gamma_{in} = 0$, and $\alpha/f = 6.5 \times 10^{-5}$ with $\alpha = 6.5 \times 10^{-3}$, a system of satellites resembling the Galilean satellites is produced with $M_T/M_J \sim 3 \times 10^{-4}$. Recall that M_T/M_J is almost independent of τ_G (eqn [12]) but that disk temperatures are affected by F_{in} (with effective disk temperature $T_{eff} \propto F_{in}^{1/4}$ (Canup and Ward, 2002)). Early in the simulation when the influx is high, the masses of the satellites are given by eqns [11] and [12], but the satellites accreted will be rocky. The properties of the disk must evolve to the point where the midplane temperature of the disk is below 200 K at least beyond the point in the disk where Ganymede accretes a significant fraction of its mass and the accretion of at least Callisto has a timescale $> 10^5$ years to accommodate the latter's possible lack of full differentiation. This timescale requirement generally persists even if Callisto turns out to be differentiated (McKinnon, 1997; Peale, 1999), since influx to the disk and hence the maximum accretion rate are limited by the low disk temperature constraint needed for ice at Ganymede. As the influx wanes, the disk temperature is expected to drop and the component of ice in the satellites is increased. A final generation of Jovian satellites from solar composition inflow with $\tau_{in} = 10^6$ years would form within a disk having temperatures below 200 K exterior to 15 R_J with $\alpha =$ a few $\times 10^{-3}$, a disk opacity $\kappa = O(0.1)\,\mathrm{cm^2\,g^{-1}}$, and a planet temperature $T_J = 500$ K (Canup and Ward, 2002). The constraint of the outer satellites having a large icy component is thereby satisfied. The corresponding timescale for the accretion of the final generation of satellites is $\sim\tau_{in} \sim 10^6$ years, which is consistent with only partial differentiation according to the criteria of Stevenson et al. (1986) and Barr and Canup (2008). Neither the ratio of the total mass of the satellites to the planetary mass, M_T/M_J, nor the distribution of the final satellites is affected much for $-1 < \gamma_{in} < 1.8$, so the results are given in Canup and Ward for $\gamma_{in} = 0$. However, whether most of the mass is deposited close to the planet or far from the planet should affect the distribution of the ice fraction, but this effect of γ_{in} has not been explored. In addition, larger values for γ_{in} may reduce the number of final large satellites (Ogihara and Ida, 2012).

In reality, the satellites are likely to be trapped into orbital resonances sometimes through differential migration of the forming satellites. Such captures were common in the integrations of Canup and Ward (2006) when there were larger outer satellites catching up with smaller inner satellites through type I drift (**Appendix A**). Peale and Lee (2002) demonstrated an assembly of the Galilean satellites into the set of 2:1 MMRs that comprise the present Laplacian relation, where Ganymede is assumed to migrate on the 10^5-year timescale of Canup and Ward and Io and Europa migrate on timescales that are double this value. All the current properties of the resonant system are produced in this scenario, which also requires significant tidal torque from Jupiter to prevent disintegration of the resonant structure from dissipation in Io. However, the assumption of the relative migration rates is ad hoc, and it remains to be shown that detailed plausible disk properties including the opacity as a function of temperature and thereby position in the disk (**Appendix A**), assumed viscosity, etc. can lead to relative migration rates that are consistent with the hypothesis. Still, during the satellite accretion, it is relatively certain that inner small satellites will be trapped into orbital resonances with outer larger satellites that are migrating faster. Such

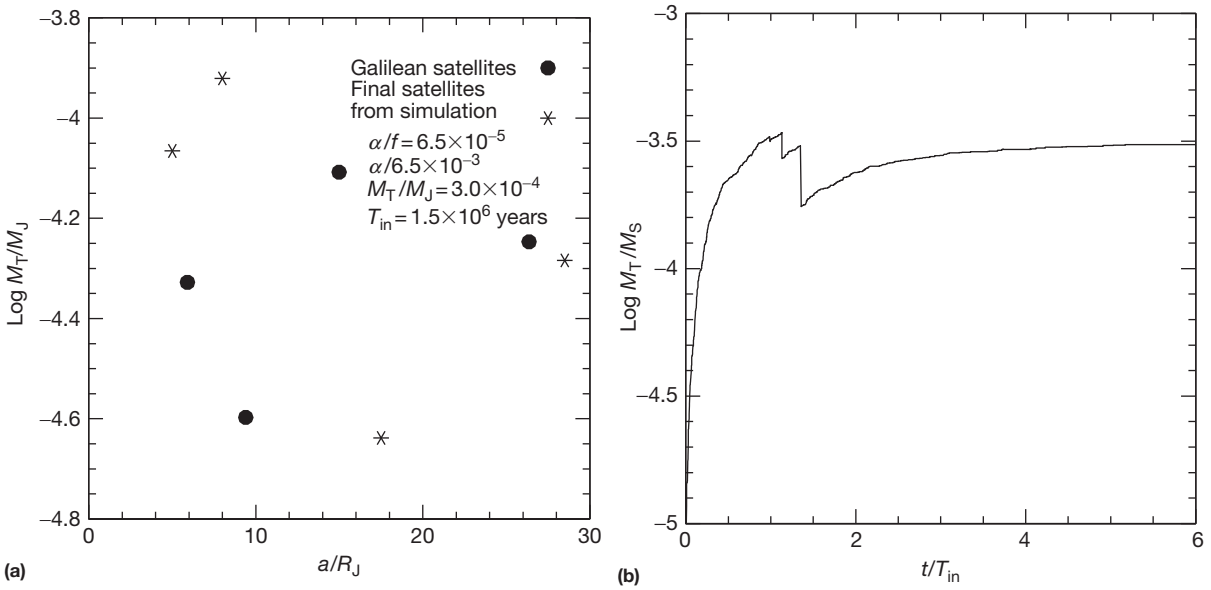

Figure 2 An example of a Jupiter-like system for a waning influx of material onto the disk. (a) Comparison of the masses and locations of the real Galilean satellites with the final set of satellites of a Jupiter-like system from a simulation of a waning influx of material. (b) The time dependence of M_T/M_J for the simulation resulting in the final set of satellites shown in (a). Modified from Canup R and Ward WR (2006) A common mass scaling for satellite systems of gaseous planets. *Nature* 441, 834–839, with permission.

trapping in resonances will hasten the demise of the small satellites interior to larger satellites, where such effects are naturally accounted for in the simulations of the mutual gravitational interactions during differential migration.

The Canup–Ward model successfully produces systems similar to the Galilean satellites (Figure 2). Its virtues include the following: (1) The model is formulated within a plausible model of a waning accretion of the planets, naturally producing not only the observed satellite–planet mass ratios for Jupiter but also those for Saturn and Uranus. (But see Sections 10.17.5 and 10.17.6 for possible caveats.) (2) The waning accretion causes the disk to evolve to sufficiently low disk temperatures to allow water ice condensation and incorporation of that ice into the satellites. (3) The main conclusions are insensitive to the inflow rate and only weakly dependent on the notoriously uncertain value of α. (4) The last generation of Jupiter's satellites accretes sufficiently slowly to allow possible incomplete differentiation of Callisto. (The latter constraint could be relaxed somewhat if it turns out that Callisto is in fact completely differentiated (McKinnon, 1997; Peale, 1999).) (5) The theory is clearly formulated in terms of parameters whose values can be adjusted and the consequences ascertained as new observations and theory provide more constraints. (6) Numerical simulations are consistent with the analytic approximations used in estimating the critical satellite mass attained before loss to the planet and for the total mass fraction M_T/M_J. (7) The simulations produce satellite systems similar to those observed for Jupiter, Saturn, and Uranus for plausible values of the parameters.

Possible caveats to these conclusions include the following: (1) The model requires that the planet contracts to a scale smaller than the satellite system while the nebula is still present, so that an accretion disk forms. While this appears consistent with current contraction models (e.g., Papaloizou and Nelson, 2005; Ward and Canup, 2010), the alternative picture in which a disk is created by spinout from a planet that contracts after the nebula has dissipated would likely produce a very different outcome. (2) A disk with viscosity α values comparable to those inferred for circumsolar disks is assumed. This seems consistent with what is needed to explain the accretion of mass to the planet, given the relatively high specific angular momentum expected for the inflowing gas. But quantitative models justifying such α values in this environment are lacking. Although the effect of the value of α on the conclusions is suppressed by small fractional exponents, the range leading to systems consistent with those of the gaseous planets still implies relatively large values of α. What values of α can be expected from the influx rate as a function of time or from other means of generating turbulence such as stirring by the satellite embryos themselves or MHD-generated turbulence? (3) The model assumes that the outer edge of the inflow region corresponds roughly to the observed scale of the outermost regular satellites. Determination of r_c from hydrodynamic simulations is very challenging, due to the required high resolution, the need to account for the tendency of the circumplanetary disk to viscously spread, and the dependence of results on the assumed nebular scale height. But on balance, current models suggest that the inflow region extended somewhat beyond the current large outer satellites (e.g., Ward and Canup, 2010). Are there processes that would have inhibited satellite accretion in the outer disk? Or could r_c be set by another process, such as the radial extent of a midplane dead zone where MHD turbulence is inactive (Lubow and Martin, 2013)? (4) The assumption that all of the solids are delivered with the gas is dependent on the view that much of the solid mass is in sizes much less than a meter and that small particles do penetrate the gap. An abundance of small particles is predicted by current 'pebble accretion' models, although their

delivery to the disk in the presence of the gap should be more thoroughly investigated. How does a realistic estimate of the solid particle size distribution affect the solid inventory of the disk? Are there viable alternative schemes for solid delivery? (5) The critical dependence on disk properties on the opacity affects in particular the inferred disk thermal profile for a given inflow rate and how type I migration rate varies with r. It is possible that the latter could affect the relative growth rates of satellites at various distances. The Canup–Ward models do not include a time-dependent opacity nor a disk that may evolve from optically thick to optically thin. Has the assumption of a constant opacity seriously altered the evolution?

Sasaki et al. (2010) considered a Canup and Ward-type model, only with two important differences. First, they terminate the accretion shortly after Jupiter opens a gap in the heliocentric nebula, which leaves a hot massive disk, which they assume is quickly reduced by a short viscous spreading timescale. This leaves the satellites that are currently in the disk to interact with the remaining gas. The properties of the disk and satellites therein are now 'frozen' at the time of gap formation, and the disk is now closed. In essence, this marries one of the main premises of the SEMM model (an abrupt end to the inflow upon gap opening) to an actively supplied disk model. A unique and crucial assumption in their model is the creation of an inner cavity in the disk through magnetic coupling to the rapidly rotating Jupiter that extends out to the synchronous orbit (2.25 R_J assumed). This inner gap is motivated from inferences about the differences between classical and weak-line T Tauri stars, where the former's properties are assumed to result from formation of an inner cavity created by the magnetic field of the star. An eccentricity barrier at the inner disk edge (Ogihara et al., 2010) is proposed as the means of stopping the satellites at the boundary. Here, a satellite crossing the boundary because of its eccentric orbit forced by a MMR experiences a positive torque because of a tailwind near apoapse but has no negative torque at the periapse because it is not in the disk on this part of its orbit. There are at least two caveats for this hypothesis: (1) Sakaki et al. adopted the timescales obtained by Ogihara et al. (2010) for type I drift in an isothermal disk. These timescales are appropriate to opposing inside and outside torques. These type I drift timescales are applied to all the satellites in the resonances – even to the satellite at the disk's inner edge. But the outer Lindblad resonances are still in the disk for that satellite and there are no opposing torques from the inside, so the satellite will experience a continued type I torque forcing it toward Jupiter that is now enhanced because there are no interior Lindblad resonances contributing an opposite torque. The timescale for the type I drift is thereby reduced for the satellite at the disk edge from that which was assumed. A possible solution could be obtained by considering the opposing action of the corotation torque at the outer edge of the disk cavity (Massett et al., 2006). (2) Type I timescales are derived for a circular satellite orbit, but the forced eccentricity of the satellite at the disk edge introduces additional resonances in the disk which contribute to the torque. A complete treatment of the disk edge dynamics must be completed before one can have confidence that the eccentricity trap will work.

If the barrier does exist, subsequent satellites are now trapped in a series of MMRs and migration of the whole stack of satellites is resisted by the cavity barrier holding the innermost satellite in place. Once the gas infall terminates, the disk is depleted by viscous spreading and the disk temperature decreases exponentially with time. When the mass of the trapped, resonantly bound satellites exceeds the remaining mass in the disk, the barrier is breached and the innermost satellite is forced into Jupiter presumably still in the MMR with the outer satellites. The next satellite in line then is halted at the barrier but may be pushed into Jupiter as the remaining satellites continue to accrete mass from the disk. The ice content of the outer satellites increases as the disk cools and the ice line moves in. When the gas content of the disk is sufficiently depleted, migration stops leaving a system comparable to the current Galilean satellites.

When Sasaki et al. considered an abrupt cessation of inflow to the disk, their outermost large satellite typically forms too quickly to be consistent with an incompletely differentiated Callisto. However, by assuming a more gradual reduction in the infall, they found a $\sim 10^6$-year accretion time for the outermost body. Callisto accretes slowly in the outer part of the disk cool enough to accrete a major fraction of ice and migrates so slowly that it is often not trapped into a resonance.

Sasaki et al. modeled satellite accretion using a semianalytic procedure developed by Ida and Lin (2004, 2008) to model planet formation. Ogihara and Ida (2012) considered the same physical conditions as Sasaki et al. but modeled satellite accretion with an N-body simulation. They found similar results for Jupiter-like systems, including the finding that a Galilean-like configuration in which several satellites are captured into mutual 2:1 resonances is a very common outcome when an inner disk cavity is included with the eccentricity trap.

There are several other aspects of the Sasaki et al. (2010) proposal that are controversial: (1) The assumption that accretion is halted at the time of gap formation is not consistent with the global 3-D calculations of Bate et al. (2003), who found accretion is not halted until $M \sim 10 M_J$. (2) There is no analysis of the disk ionization needed to establish the magnetic coupling to the gas that creates the inner cavity. (3) It is not clear that the large magnetic field necessary to effect the disk standoff is actually to be expected. On the other hand, the existence of a cavity at some point may well be required to explain the current subcritical rotation rates of Jupiter and Saturn (Takata and Stevenson, 1996). (4) And their model assumes a satellite accretion timescale that increases with orbit radius, whereas in an inflow-regulated disk, this timescale decreases with increasing r. This appears likely to have affected the architecture of their final satellite systems, particularly in the case of Saturn-like systems without an inner cavity (see the discussion in the next section).

The Canup–Ward (2002, 2006) model is a reasonably complete and plausible model of satellite formation within a model of the latter stages of the accretion of Jupiter, albeit not without caveats. It is consistent with the composition and positional constraints and produces the gross features of the satellite systems of the giant planets for plausible choices of the controlling parameters, which differ from planet to planet. Some choices of the parameters yield systems comparable with the observed Galilean satellites. The vertical accretion onto the disk is consistent with the high-resolution 3-D simulations. The accretion of the satellites in the circumplanetary

disk is specifically treated as a function of disk properties that change as the accretion winds down, where plausible timescales for the various processes are assigned that are consistent with the observed properties of the satellites. The encouraging conclusions from the model depend on the assumed value of α, the presence of sufficient small solids that can be efficiently delivered to the disk by the gas, and the disk's thermal model (and therefore the assumed opacity). Refinement of the model should develop realistic constraints on these parameters.

10.17.5 Saturn System

The Saturn system is far different from the Jupiter system, and aside from the conclusion that the regular satellites formed in a cold, dissipative disk, the details of the formation of the satellites therein are less understood. The Saturn system is dominated by a single satellite, Titan, which contains 96% of the combined mass of all Saturn's satellites. Whereas Jupiter's satellite densities decrease progressively with increasing distance from the planet, at Saturn, they are strikingly nonmonotonic: the densities of the satellites Mimas, Enceladus, Tethys, Dione, Rhea, Titan, Hyperion, and Iapetus are 1.15, 1.61, 0.97, 1.48, 1.23, 1.88, 0.57, and 1.08 g cm^{-3}, respectively (e.g., Jaumann et al., 2009). These densities imply a substantial ice content for all the satellites, but in common with Jupiter, the fraction of the planet's mass contained in the satellites is near 2×10^{-4}. Interior to these satellites are Saturn's main rings, which together contain about the mass of a Mimas-sized satellite, and multiple smaller ringmoons. The ringmoons are dynamically young (e.g., Esposito, 1986; Goldreich and Tremaine, 1982) and may be recent products of the collisional expansion of ring material beyond the Roche limit (Charnoz et al., 2010). The small mass of the satellites other than Titan, the lack of any rock-dominated satellites inside Titan's orbit, the nonmonotonic distribution of densities, and the origin of the rings comprise the major mysteries of the formation of Saturn's satellite system.

While the low density of Hyperion (mean radius $\langle R \rangle \sim 150$ km) is significantly affected by porosity, this is expected to have a minor effect on the densities of larger Tethys ($R = 530$ km) and Iapetus ($R = 718$ km). In particular Tethys' density is the lowest of all outer solar system objects having $R > 500$ km and, for plausible densities for rock and nonporous ice, implies a rock content between 0% and 6% (e.g., Thomas, 2010). The main rings are also more than 90–95% pure water ice (e.g., Cuzzi et al., 2010). These are extremely ice-rich compositions compared to a bulk solar composition of roughly half rock/half ice. In contrast, the mass fractions of rock in Enceladus, Dione, and Titan are similar to those of Ganymede and Callisto. The current high density of Enceladus may reflect loss of water from the observed plumes at the south pole (Porco et al., 2006). The loss rate of neutral H_2O is estimated to be ~75–1600 kg s^{-1} (e.g., Fleshman et al., 2010). The history of activity on Enceladus is totally unknown, but if current activity has persisted for a significant fraction of Enceladus' lifetime, the satellite could have lost a significant fraction of its ice and started with a more Mimas-like density.

Titan is about 50% water as deduced from its mean density. Estimates of its moment of inertia from Cassini data suggest that its interior may be incompletely differentiated like Callisto (Iess et al., 2010), although this result assumes hydrostatic equilibrium and is therefore uncertain due to the possible contribution of nonhydrostatic structures (e.g., Gao and Stevenson, 2012). The mole fraction of methane in Titan's atmosphere is about 5% in the lower atmosphere and the rest is essentially all N_2 except for traces of argon, a tentative detection of neon, and small amounts of heavier hydrocarbons (Niemann et al., 2005, 2010). Aside from a mole fraction of $2.1 \pm 0.8 \times 10^{-7}$ for ^{36}Ar and $2.8 \pm 2.1 \times 10^{-7}$ for ^{22}Ne, no other primordial inert gases have been detected (Niemann et al., 2010).

If the N_2 in Titan's atmosphere were trapped in the icy planetesimals that went into Titan as direct condensation from the gaseous phase, or if it were trapped in amorphous ice or as a clathrate hydrate, the noble gases would have also been trapped. The low upper bound on the noble gases implies then that the N_2 came into Titan in the form of NH_3 (Niemann et al., 2005, and references therein). The nondetection of krypton and xenon led to several suggestions for the origin of the atmosphere consistent with the lack of these gases. One possibility is that the icy planetesimals formed at temperatures >75 K so that the noble gases and CH_4 were not captured, but NH_3 and CO_2 were. However, Owen and Niemann (2009) showed that the detection of Ar but not Kr or Xe could instead be due to the limited sensitivity of the Huygens probe instrument given the relative abundance of these elements in other solar system bodies, making such arguments inconclusive.

Heavier hydrocarbons are thought to be products of photochemistry initiated by photodissociation of methane (e.g., Niemann et al., 2005). The relatively short timescale for the survival of CH_4 from photodissociation of 10–100 million years (Wilson and Atreya, 2004; Yung et al., 1984), together with the lack of any isotope fractionation in the carbon of CH_4 like that seen in nitrogen and oxygen, means that CH_4 must be continuously supplied from Titan's interior (Niemann et al., 2005). This scenario may require the continuous supply of CH_4 to Titan's atmosphere to be created through chemistry within Titan (Zolotov et al., 2005). We are certainly left with the constraint that the temperature eventually becomes cool enough in the Saturn disk to allow water ice to persist but perhaps not so cold as to permit stable methane clathrates.

Most models of the Saturnian protosatellite disk invoke a surface density, midplane temperature, and pressure that increase with decreasing r as in the Jupiter examples in the preceding text. This would normally favor the formation of rocky satellites close to the planet with icy satellites further out, yet the inner satellites are ice-rich at Saturn. For an accreting disk, the rate of heat generated by viscous dissipation is proportional to the inflow rate (Canup and Ward, 2002), and so for very slow rates of inflow, ice can be stable in the inner disk. In the limit that viscous dissipation is unimportant and the planet's luminosity is the dominant heat source in the disk, the ice stability distance is within three Saturnian radii once the planet's temperature falls below about 500 K (e.g., Canup, 2010). A cold, solar composition inner disk would produce ice-rock satellites, rather than extremely ice-rich objects like Mimas and Tethys. Furthermore, a smooth disk surface density profile consistent with Titan's mass would generally yield much more massive satellites in the inner disk than those observed. Thus, the inner Saturnian satellites are not easily explained by a standard disk model.

The Mosqueira–Estrada SEMM model for the Saturnian disk (2003a) starts with a smoothed minimum mass nebula based on the total satellite system mass, rather than on the specific distribution of mass in the current inner satellites. The temperature and surface mass densities are assumed to vary as $1/r$ as in the Jupiter model. As in the Jovian SEMM disk, a steep surface density gradient is assumed just outside the centrifugal radius defined earlier, which for Saturn is just outside the orbit of Titan. We argued earlier that it is improbable that such a steep gradient could have been maintained during the disk's formation, when the viscosity required to transport angular momentum outward so that the planet can accrete mass (e.g., Estrada et al., 2009) would have smoothed out such variations (e.g., Ward and Canup, 2010). But interestingly, capture of Hyperion into its current 4:3 MMR with Titan seems to require such a steep density gradient ($\sigma_g \sim r^{-3}$) if Hyperion formed as Titan formed and was brought into the resonance by gas drag, as seems likely (Lee and Peale, 2000). As Hyperion nears its final mass, which was probably considerably larger than its current mass because pieces chipped off Hyperion typically do not remain in the resonance and are not reaccreted, gas drag overwhelmingly selects the 3:2 MMR preventing migration to the 4:3 if the surface mass density decreases less rapidly than r^{-3} (Lee and Peale, 2000).

In the SEMM model, Titan forms in the inner, dense disk in 10^4–10^5 years and would likely be fully differentiated (Mosqueira and Estrada, 2003a). Melting of ice occurs in Titan's interior if it forms in $\lesssim 10^6$ years even in the limit that there is no radiogenic heating and the satellite forms from small impactors that deposit their energy close to the surface (Barr et al., 2010), so that substantially more rapid formation implies differentiation. In the SEMM model, Titan is saved from loss due to inward type I migration by opening a gap in the very low viscosity disk, with the disk then removed due to nonviscous processes (e.g., photoevaporation) so that Titan is not lost by type II migration. Mosqueira and Estrada form Iapetus in their outer, low surface mass density disk, where it migrates inward by type I drift to the point where this torque vanishes because of the steep density gradient between the inner and outer disks. The ice-rich composition of Iapetus is then ascribed to the preferential delivery of water to the outer disk by the ablation of differentiated heliocentric planetesimals, because objects passing through the low-density outer disk become hot enough to lose their ice but not their rock (Mosqueira et al., 2010).

To account for the ice-rich compositions of the inner moons, Mosqueira and Estrada (2003b) suggested that the inner Saturnian disk was initially too warm for ice and that early rocky embryos that formed there were lost as they spiraled into Saturn. Subsequently, as the disk cooled, the ice condensed to form ice-rich satellites about 10^5 years after the end of Saturn's accretion when the disk gas surface density had decreased to $\sim 10^4$ g cm^{-2}. However, the survival of the inner moons would then require a very rapid removal of the inner gas disk just after they formed; otherwise, they too would be lost to gas drag in the order of a few $\times 10^4$ years (for Mimas) to $\sim 10^5$ years (for Rhea). Mosqueira and Estrada (2003b) qualitatively discussed seven different reasons for why there might be no large satellites interior to Titan. Their preferred explanation is that the tidal torque from a fully formed Titan removed the inner disk before other large inner satellites could form, but how a tidal torque causes the inner material to flow rapidly inward is not explained. For a disk with no inflow, satellite growth would generally proceed more rapidly in the inner disk due to shorter orbital periods and a higher disk surface density, implying that if the inner disk contained a mass much larger than that in the current inner moons (and this is the case for the SEMM disk), satellites much larger than the current inner Saturnian moons would likely form before Titan formed.

An underlying assumption of the SEMM or any minimum mass model is that the satellites form after the planet has finished accreting gas, so that there is no inflow supply to the disk. However, the period of inflow to the disk is long (comparable to the lifetime of the nebula), while the timescale for solids orbiting in the disk to accrete into satellites is short. Thus, it seems more probable that Saturn's satellites formed throughout the lifetime of its disk as it was being supplied by an inflow, rather than waiting until after the inflow had ended, similar to the conditions advocated for the Jupiter system. The Canup–Ward model (2002, 2006, 2009), as well the simulations of Sasaki et al. (2010) and Ogihara and Ida (2012), adopt this premise.

Canup and Ward (2006) simulated the accretion of Saturn's satellites from an actively supplied disk with an N-body model as described in **Section 10.17.4**. Jovian-like systems with four or five similarly sized large satellites were the most common outcome in the Canup and Ward simulations. But depending on the stochastic timing of when the inflow ends relative to the oscillations of satellite growth and loss seen in **Figure 1**, other system structures were also produced. **Figure 3** shows a simulation with $r_c = 30R_S$, $\gamma_{in} = 0$, $\alpha/f = 6 \times 10^{-5}$, and $\alpha = 6 \times 10^{-3}$ that produced a Saturn-like system with one large satellite and numerous small satellites (Canup and Ward, 2006). Initially, four large satellites formed, but the inner three are lost to collision with the planet as the inflow wanes. After the last large inner satellite is lost, the final inflow delivers enough mass to produce Dione- and Rhea-sized satellites in the vacated inner region of the disk. During this period, the inflow rate is so slow that the ice stability line moves inward to a few Saturnian radii. When the infall ends and the gas disk dissipates, a seven-satellite system remains with $M_T/M_S = 1.8 \times 10^{-4}$ and the most massive satellite at $\sim 14.6R_S$ that contains 70% of the mass of the total satellite system mass. Its close orbital spacing to the satellite at $11.3R_S$ suggests a future collision may occur. There are two satellites bracketing the position of Iapetus but with larger orbital eccentricities. The inner satellites in this simulation are sufficiently close together that collisions are likely with a reduction in the total number of satellites.

The Canup and Ward simulations were the first to show that a smooth disk could produce approximate analogs to Saturn's satellite system. However, systems with only one large satellite were not common, and they did not produce any systems in which one satellite contained $>70\%$ of the final satellite system mass. Although their calculations produced the small, ice-rich satellites inside Titan's orbit, they could not account for the large increase in the ice fraction of these satellites over the half rock/half ice content of the influx nor could they account for the nonmonotonic distribution of the rock–ice content of the inner satellites. This difficulty has motivated an alternative scenario described in the succeeding text that

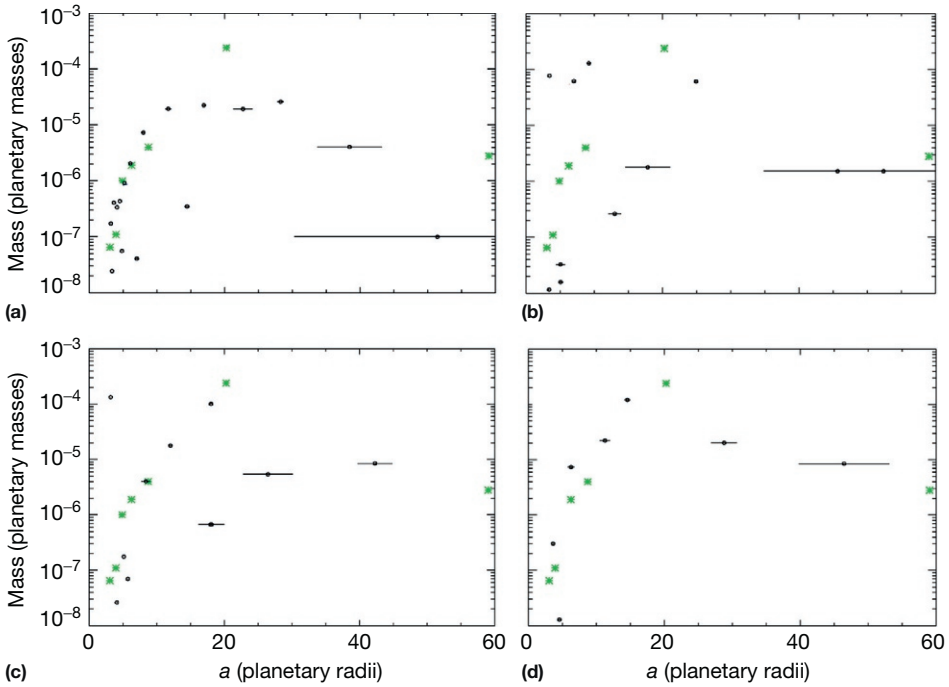

Figure 3 Results of a satellite accretion simulation from Canup and Ward (2006) that produced a Saturn-like system of satellites. Here, the inflow to the disk is assumed to decrease exponentially with time with a time constant τ_{in}. Black circles show the simulated satellites (with horizontal lines proportional to orbital eccentricities); Saturn's satellites are shown as green stars. (a) Multiple satellites form as solid material flows into the disk ($t = 0.2\tau_{in}$). Once satellites grow to $M \sim$ few $\times 10^{-5}$ planet masses, they begin to migrate inward. (b) At $t = 1.4\tau_{in}$, the system resembles Jupiter's Galilean system, with four similarly sized large satellites. The inner three large satellites are lost to collision with Saturn, with the last large satellite lost at time $t = 3\tau_{in}$ (c), when the inflow rate has slowed substantially. The final system (d) at $t = 10\tau_{in}$ has a single large Titan-like satellite orbiting at 15 planetary radii.

produces nearly pure ice inner satellites as well as a nearly pure ice ring system.

Sasaki et al. (2010) simulated the accretion of satellites using a semianalytic, Monte Carlo model. This model closely reproduced the oscillations in the total satellite system mass seen in **Figure 1**. However, when considering the same conditions as Canup and Ward (an inflow that decayed exponentially with time and a planet without an inner cavity in its disk), they found the most common result was a Saturn-like system with a single large satellite. Ogihara and Ida (2012) performed N-body simulations of the conditions considered in Sasaki et al. and found Jupiter-like systems were the most common result for disks without inner cavities, similar to the Canup and Ward (2006) findings. All three works use the same expressions for the rate of type I migration and the quasi steady-state gas surface density. However, their treatment of the satellite growth rate differs. Sasaki et al. used a semianalytic procedure in which they use a satellite accretion timescale that is proportional to the local orbital period, leading to $\tau_{acc} \propto r^{5/4}$ (their eqn [13]) and a longer growth timescale for outer satellites compared to inner ones. But in an inflow-supplied disk, the rate of satellite growth is controlled by the rate of delivery of material to the disk rather than by the local orbital period (Canup and Ward, 2002). For a uniform inflow per area, this leads to $\tau_{acc} \propto 1/r^{4/5}$ (Canup and Ward, 2006) or $\tau_{acc} \propto 1/r^{2}$ (Ogihara and Ida, 2012), depending on how the width of a satellite's feeding zone is defined. In both the Canup and Ward (2006) and Ogihara and Ida (2012) simulations, satellites in the outer disk thus have shorter growth timescales than those in the inner disk.

By imposing a slower accretion in the outer disk, the Sasaki et al. model would tend to artificially delay the growth of outer Titan-sized objects in the time it takes an inner Titan-sized object to migrate inward. This appears to have biased their results in favor of single satellite systems. Ogihara and Ida (2012) suggested that a radially nonuniform inflow, in particular one that is centrally concentrated, might be able to produce a similar result, although this has yet to be demonstrated.

Can the very ice-rich compositions of the inner moons be explained in the context of such models? Canup (2010) proposed that as the last of the large satellites was lost, tidal stripping from its outer layers created Saturn's rings and ultimately the inner satellites out to Tethys. This scenario requires that this last satellite be differentiated as it crossed the Roche limit with the outer layer being nearly pure ice or an ice-covered ocean. This possibility is supported by Canup (2010) who notes that accretion should bring a Titan like body to near the melting point of ice even on the relatively long accretion time scale of 10^6 years expected under the waning influx of material to the disk. A sustained eccentricity $\sim 2 \times 10^{-3}$ for $k_2/Q \sim O(10^{-2})$, which is a balance between excitation by perturbations of other satellites and damping by tidal dissipation in the satellite, would provide somewhat more than the latent heat of melting an ice shell in the $\sim 10^4$ years the satellite spends near the Roche limit before colliding with Saturn. This heat input plus that from accretion is not

unlikely to produce the needed differentiation into an ice water mantle over a rocky core.

When the satellite's orbit decays within the Roche limit set by its mean density (located at $\sim 1.75R_S$ for a Titan-density satellite, where R_S is Saturn's current mean radius), tidal distortion begins to remove material from its ice shell. The removal of ice causes the satellite's mean density to increase until the remnant satellite is marginally stable. This continues until either the remnant collides with the planet or its higher-density rocky core disrupts. The Roche limit for rock is at $a_{R,rock} \sim 1.5R_S$. Planet contraction models predict that the newly formed Saturn's radius would have been between $R_P = 1.5R_S$ and $R_P = 1.7R_S$ (e.g., Fortney et al., 2007; Marley et al., 2007). For $a_{R,rock} \leq R_P$, the remnant satellite collides with the planet before its core disrupts, and tidal stripping produces a pure ice ring.

Canup (2010) used SPH to simulate a differentiated Titan-sized satellite as it spirals inward from its initial Roche limit. The total mass of ice produced via tidal stripping depends on the location of the planet's surface: In the limit that $a_{R,rock} = R_P$, $\sim 10^{25}$ g of ice is stripped into orbits exterior to the satellite ($\sim$10% of the original satellite's mass), while if $a_{R,rock} < R_P$, less ice is produced before the remnant satellite hits the planet. As each ringlet of ice is stripped, strong shepherding torques from the remnant satellite rapidly repel it, driving exterior material into orbits beyond the Roche limit for ice in 10^2 years. Here, the stripped material accumulates in a pure ice moon whose final mass is $m_o \leq 10^{25}$ g. Canup estimated that the location of synchronous orbit around a newly formed Saturn would be located at about $3R_S$ due to the slower rotation of the more distended planet, so that this ice moon eventually spirals inward due to planetary tides, but at a slower rate than the original satellite due to its smaller mass. For planetary tidal parameters $(k_2/Q)_P$ (with likely values $10^{-6} \leq k_2/Q_P \leq 10^{-5}$; e.g., Charnoz et al., 2009), the ice moon takes $\sim 10^6$ years $[5 \times 10^{-6}/(k_2/Q)_P]$ $[10^{25}\, g/m_o]$ to decay within the ice Roche limit, where it disrupts into a massive ice ring. This timescale is long enough that the ring forms after the remnant satellite has collided with Saturn and when the circumplanetary gas disk has essentially dissipated. Mosqueira and Estrada (2011) claimed that such a ring would be destroyed by gas drag, because its surface density decreases with time (and with it, the ring's lifetime against gas drag) as the ring spreads. But a ring formed at the very end of gas accretion can survive, because there is also a decrease in the gas surface density with time both before the ring forms and as the ring evolves due to the waning inflow, which they did not consider. However, their point is a good one for any rings formed by satellites that decayed within the Roche limit earlier in a planet's gas accretion.

The Canup model implies an initial ring that is a factor of 20–500 times more massive than Saturn's current rings. In contrast, prior ring origin models produce an initial ring comparable in mass to the current rings (Charnoz et al., 2009; Dones, 1991). Salmon et al. (2010) found that such dense rings can evolve to something resembling Saturn's ring by viscous spreading after $O(10^8)$ years, but it is not clear how the ignored MMRs with the closest satellites such as Mimas would affect this evolution. As a ring viscously spreads, it spawns satellites from its outer edge (e.g., Charnoz et al., 2010), and Canup estimated that for such a massive ring, the first spawned satellite would have a mass comparable to that of Tethys, whereas Charnoz et al. (2011) found the first mass spawned to be comparable to Rhea's mass. Spawned moons evolve outward due to first resonant interactions with the ring and then by tidal evolution, with the mass of spawned moons decreasing with time as the mass of the ring decreases due to viscous spreading (Charnoz et al., 2010, 2011). Mimas, Enceladus, and Tethys would be by-products of the formation of Saturn's rings. However, the dynamics of such satellite orbit expansions have not been investigated (see succeeding text).

Extending this idea, Charnoz et al. (2011) proposed that all of the satellites interior to and including Rhea were spawned from an initial ring containing a few $\times 10^{24}$ to few $\times 10^{25}$ g. Dione and Rhea contain $\sim 10^{24}$ g in rock, much greater than the total rock in the inner moons ($\sim 10^{23}$ g) that could be delivered by external bombardment during the LHB (Canup, 2013). The Charnoz et al. (2011) model thus requires an initial ring with a substantial rock component. To leave the rings as essentially pure ice, they creatively suggested that the rock in the rings was initially in the form of large chunks that were able to open gaps in the ring and undergo type II migration. A direct simulation of a Rhea-sized chunk embedded in a ring is used to show that the chunk is expelled from the ring's outer edge, where it would then form the core of a spawned satellite. It is, however, not clear why the ring's rock would be contained in fragments many orders of magnitude larger than the accompanying ice particles, since the strength of rock and ice is similar and because ice and rock particles would likely form rock–ice aggregates of varying mean densities, nor whether a simulation that included a large number of rock chunks would be able to remove them all from the ring with nearly perfect efficiency. A second condition of the model is that Dione and Rhea evolve out to their current orbits through tides, which requires an extremely small tidal Q parameter for Saturn of $Q < 2000$. It is generally believed that the Q is of order 10^4–10^5 for gas giants. Lainey et al. (2012) considered astrometric observations of Saturn's satellites over the last century and found $Q \sim 1700$. This result is controversial, both because it implies a much different Q for Saturn than similar techniques predicted for Jupiter (Lainey et al., 2009) and because their data also showed Mimas migrating inward rapidly, whereas it should be migrating outward due to both tides and ring torques.

There are several important caveats to both the Canup (2010) and Charnoz et al. (2011) models. First, neither can produce the nonmonotonic distribution of satellite compositions without invoking ad hoc degrees of freedom. In Charnoz et al., a pure ice initial Tethys is proposed to result from stochastic variation in how rock is delivered from the initial ring. The Canup model implies an essentially pure ice initial Tethys but then requires additional processes to explain Enceladus' rock content while avoiding the subsequent accretion of too much rock onto Tethys. Next, can the initial satellites accreted outside the Roche radius retreat far enough before the next one is spawned to allow the minimum spacing of the satellites, or is an additional sequence of mergers required? The simulations of Charnoz et al. (2011) show that typically more inner moons are formed than are currently in the system, although they utilize a simplified accretion model. Crida and

Charnoz (2012) used an analytic merger model and predicted a mass–distance distribution of satellites in good agreement with that seen at Saturn. However, their accretion model does not include gravitational interactions between the moons, including MMRs.

The most critical constraint comes from the limited tidal evolution of the current satellites. Slow differential expansion of the orbits will lead to a plethora of MMRs that will be encountered, and capture within will lead to eccentricity growth that will destabilize the system. That the tidal evolution of the system has been limited is implied by calculations of evolution of the Saturn system that brings Enceladus to the 2:1 MMR with Dione (Peale, unpublished). Reducing the satellite semimajor axes to start the integrations consistent with their mutual tidal evolution brings Tethys and Dione and, almost at the same epoch, Mimas and Enceladus inside 3:2 MMRs. The integrations had to start outside these resonances to avoid the certain captures therein, which implies that the evolution of the satellite system is limited over the 4.6×10^9-year history to start outside these resonances. There is no obvious means to escape from these resonances and the eccentricity growth therein leads to crossing orbits before the resonances become unstable. The implied lower bound on the average Q of Saturn exceeds 90 000, which is higher than that inferred from the proximity of Mimas to Saturn. The system configuration is such that Enceladus' semimajor axis must start outside 0.9832 its current value if the two 3:2 MMRs are to be avoided.

One way MMRs among the satellites spawned by the massive icy ring in the Canup and Charnoz et al. models can be traversed without capture is to note that the initial orbital expansion of these satellites as they interact with a massive ring will be very rapid compared to tidal evolution. If the orbit of the inner satellite expands the width of the MMR in a time less than the libration period of the resonance variable, capture can be avoided. It is possible that the inner moons (Mimas, Enceladus, and Tethys) achieved nearly their current positions through the ring interactions, and subsequent tidal evolution can be severely limited. But this possibility has not yet been demonstrated. In the Charnoz et al. (2011) model, Dione and Rhea become too distant to experience ring torques and they must migrate over vast distances at the much slower tidal rates. If 90 000 is the real lower limit on the historical tidal Q, such distant tidal migration is unlikely. If Q is much lower than this and the extensive migration could ensue, the capture of Dione and Rhea and the inner satellites into destabilizing MMRs is likely. Details of the orbital evolution of the satellites under the variety of possible constraints discussed have not been investigated.

The challenge of explaining the variation in densities among the mid-sized Saturnian satellites has motivated alternative origin scenarios that form these satellites as intact ejected clumps from large impacts. If the impacting objects are differentiated, such clumps can have compositions that vary significantly from those of the parent objects. Sekine and Genda (2012) considered the collision between a smaller satellite and a Titan-sized body as the latter migrated into the inner disk due to type I migration. Asphaug and Reufer (2013) proposed that an initial multiple moon system at Saturn was destabilized through mutual collisions that ultimately left only Titan and that the current mid-sized moons were clumps ejected from such collisions. Both works use SPH simulations to demonstrate that such collisions can produce large intact fragments having similar sizes and a wide range of rock fractions as observed among Saturn's mid-sized moons. However, both works face a common challenge: how to avoid having the clumps ejected from an impact reaccrete onto the target object. Ejecta are initially on crossing orbits with the target and would generally be rapidly reaccreted. If ejecta are in the form of small particles, then their mutual collision times can be shorter than the reaccretion timescale, and in this case, they can collisionally damp to a ring, which could potentially accrete into separate stable satellites. But this process would also seem likely to remix the compositions of the clumps and seems unlikely to yield multiple satellites with well-separated orbits as observed.

We conclude our discussion of Saturn with Iapetus, which presents a special problem in that its orbit is nearly circular, but inclined by about 7.49° relative to the local Laplacian plane. The latter inclination would imply a capture origin, but because eccentricity damping due to the tidal dissipation in Iapetus is very weak, a capture origin is inconsistent with its current small orbital eccentricity ($e_I = 0.0283$). The Laplacian plane is that plane on which a satellite's orbit precesses at nearly a constant rate with nearly a constant orbital inclination. The Laplacian plane nearly coincides with the equatorial plane for close satellites due to torque from the planetary oblateness, but it coincides nearly with the planet's orbital plane for distant satellites due to the solar torque. An extensive debris disk settling to this plane would therefore be warped as the local Laplacian plane changed from equatorial plane to orbital plane with distance from the planet (e.g., Ward, 1981). The regular satellites accumulated from debris disks at distances where the oblateness of the planet dominated the location of the Laplacian plane. But at Iapetus' distance from Saturn, the local Laplacian plane is inclined by 15° to Saturn's equator, where the ascending nodes on the orbital plane of Saturn's equator (obliquity = 26.7°) and the Laplacian plane coincide. Can Iapetus have accumulated in the debris disk as implied by its small orbital eccentricity yet be inclined to the local Laplacian plane by 7.49° today?

Ward (1981) offered a tidy affirmative answer by pointing out that the debris disk itself contributes to the precession of objects within it. The Laplacian plane thereby would have a lower inclination to Saturn's equatorial plane at the time the disk was present, and Iapetus could have accreted there as assumed in the previously mentioned discussion. Iapetus' orbital plane precesses with a current period of about 3000 years (Ward, 1981), and this period would have been shorter when the disk was present. If the disk could be dispersed on a timescale short compared to the orbit precession period at the time, the Laplacian plane would rotate toward its current position and leave Iapetus with its observed low eccentricity and 7.49° orbital inclination. The short dispersal time necessary, $O(100)$ years, is not consistent with accretion times of the satellites of order 10^3–10^4 years in the theories discussed in the preceding text or for allowing sufficient time for rocky satellites to spiral into Saturn in the inner disk, leading to the formation of icy satellites there. Viscous dissipation of the disk on this short timescale requires values of $\alpha = O(1)$ (Ward, 1981), which is implausible. Because of the difficulties imposed by such rapid disk dispersal, the anomalous orbit of

Iapetus is still a puzzle. A capture origin seems unlikely, because sufficient gas drag to circularize the orbit would also have damped the inclination to the local Laplacian plane.

Although the structure of the circumplanetary disk is still poorly constrained and there are uncertainties about the nature of the solid content in the gas inflow, the Canup–Ward model is perhaps a first step toward an understanding of the origin of Saturn's satellite system, since a system with no large satellite interior to Titan appears attainable. The loss of large inner satellites to type I migration provides a means to produce a pure ice initial ring and ice-rich inner satellites. The loss of silicate embryos while the nebula was too warm to allow water ice condensation followed by cooling to allow the remnant ice to accrete onto the small satellites is an attractive alternative (Mosqueira and Estrada, 2003a,b). But there have been no detailed disk evolution models to show that the sequence of events needed for this scenario can occur. Explaining the distribution of densities in the inner satellites remains a challenge, and current ideas ultimately depend on stochastic events, which are difficult to model with great confidence due to inherent uncertainties in the relevant processes. We are much closer to understanding the details of the origin of Jupiter's satellites than we are to understanding the origin of the Saturn system.

10.17.6 Uranus System

The Uranus system of satellites is Jupiter-like in the sense that it contains a few large satellites with $M_T/M_U \sim 1 \times 10^{-4}$ (M_T is the total mass of the satellites). All the satellites out to Oberon with the exception of Miranda have nearly equatorial orbits with densities–radii of the major satellites Miranda, Ariel, Umbriel, Titania, and Oberon of 1.2/236, 1.7/579, 1.4/585, 1.7/789, and 1.6/761 ($g\,cm^{-3}\,km^{-1}$), respectively. Inside Miranda's orbit are 13 small satellites that are the most densely packed in the solar system and are thereby unstable and experience relatively frequent collisions (French and Showalter, 2012). Thirteen remnant rings in the inner system are testimony to the frequent destruction and reassembly of the satellites in the inner system. The Canup–Ward (2006) model can produce a Uranus-like system of the major satellites, where the lower rate of inflow and cooler disk temperatures about the smaller mass planet produce satellites with a mixture of rock and ice that is consistent with the densities. However, these authors note the difficulty of moving the disk material from heliocentric orbit to the equatorial plane of Uranus when the obliquity of Uranus is 98°. On the other hand, if the Uranus obliquity were small when the satellites formed and only later tipped over by an adiabatic process, the Canup–Ward model would be immediately applicable. But with more certainty than the Saturn case, Uranus will not open a gap in the solar nebula, and the influx may have a different distribution over the disk than that appropriate for Jupiter. So, the Canup–Ward model may have to be modified.

Accounting for the maintenance of a coplanar, equatorial system of satellites about Uranus as the planet gains its large obliquity is the major obstacle to understanding their origin. An adiabatic scheme for tilting Uranus, where equatorial orbits would be maintained by adiabatic invariance (e.g., Goldreich, 1965), requires a resonance between the precession rates of the spin axis about the orbit normal and the precession of the orbit about its local Laplacian plane. This requires the spin precession rate to be increased drastically from its current value. Boué and Laskar (2010) accomplished this by assuming that Uranus originally had a massive satellite with an orbital radius of about 0.01 AU. However, Morbidelli et al. (2012) pointed out that the Laplacian plane for such a satellite is close to Uranus' orbital plane and this satellite orbit would not follow the equator as the Uranus obliquity increased. Because of its large mass, this satellite would also hinder at least Oberon and Titania from doing so. Morbidelli et al. concluded that a sudden tilting of Uranus with a giant impact is the only remaining viable means of accounting for the large obliquity, a scheme which had been proposed before (e.g., Slattery et al., 1992).

The most viable timing of the impact is after the planet has completed its gas accretion and thereby already possessed a satellite system. The impact would likely disrupt this system into crossing orbits where collisions would disintegrate the satellites into a debris disk. The latter scenario was verified numerically by Morbidelli et al. (2012), so these authors consider the evolution of a protosatellite disk after the massive collision that tilts Uranus modeled as gravitationally interacting concentric rings. After the tilt, the disk is still in the former equatorial plane, but Uranus' new equatorial plane corresponds to the new 98° obliquity. The rotational oblateness of Uranus, parameterized by the gravitational harmonic coefficient J_2, causes differential precession of the ascending nodes of the disk rings (or of particles in the disk) so the disk becomes a thick torus spanning the equatorial plane. Collisions within the torus damp the ring to the new equatorial plane, where the new disk can accrete into equatorial satellites. However, the J_2 effect competes with the self-gravity of the disk, where the latter dominates for those portions of the disk that are further from Uranus and cause the disk to precess as a unit while maintaining its original inclination to the equatorial plane. Such dominance of self-gravity of the particles was first realized for the epsilon ring of Uranus, where the periapse longitudes precessed together maintaining the ring coherence (Goldreich and Tremaine, 1979).

If the current value of J_2 is assumed, the nodes are randomized by differential precession only slightly beyond Miranda's orbit near 0.001 AU. Beyond Miranda's distance, the inclined ring would lead to satellites highly inclined to the equatorial plane. But existing simulations indicate that the impact should create an equatorial disk near 0.01–$0.03M_U$ extending out to $3R_U$, where R_U is Uranus' radius (Slattery et al., 1992). This equatorial ring enhances J_2 sufficiently to extend the randomization of the node longitudes of the rings comprising the disk out beyond Oberon's orbital distance. The mutual collisions damp the disk down to the equatorial plane where the equatorial satellites can be formed. But if the tilt to the current obliquity is from 0° to 98° with the single impact, the satellite orbits will be equatorial but retrograde! On the other hand, if Uranus had a preimpact obliquity >30°, the probability of prograde orbits exceeds 40% (Morbidelli et al., 2012). This complicates the scenario somewhat as it requires Uranus to have had at least two giant impacts, but such impacts near the end of planetary accretion are thought to have been common (Morbidelli et al., 2012). The equatorial disk formed from the impact probably could

not contribute significantly to the major satellites as they are too far away, but contribution to the small inner satellites is possible.

In contrast to the opinion expressed in Section 10.17.4 against starting with a pristine disk for the formation of the regular satellites of Jupiter, here is an example of the creation of a disk around a giant planet from which the satellites containing about 10^{-4} of the Uranus mass could be formed. If the solar nebula had already been removed at the time of impact, there would be no further accretion onto the disk after the disk was formed. If the debris disk from the collisional breakup of the original satellites contained little gas, loss of solids from gas drag would be eliminated, and the total satellite mass would then be $O(10^{-4}\,M_U)$ appropriate for the Canup–Ward model of the original accretion.

An alternative to this scheme has been proposed by Crida and Charnoz (2012). Here, the satellites are created from a massive disk mostly inside the Roche radius that was created at the time of the giant impact that tilted Uranus. The satellites are created one by one just outside the Roche radius as the disk spreads viscously, and they migrate away from the disk from disk torques initially and eventually through tidal expansion of the orbits. This idea has the appealing features that only a single impact is necessary to create a system that will be equatorial and prograde. However, the details of its execution pose some severe problems. First, there most likely would have been an accretion disk about Uranus as it was being formed, and satellites would have formed in this disk. Since Uranus must have been mostly completely formed at the time of the impact, it must have had a preexisting satellite system in its equatorial plane as assumed by Morbidelli et al. (2012). This preexisting system is assumed not to exist in the Crida and Charnoz scheme. Next, the disk formed by the impact is inside about $3R_U$ so that Oberon must be moved from this distance to almost $23R_U$ if it is spawned from the ring. Even if the tidal dissipation function Q for Uranus were sufficiently small to accomplish this feat over the age of the solar system, Titania, more massive than Oberon and at a smaller orbital distance, would have moved out more rapidly. Finally, the disk produced by a Uranus-tilting impact would initially be vapor, which would evolve differently than a disk of solid particles as considered by Crida and Charnoz. It is difficult to see how the Crida–Charnoz scheme could be the origin of the Uranian satellites.

The Slattery (1992) simulation of the giant impact contained only 5000 particles in the proto-Uranus and 3000 particles in a $2M_E$ impactor. Rather substantial changes in the outcome resulted from SPH calculations of the lunar-forming impact on the Earth as the resolution was increased substantially above that of earlier calculations (Canup, 2004b), so it is important to do simulations of the Uranus impact with the highest resolutions currently practical to see if conditions assumed (e.g., the mass and extent of the equatorial disk generated by the impact) in the successful scheme for forming the prograde, equatorial satellites by Morbidelli et al. actually prevail.

10.17.7 Neptune System

A plausible theory has emerged for the current configuration and content of the Neptune system of satellites. Here, the task is simpler than for the other gas planet systems, because Triton's destruction of the original system during its capture has erased all concern for accretion disks, gaps, solar nebula interactions, etc. The dominant characteristic of the Neptune satellite system is the existence of the large satellite Triton (NI) ($R = 1353$ km), in a close ($r \approx 14.3R_N$, $R_N = 24\,766$ km) circular, retrograde orbit (obliquity 156.8°). The remaining regular satellites are prograde. Neptune also has relatively few known satellites compared with the other major planets, and all but two of those, Triton and Nereid (NII), were unknown until the Voyager spacecraft observations (Smith et al., 1989) and subsequent ground-based discoveries (Holman et al., 2004). Nereid's orbital eccentricity of 0.75 brings it no closer than about 1.4×10^6 km from Neptune's center because of its extremely large semimajor axis of 5.51×10^6 km ($222.6R_N$) – well outside Triton's distance.

The massive satellite Triton is blamed for most of the features of this unusual system. The retrograde orbit means that Triton was almost certainly captured intact from heliocentric orbit. It has been proposed that Triton was captured in a three-body exchange where Pluto was expelled from orbit around Neptune (Farinella et al., 1980), that it was captured by gas drag (Mckinnon, 1984; McKinnon and Leith, 1995), or that it collided with a satellite already in orbit about Neptune with a mass a few percent of Triton's mass (Goldreich et al., 1989). The first hypothesis suffers from the likely multiple subsequent close encounters of the ejected Pluto with Neptune and essentially no means of leaving Pluto in the currently stable 3:2 MMR with Neptune, whereas the second has low probability. A collision would have been sufficient to capture Triton into a very eccentric orbit extending a significant fraction toward the Hill sphere boundary at $r_H \approx (M_N/3M_\odot)^{1/3} a_N \approx 4.5 \times 10^3 R_N$ (a_N = heliocentric distance) while not destroying it.

An alternative method of capture of Triton involving the disruption of a binary KBO with characteristics similar to the Pluto–Charon binary pair has been proposed (Agnor and Hamilton, 2004, 2006). Binary systems among the small bodies in the solar system appear to be ubiquitous with ~16% of near-Earth asteroids (Margot et al., 2002), ~2% of main belt asteroids (Merline et al., 2002), and ~11% of KBOs (Stephens and Noll, 2006) having companions. The fraction of small bodies in binary pairs is probably larger than these such that binary–planet encounters are likely. When a binary pair comes sufficiently close to a planet such that the Hill sphere of the pair in the planetary gravitational field is smaller than their separation, they become tidally unbound. Depending on the phase of the relative motion in the binary and the inclination of the orbital plane with that of the encounter trajectory, one of the planetesimals can be left in bound orbit about the planet while the other escapes. A simulation with binary pair masses $m_1 = m_T$ and $m_2 = 0.1m_T$ separated by $20R_1$ in circular orbit, where m_T is the mass of Triton and R_1 is the radius of m_1, closest approach distance $8R_N$ well inside the tidal disruption radius $r_{td} = 26R_N$ (R_N = Neptune radius), resulted in 95% of the binaries being disrupted for $0 < v_\infty < 2.0$ km s^{-1}, ~50% of the encounters resulting in capture of either m_1 or m_2 for $v_\infty < 0.35$ km s^{-1}, and ~50% of the encounters resulting in capture of m_2 for $0.35 \lesssim v_\infty \lesssim 1.55$ km s^{-1}. For the latter velocity interval, capture of m_1 is still possible but rare.

Although either collisional capture (Goldreich et al., 1989) or binary exchange capture (Agnor and Hamilton, 2004, 2006)

can yield reasonable orbits that can damp to the observed retrograde circular orbit observed today, Agnor and Hamilton show that with at least 11% of KBOs being binary systems, capture by collision has negligibly small probability compared with the binary exchange capture. If the original satellite system of Neptune were similar to that of Uranus, collision of Triton with any satellites this large would have destroyed it, making the currently inclined orbit of a recollected Triton impossible (Ćuk and Gladman, 2005). So, it is almost certain that Triton was captured gently without such a risk, although a collisional capture remains an improbable possibility. Nogueira et al. (2011) verified the arguments for the capture of Triton by the disruption of a binary KBO, and Vokrouhlicky et al. (2008) argued that the capture must have occurred early in solar system history in the context of the Nice model of this history (Gomes et al., 2005; Morbidelli et al., 2005; Tsiganis et al., 2005).

The properties of a prograde satellite system that likely existed around Neptune prior to Triton's capture are of course unknown. An original satellite system like that of Uranus extending from about $5R_N$ to beyond $20R_N$ would have been perturbed into crossing orbits, and the satellite system would be thereby destroyed. During the times when Triton's periapse was inside $20R_N$, energy would be removed from Triton's orbit impulsively at each passage through the disk of material leading to circularization times of 10^4–10^5 years while Triton cleared most of the material from the disk outside of about $5R_N$ (Ćuk and Gladman, 2005).

If interactions with such a disk were not sufficient to circularize Triton's orbit, subsequent tidal dissipation would suffice. With $k_T(=k_2)=0.1$ and $Q_T=100$, Goldreich et al. (1989) found that an initial Triton orbit with semimajor axis $a_T \approx 10^3 R_N$ would damp to nearly its current circular orbit with $a_T \sim 14.3R_N$ from tidal dissipation in Triton in about $4–5\times10^8$ years – comfortably shorter than the age of the solar system. However, the large amount of dissipation probably melted a significant fraction of the satellite, which drastically hastens tidal evolution (Mckinnon et al., 1995; Shock and McKinnon, 1993). The Love number k_2 would then be $O(1)$ (closer to that of a fluid sphere) instead of $O(0.1)$ and $Q_T \sim O(10)$ instead of $O(100)$, leading to a factor of $\sim$100 shorter eccentricity decay timescales.

We can estimate the time required to damp Triton's eccentricity (e_T) with the following procedure. During the damping of Triton's eccentricity, it probably existed in an asymptotic rotation state defined by the zero of the averaged tidal torque given, for example, by eqn [B.17] in **Appendix B**. We determine de/dt from eqn [B.27], where we assume $\dot{\psi}_s$ is the asymptotic value given as a function of e by the zero of the third component of eqn [B.17]. If we also assume that the periapse position is maintained at Triton's current distance, then the semimajor axis can be represented as $a_0/(1-e)$ where a_0 is the current value. With these assumptions, the time to decrease Triton's eccentricity from 0.9 to 0.01 is $3.3\times10^5\ Q_T/k_T$ years. The tides raised on Neptune by Triton will have a negligible effect (Banfield and Murray, 1992; Goldreich and Soter, 1966). With the Goldreich et al. choices of k_T and Q_T, the time to damp Triton's eccentricity is 3.3×10^8 years, which is the several hundred million years damping time found by Goldreich et al. With the more likely value of k_T/Q_T, this time is only 3.3×10^6 years.

But tidal dissipation may have been less efficient in the circularization of Triton's original eccentric orbit than inferred by Goldreich et al. because solar perturbations cause periodic increases in periapse distances (Benner and McKinnon, 1995). The Goldreich et al. analysis ignored these Kozai oscillations in eccentricity (see **Section 10.17.9**), which would have occurred if the original maximum orbital inclination was comparable to the current one. These 1000-year variations in e_T cause the mean periapse distance to be much larger than that obtained by Goldreich et al. with the consequence that the tidal damping time, with the same values of Q_T and k_T, and expression for dissipation used by Goldreich et al. would yield a timescale of 3.5 Gy for the eccentricity reduction (Ćuk and Gladman, 2005). Reducing this number to 35 My with the more likely values of Q_T and k_T in the preceding text still makes the tides adequate.

Consistent with the capture scenario and subsequent melting, Triton was found to have a young and active surface. The observed, currently active plumes are almost certainly solar-driven (Smith et al., 1989), but the geologically young volcanic plains and cantaloupe terrain are clearly endogenic, where such surface modification may be ongoing (Shenk and Jackson, 1993; Stern and McKinnon, 2000). Triton's density is about 2 g cm^{-3}, which indicates some ice content. Triton's original constituents were obtained directly from the solar nebula at its location of formation, but there may be significant contamination with debris from the original satellite system. The volatile content was probably reduced during the rather extreme tidal heating during the eccentricity damping, although some N_2 was retained from the early dense atmosphere and most of the water is still there (Lunine and Nolan, 1992). Triton and Pluto are similar in size and density, but Pluto may have lost a lot of volatiles from the impact that created Charon (see **Section 10.17.8**), and one cannot infer that this loss is the same as that from Triton. The current density does not constrain the place in the solar nebula where Triton may have been formed. But an initial composition similar to that of Halley's comet is consistent with observations of the surface ices, where the severe reduction of CO relative to N_2 and CO_2 can be understood by hydrothermal processing resulting from the tidal heating (Shock and McKinnon, 1993).

While Triton's orbit was extended, any regular satellites inside about $5R_N$ would also have been disrupted and destroyed from the periodic dips of the periapse inside $5–8R_N$, depending on the initial semimajor axis. There are likely to have been several satellites inside the periapse distance of Triton in comparison with the regular systems of the other major planets. Orbit eccentricities would have been limited to maximum values near 0.3, since the rate of decrease of the eccentricity by tidal dissipation within the satellite exceeds Triton's ability to increase it for larger values (Banfield and Murray, 1992). Two satellites with semimajor axes of $3R_N$ and $5R_N$ would have overlapping orbits that would persist in overlapping for times at least of the order of the eccentricity damping time of 10^5–10^7 years. A collision between any of Neptune's current inner satellites with its neighbor would lead to their mutual destruction. This follows from the relation (Stevenson et al., 1986)

$$\frac{1}{2}m_i v_i^2 \sim m_s S + \frac{3}{5}\frac{Gm_s^2}{\gamma R_s} \qquad [14]$$

where m_i and m_s are the masses of the impactor and satellite, respectively; v_i is the relative velocity at impact; R_s is the satellite radius; $S \sim 10^6$ erg g^{-1} is the material binding energy; and $\gamma \sim 0.1$ is a factor introduced to account for the inefficiency in converting the impact kinetic energy into kinetic energy of the fragments. The impactor kinetic energy must exceed the energy stored in material strength plus the self-gravitational energy by a sufficient amount to break up the body. From eqn [14] and eccentricities of 0.3, Naiad (NIII) could destroy all of the satellites except Proteus (NVIII), and any of the satellites NIV to NVII could destroy Proteus. This implies that the current satellite system could not have existed prior to Triton's orbit circularization (Banfield and Murray, 1992). The debris from the first generation of satellites would settle into the equatorial plane in circular orbits and recollect into a second generation of inner satellites with nearly circular orbits and zero inclinations, where all memory of Triton's perturbations would be thereby lost. Had any of these inner satellites survived destruction, their orbits would have been left inclined to Neptune's equatorial plane. The lack of such inclined orbits among the inner satellites must mean that there are no survivors among those early inner satellites.

The inner satellites observed today are not those formed after the circularization of Triton's orbit. The flux of comets through the system would have destroyed all of the current inner satellites except for Proteus (1989N1) over the lifetime of the solar system (Colwell and Esposito, 1992; Smith et al., 1989). The debris from such a destructive collision would settle to the equatorial plane where the satellites can reaccrete. The rings of small particles are likely to be remnants of these collisional breakups. Any distant irregular satellites of Neptune (Holman et al., 2004) would also have their orbits perturbed drastically by Triton if they were captured before or during Triton's capture and orbital decay and their numbers depleted (Ćuk and Gladman, 2005).

10.17.8 Pluto System

Pluto and its large satellite Charon orbit about their center of mass with a period of 6.3872273(3) days at a separation of 19,573(2) km with zero eccentricity (Buie et al., 2012a). (The numbers in parentheses denote the 1σ uncertainty in the last digits.) The rotation of both bodies is synchronous with the orbital motion, which makes this system the only one in the solar system known to have reached the end point of tidal evolution. Like the Earth–Moon system, the Pluto system has a high specific angular momentum that favors the formation of Charon by a large oblique impact (Mckinnon, 1984, 1989; Stern et al., 1997). Canup (2005) had performed SPH simulations of impacts on the Pluto precursor with impactor mass a significant fraction of the target mass with a variety of compositions and differentiation states. The most probable outcome of a simulation that is successful in placing a sufficient amount of mass in orbit outside the Roche distance is for Charon to be launched as an almost intact satellite in a highly eccentric orbit. In these examples, the impactor is undifferentiated and Charon is composed almost entirely of material from the impactor, which results from its being sheared off in the oblique impact. Some of the discussion of the giant impact creating the Moon in Section 10.17.2 is applicable to Pluto–Charon, but the impact associated with the latter involves much less energy. There is little heating of Charon, little water ice is vaporized, but there is probably sufficient energy deposited in Pluto at impact coupled with radiogenic heat to cause its differentiation (Canup, 2005). An impact thus appears a quite natural mechanism to produce Charon, assuming that large collisions were probable in the early Kuiper Belt. However, the impact does not, as it turns out, provide a straightforward explanation for Pluto's tiny satellites discovered in recent years. The objects present a current puzzle, which we describe in some detail later in the text. The gravitational collapse scenario pointed out earlier in the text for widely spaced, massive Kuiper Belt binaries probably is not applicable to the Pluto system because of the difficulty of assembling a sufficient amount of mass into a gravitationally unstable swarm (Nesvorny et al., 2010).

Pluto has four known additional satellites in nearly circular orbits that are nearly coplanar with the orbit of Charon. The first two discovered (Weaver et al., 2006) are named Nix and Hydra. Best-fit Kepler orbits by Buie et al. (2012b) yield periods, semimajor axes, and eccentricities of 24.85494(6) d, 38.20163(7) d; 48 831(25) km, 64 736(11) km; and 0.00232(19), 0.00658(15), respectively. Pluto's fourth satellite, S/2011 (134 340) 1, also known as P4, was discovered on 28 June 2011 (Showalter et al., 2011). The satellite was found in archival images, where the long time span allowed the determination of the following Kepler orbit parameters (Buie et al., 2012b): period = 32.1866(22) d, semimajor axis = 57 890(120) km, and eccentricity = 0.0045(11). The fifth satellite, S/2012 (134 340) 1, also known as P5, was discovered on 14 separate sets of images from the Wide Field Camera on the Hubble Space Telescope on June 26, 27, and 29 and July 7 and 9 (Showalter et al., 2012). P4 is about 1/10 as bright as Nix, and P5 is about 1/2 as bright as P4. The orbital period of P5 is 20.2 ± 0.1 days with orbital semimajor axis near 42 000 km. All of the orbital planes are within $\lesssim 0.15^\circ$ of Charon's orbital plane. With the orbital period of Charon at 6.3872273 days, the ratio of the orbital periods of each of the satellites to that of Charon is 3.16 (P5), 3.89 (Nix), 5.03 (P4), and 5.98 (Hydra) reasonably close to 3:1, 4:1, 5:1, and 6:1, respectively. The parameters of the Pluto system are summarized in Table 1.

Although the orbital periods of Charon, Nix, and Hydra are nearly in the ratios 1:4:6, no resonance variables are likely to be librating at the present time (Lee and Peale, 2006). The small satellites orbit about the center of mass of Pluto and Charon, and that position from the orbit-fitting procedure gives a Charon–Pluto mass ratio of 0.1168(55). Pluto's radius from the mutual event light curves is 1164(22.9) km (Young and Binzel, 1994) and Charon's radius from a stellar occultation is 603.6(1.4) km (Sicardy et al., 2006). With the masses determined by Buie et al., these radii yield densities of 2.03(0.06) and 1.65(0.08) g cm^{-3} for Pluto and Charon, respectively. The physical parameters of Pluto and Charon are consistent with the results of the giant impact origin of the system (Canup, 2005). Lee and Peale (2006) showed that the orbital motions of Nix and Hydra are markedly non-Keplerian because of the large Charon–Pluto mass ratio. As the masses of the new satellites are increased within the range allowed by the uncertainty in the albedos, the close proximity of the 3:2 MMR between Nix and Hydra causes increasing fluctuations in the

Table 1 Pluto system

	Mass (g)	*Radius (km)*	*Rotation period (days)*	*Orbital period (days)*	a *(km)*	*e*
Pluto	1.302×10^{25}	1151	6.38723	6.38723	–	–
Charon	$0.1165 m_P$	603.6	6.38723	6.38723	$19573 = 17.0 R_P$	0
P5	?	5–14[a]	?	20.2	$42000 = 36.5 R_P$	~0
Nix	$O(3 \times 10^{-5}) m_P$[b]	23–68[a]	?	24.855	$48831 = 42.4 R_P$	~0
P4	?	7–20[a]	?	32.2	$57890 = 50.3 R_P$	~0
Hydra	$O(6 \times 10^{-5}) m_P$[b]	30–84[a]	?	38.202	$64736 = 56.2 R_P$	~0

[a]Assumed albedo range (0.04–0.35).

[b]The stability of P4 places upper limits on the masses of Nix and Hydra that are about an order of magnitude less than these estimates from astrometry (Youdin et al. 2012).

eccentricities. Although the maximum masses allowed within these constraints allow possible libration of the 3:2 resonance variable involving the periapse longitude of Hydra, these maximum masses are probably already ruled out because they would also excite Charon's eccentricity beyond the current observational uncertainties (see Buie et al., 2012a). A dynamic fit to a sufficiently dense set of observational data will yield constraints on the masses of Nix and Hydra (Lee and Peale, 2006). The fact that Nix, Hydra, P4, and P5 are in orbits coplanar with Charon's orbit is consistent with their being accreted in a dissipative disk of much smaller particles.

One way to create such a disk is from the debris left over from the giant impact that trapped Charon into its orbit about Pluto. However, Nix and Hydra reside at ~42 and 56 Pluto radii (R_P) from the Pluto–Charon center of mass, and debris from the impact will not extend out to these distances (Canup, 2004a, 2005, 2011). A disk extending beyond the location of the 6:1 mean motion commensurability with the initially close orbit of Charon is likely formed from partially differentiated impactor and target although usually not from impacts of homogeneous bodies (Canup, 2011). If the small satellites accreted from this disk of material, an appealing hypothesis for transporting Nix and Hydra, and presumably P4 and P5 discovered later, was investigated by Ward and Canup (2006).

Charon's orbit must expand from its initial size in the process of reaching the current state of completed tidal evolution of dual synchronous rotation (Cheng et al., 2014). One can infer from the closeness of Nix and Hydra to the 4:1 and 6:1 mean motion commensurabilities with Charon that the satellites may have occupied a MMR at each commensurability. Being so trapped would mean they could be pushed out ahead of Charon as Charon's orbit tidally expanded. But the resonance must be chosen with care for this to happen.

There are a number of resonances that can be occupied at the 4:1 and 6:1 mean motion commensurabilities characterized by the angular arguments of terms in the expansion of the perturbing potential

$$\phi_{ml} = (m+1)\lambda - \lambda_C - (m-l)\varpi - l\varpi_C \qquad [15]$$

where λ and λ_C are the mean longitudes of the satellite and Charon and ϖ and ϖ_C are the longitudes of periapse. The angle ϕ_{ml} is written for mth-order resonances of the form $m+1$:1 with $m=3$ for Nix and $m=5$ for Hydra. The terms in the expansion of the perturbing potential are represented by $\Phi_{ml}(a, a_C, e, e_C) \cos \phi_{ml}$, where terms involving orbital inclinations are ignored and where $\Phi_{ml} \sim e^{m-l} e_C^l$. The only resonances at the $m+1$: 1 mean motion commensurability that can preserve the satellites during Charon's orbital expansion are for $m=l$ involving only the eccentricity of Charon's orbit in the coefficient Φ_{ml}. This follows from the fact that all those resonances involving e and hence ϖ lead to steady growth in e as the orbits expand with eventual instability. The resonance involving only the eccentricity and longitude of periapse of Charon is called a corotation resonance, since the satellite orbits at the same angular velocity as the resonant potential in the expansion of the perturbing potential due to Charon, the so-called pattern speed. In resonances of this type, there are forced eccentricities for Nix and Hydra whose magnitudes vanish with e_C, but these do not lead to crossing orbits or other unstable configurations. The stability of a corotation resonance vanishes as $e_C \to 0$.

Inspection of eqn [B.22] in **Appendix B** and the local text show that tides raised on Pluto can generally either increase or decrease the orbital eccentricity e depending on the values of both rotation rate $\dot{\psi}_P$ and e but that tides on Charon always decrease the eccentricity, since Charon's angular velocity $\dot{\psi}_C$ will always be near the mean orbital motion n. For relatively larger values of $\dot{\psi}_P$, there is a competition between tides on Pluto trying to increase e and those on Charon trying to decrease e. Cheng (2011) and Cheng et al. (2014) had shown that with a judicious choice of the ratio of the rate of dissipation in Charon to that in Pluto, it is possible to keep Charon's e nearly constant near its initial value throughout the tidal evolution from its close proximity to Pluto to its current separation in dual synchronous rotation. Thereby, the condition for maintaining Nix and Hydra in the 4:1 and 6:1 corotation resonances with Charon during the expansion of the latter's orbit can be satisfied, but that is not the end of the story.

There are two difficulties with the Ward and Canup hypothesis. First, in an investigation to test the migration hypothesis for Nix and Hydra, where the two small satellites are initially placed outside the 4:1 and 6:1 commensurabilities and Charon's orbit is tidally expanded, there were no captures into either corotation resonance by itself in thousands of trials (Cheng, 2011; Cheng, Lee and Peale (2014a)). Next, by carefully placing one of the satellites into a corotation resonance, it was possible to transport it to its current position. But the parameter space that permitted the migration of one satellite in a corotation resonance does not overlap with that which permitted the other to be so transported (Lithwick and Wu, 2008). It is not possible to transport both Nix and Hydra within corotation resonances. A possible alternative was found by Cheng (2011) where in many cases, a test particle was trapped into more than one resonance at the 5:1, 6:1, 7:1, and 8:1 commensurabilities during thousands of trials with the

gravitational coefficient $J_2 = 0$ for Pluto. Interestingly, when caught in the multiple resonances at a given commensurability, the evolution proceeded to the final state without e growing to instability. All the resonance variables stopped librating at the end of the evolution, but the test particle was often left with a significant eccentricity. There was one example where all of the resonance variables librated about 0° with Charon's and the test particle's orbit aligned that proceeded to the current configuration for Hydra near the 6:1 commensurability with both eccentricities damping to zero. There was no example of stable transport in multiresonances at the 4:1 commensurability.

Unfortunately, this mechanism for transporting Nix and Hydra in multiple MMRs has a fatal flaw. A condition for occupying several resonances at a mean motion commensurability is that the orbits be aligned or antialigned with $\langle \dot{\varpi}_C \rangle = \langle \dot{\varpi} \rangle$. This was possible in the examples because $J_2 = 0$ was assumed. But the rapidly rotating Pluto, softened by the impact, will have a large hydrostatic J_2 (initially >0.1) leading to $\dot{\varpi}_C \gg \dot{\varpi}$. The conditions for multiresonance transport of the small satellites will not prevail.

Lithwick and Wu (private communication) successfully transported Nix and Hydra in three-body resonances (with $J_2 = 0$) that were so delicate that their assembly is very unlikely by natural processes and the presence of P4 and P5 and the finite value of J_2 are major obstacles. Cheng, Peale and Lee (2014b) integrated more than a million sets of initial conditions distributed over eccentricities, semimajor axes, and true anomalies with Nix at a range of initial positions relative to Charon but always starting outside the 4:1 mean motion commensurability. Hydra was always just outside the 3:2 mean motion commensurability with Nix or within one of the resonances at that commensurability. Finite but minimal masses of Nix and Hydra were assumed with Charon's albedo. There were no survivors for either $J_2 = 0$ or $J_2 =$ the hydrostatic value. The frustrating failure of the resonance transport hypothesis to place the small satellites, formed simultaneously with Charon at the time of the impact, at their current positions relative to Charon has inspired alternative suggestions.

Establishing a disk of material after the Pluto–Charon evolution is complete has been suggested by Lithwick and Wu (2008). Such a disk, if sufficiently dissipative, will settle to the plane of the Pluto–Charon orbit. To produce satellites orbiting in the same direction as Charon, the disk would need to have a negative specific angular momentum in the frame rotating with Pluto's orbital motion, since Pluto–Charon have a retrograde orbit. Existing studies of the stability of the Pluto–Charon phase space establish an unstable region spanning Charon's orbit. Stern et al. (1994) found $0.47a_C \lesssim a \lesssim 2.0a_C$ and $0.65a_C \lesssim a \lesssim 2.15a_C$ to be unstable for prograde and retrograde orbits, respectively. Pires dos Santos et al. (2011) found that Nix and Hydra decrease the stability of the region beyond $2a_C$ and that the only stable region between Nix and Hydra is near the 5:1 mean motion commensurability with Charon, where we find P4. The unstable region includes the 2:1 and 3:1 mean motion commensurabilities, and we find P5 just outside the 3:1. It would appear that the small satellites may have selected only the nearest stable regions in the Pluto–Charon phase space. N-body calculations to test this hypothesis have not yet been performed.

A conceivable way of establishing the disk after the evolution of the Pluto–Charon system is a collision of two large objects within Pluto's sphere of influence. At best, this is an event of low probability, but Pires dos Santos et al. (2012) maximized that probability by assuming a heliocentric disk density 1000 times that of the current Kuiper Belt, which would prevail before the orbits of the outer planets were expanded. The probability of collision within the Pluto–Charon sphere of influence is further enhanced by one of the objects in the collision being already in a temporarily captured orbit about Pluto–Charon. With the maximum lifetime of such captured orbits being only $O(100)$ years, Pires de Santos et al. found the time between collisions of objects with sufficient mass to account for Nix and Hydra to be so much longer than this that they abandoned this scenario as a possible origin of a dissipative disk that could have produced the small satellites.

Although it is generally agreed that Charon is the result of a glancing impact on the Pluto precursor with subsequent tidal evolution to the current dual synchronous state, the origin of the small satellites remains uncertain. It seems clear that these satellites formed from a dissipative disk of material, but collisional creation of a disk with sufficient mass that extends throughout the region of the small satellites remains improbable.

10.17.9 Irregular Satellites

The irregular satellites that orbit all of the major planets occupy large orbits with significant inclinations and eccentricities. Recent observations have increased the number of known irregular satellites to 96 (Gladman et al., 1998, 2000, 2001; Holman et al., 2004, http://ssd.jpl.nasa.gov/sat_elem.html, http://ksiezyce.republika.pl/table_en.html). They often extend to distances from their primaries that are close to the stability limits of about half of the planet's Hill sphere radius (Hamilton and Burns, 1991; Hamilton and Krivov, 1997). Similar orbital elements for members of clusters of the irregular satellites imply breakup events after the primary body was captured (e.g., Gladman et al., 2001). The only viable means of establishing these systems of large orbits with high eccentricities and inclinations is through capture from the large number of planetesimals orbiting the Sun early in solar system history (e.g., Burns, 1986). Capture can result from a loss of energy by the planetesimal while it is within the planet's Hill sphere. Such energy loss can be either from gas drag in an extended planetary atmosphere (Pollack et al., 1979), from a collision between two unbound planetesimals leaving one with sufficient energy loss to be bound, or from a collision with a smaller object already in stable orbit about the primary (Colombo and Franklin, 1971). The gas drag mechanism for at least the progenitor of the Himalia group of prograde irregular satellites orbiting Jupiter has been explored in detail by Ćuk and Burns (2004), where it is shown that such capture must occur near the end of a waning gas disk lifetime to avoid losing the satellites to the planet. Gas drag no doubt resulted in the capture of many planetesimals into stable orbits about the major planets, but only the very last ones have survived. The occupancy of orbital resonances by two of the retrograde satellites of Jupiter implies that at least a thin disk was necessarily in place at the time of the capture to allow a weak gas drag to bring the satellites to the resonances (Saha and Tremaine, 1993). An alternative mechanism of capture involves a rapid

growth of the primary, while a planetesimal is temporarily trapped in the Hill sphere, to expand the region of stable orbits (Heppenheimer and Porco, 1977; Saha and Tremaine, 1993). The binary exchange capture for the irregular satellites that is highly probable for the capture of Triton (Agnor and Hamilton, 2004, 2006) is probably not as effective for the capture of the distant irregular satellites, since an irregular satellite is less likely to have ever been close enough to the planet for the binary Hill sphere to have been smaller than the separation of the binary members (Vokrouhlicky et al., 2008).

Still another means of capture of the irregular satellites is a two-body encounter within the Hill sphere, where one of the two participants has sufficient energy loss to remain captured. An interesting variation of nondissipative capture has been proposed by Nesvorny et al. (2007) within the Nice model of early solar system evolution (Gomes et al., 2005; Morbidelli et al., 2005; Tsiganis et al., 2005). In the Nice model of solar system evolution, all the major planets were formed between 5 and 20 AU with a sea of planetesimals with total mass between 20 and 35 Earth masses between 20 and 35 AU from the Sun. The initial separation of Jupiter and Saturn is inside the 2:1 MMR. Jupiter migrates inward and Saturn outward from the scattering of the remaining planetesimals in their vicinity such that near 700 million years after formation, Jupiter and Saturn cross the 2:1 MMR in the wrong direction for capture, but Saturn's eccentricity is excited that destabilizes Neptune and Uranus into crossing orbits between themselves and with Saturn. There are repeated planetary encounters, Neptune and/or Uranus is scattered into the sea of planetesimals leading to a vastly increased flux of planetesimals into the inner solar system, and the asteroid belt is disturbed. The flux of objects into the inner solar system results in the late heavy bombardment (LHB) therein. After many close encounters, the orbits of Neptune and Uranus decouple and the eccentricities and inclinations are damped by dynamic friction as the orbits migrate outward by scattering the abundant planetesimals. The current architecture of the outer solar system is thereby produced.

But the many close encounters among Neptune, Uranus, and Saturn within the population of planetesimals led to the capture of planetesimals in stable orbits around these planets. Planetary encounters with Jupiter are rare, so Jupiter's irregular satellites must be captured by some other mechanism, like the gas drag and collisions discussed earlier in the text. In a typical computer run that produces the current architecture, Neptune, Uranus, and Saturn capture many more irregular satellites than are observed with distributions in orbital elements that match the observed distributions remarkably well. So, if the Nice model or some modification of the same that results in many planetary encounters in the presence of planetesimals is close to reality, the Nesvorny et al. scheme must be important in the capture of irregular satellites. Of course, this mechanism of capture only occurs more than 700 million years after the initial formation of the planets, which may mean that irregular satellites captured before this time by, say, the collision or gas drag mechanisms are replaced by the new population – except Jupiter's irregular satellites may be those captured at earlier times. It is interesting that the systems of irregular satellites are so similar if scaled to the Hill sphere of each planet (Jewitt and Sheppard, 2005), when a different mechanism may be important for Jupiter than for the other three giant planets.

The capture of satellites should lead to a random distribution of orbital inclinations relative to the planet's orbital plane (~ecliptic), but there are few irregulars known with inclinations between 47° and 141°. Carruba et al. (2002) gave a lucid explanation of the scarcity of satellites with orbital inclinations within this range. Solar perturbations dominate the variations in the orbits of these satellites, and in an analytic secular theory of the restricted three-body problem involving perturbations of the satellite orbit by the lowest-order solar tidal term, the motion is averaged over the mean motions of both the planet and the satellites. In this approximation, the component of the satellite's angular momentum that is perpendicular to the planetary orbital plane, $\sqrt{Gm_p a_s(1-e^2)}\cos i$, is conserved, so that the variations in e and i are linked. When the satellite orbital plane is closest to the planetary orbital plane, the eccentricity is maximal. The variations in e and i are thus of opposite algebraic sign for prograde orbits ($i<90°$), but for retrograde orbits ($i>90°$), increasing i brings the orbit closer to the planetary orbital plane so variations in e and i have the same algebraic sign. For $i<i_{crit}=39.2°$ or $i>i_{crit}=140.8°$, the amplitude of the variations in e and i are limited, but for inclinations between the values of i_{crit}, large variations in e can drive the periapse into the region of the regular satellites or the apoapse close to R_H when the argument of periapse ω is circulating. Either consequence can lead to the elimination of the satellite. The only way a high inclination satellite is likely to survive is if ω is librating about 90° or 270° (Kozai resonance) where variations in the eccentricity are more modest. By estimating the fraction of the available phase space for a captured satellite to be in Kozai resonance, Carruba et al. predicted that perhaps 10% of captured satellites should be in stable Kozai resonances at high inclination. The irregular satellites S/2003 J10, Kiviuq (S/2000S5), and Ijiraq (S/2000S6) are apparently currently librating in Kozai resonances. But at least Kiviuq is close to the chaotic zone separating libration from circulation, so its libration may be only temporary (Carruba et al., 2003, 2004).

Numerical integrations of the complete equations of motion of irregular satellites, including the perturbations of the other major planets, show that highly inclined orbits outside the Kozai resonance are more unstable for orbital planes further from the planetary orbital plane between the values of i_{crit} (Carruba et al., 2002). As the extremes of the variable inclinations approach the limits of the zone of exclusion, the satellites can survive for longer periods of time, but the unstable region seems to approach the observed limits asymptotically as the integrations progress. The nonrandom distributions of orbital inclinations and values of the other observed orbital parameters of the irregular satellites are therefore completely consistent with the satellites having been captured into random orbits from the solar nebula population of planetesimals by any of the means discussed in the preceding text.

Appendix A Accretion Disks

The regular satellites of the major planets are in nearly circular orbits in the planes of the planets' equators. This means these satellites had to have formed in dissipative disks of gas and particles that settle to the midplane of the disk before the accretion of the satellites occurs. Given that these satellites

form in such a disk during the formation of the planet, it is important to understand the nature of the accretion in such disks. Our ultimate goal is the determination of the timescales for accretion of such satellites as a function of the disk and particle parameters, for these timescales constrain the current observable properties of the regular satellites. Once formed, the satellites interact with the disks primarily through gas drag when they are small and through density waves generated in the adjacent regions of the disk at mean motion commensurabilities with the satellite when they are large. If the midplane pressure of the disk decreases with distance from the primary, gas drag causes a satellite to spiral toward the planet. Generally the same type of disk causes a similar spiral toward the planet through interaction of the satellite with density waves generated in the disk.

A.1 Accretion of Solids

First, we consider the idealized case of an isolated spherical body m_1 of radius R_1 in a swarm of particles with a distribution $n(m_2, v)\mathrm{d}m_2\,\mathrm{d}v$ representing the number density of particles of mass within $\mathrm{d}m_2$ of m_2 and speeds within $\mathrm{d}v$ of v. If the relative velocities are isotropic, $n(m_2, v)\sin\theta\, d\theta\,\mathrm{d}\phi\,\mathrm{d}m_2\,\mathrm{d}v/4\pi$ represents the number density of the particles with velocities aimed within $\mathrm{d}\theta\,\mathrm{d}\phi$ of spherical polar coordinates θ, ϕ in a coordinate system where the mean particle velocity is zero. One of these particles of radius R_2 and speed v far from m_1 will collide with m_1 during an encounter if the impact parameter is $<R_g$, where

$$R_g^2 = (R_1+R_2)^2\left(1+\frac{v_e^2}{v^2}\right) \qquad [A.1]$$

with $v_e = \sqrt{2G(m_1+m_2)/(R_1+R_2)}$, the escape velocity of m_2 from m_1 when they are in contact. Equation [A.1] is found by conserving energy and angular momentum when m_2 just grazes m_1 during the encounter. The factor $(1+v_e^2/v^2)=F_g$ is called the gravitational enhancement factor for the collisional cross section of m_1 for particles of radius R_2 and speed v relative to m_1. The mass flux of particles with mass within $\mathrm{d}m_2$ of m_2 and velocity within $\mathrm{d}v$ of v directed within $\mathrm{d}\theta\,\mathrm{d}\phi$ of θ, ϕ onto m_1 is $\pi R_g^2 n(m_2,v)m_2 v\,\mathrm{d}m_2\,\mathrm{d}v\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi/4\pi$ such that

$$\dot{m}_1 = \int_{m_2}\int_v \pi n(m_2,v)m_2 v(R_1+R_2)^2\left(1+\frac{2G(m_1+m_2)}{(R_1+R_2)v^2}\right)\mathrm{d}m_2\,\mathrm{d}v \qquad [A.2]$$

is the rate of growth of m_1, if we assume each m_2 that collides is accreted. In eqn [A.2], we have assumed the velocities are isotropic relative to m_1 and integrated over the solid angle and use $R_2=(3m_2/4\pi\rho_p)^{1/3}$, with ρ_p being the mass density of the individual particles. Because $n(m_2, v)$ is not very well constrained, eqn [A.2] is often replaced by the much simpler form

$$\dot{m}_1 \approx \frac{\sigma_s}{2H_s}v\pi(R_1+R_2)^2F_g \qquad [A.3]$$

where R_2, v_e, and v are now suitably averaged values. We have replaced the spatial mass density of the particles by $\sigma_s/2H_s$, where σ_s is the surface mass density of solids and $2H_s$ is the disk thickness. H_s depends on the velocity dispersion v and can be estimated by

$$0.5v_\perp^2 = \int_0^{H_s}(GMz/r^3)\,\mathrm{d}z = 0.5\Omega_K^2H_s^2 \qquad [A.4]$$

where $v_\perp = Kv$ $(K=O(1))$ is the component of the averaged velocity that is perpendicular to the plane of the disk, G is the gravitational constant, M is the mass of the primary, r is the distance from the primary, z is the vertical distance from the midplane, and $\Omega_K=\sqrt{GM/r^3}$ is the Kepler orbital angular velocity of a test particle at distance r from the primary. GMz/r^3 is just the local vertical component of the gravitational acceleration due to the primary. Hence, $H_s = v_\perp/\Omega_K = Kv/\Omega_K$. This value of H_s is generally smaller than the gas pressure scale height c_s/Ω_K (derived later in the text), with c_s being the speed of sound, because of settling of particles toward the midplane.

From eqn [A.3], we can write

$$\dot{R}_1 = \frac{\sigma_s\Omega_K}{8K\rho_p}\left(1+\frac{R_2}{R_1}\right)^2F_g \qquad [A.5]$$

where ρ_p is the mass density of the particles as distinguished from ρ_s, the spatial density of solids in the disk. If we assume $R_2 \ll R_1$ and ignore factors of order unity, we can write the timescale for the growth of a body as (Canup and Ward, 2002)

$$\tau_A = \frac{R_1}{\dot{R}_1} \approx \frac{\rho_p R_1}{\Omega_K\sigma_s F_g} \sim 50\,\text{years}\left(\frac{R_1}{2500\,\text{km}}\right)\left(\frac{\rho_p}{2\,\text{g cm}^{-3}}\right)\left(\frac{10}{F_g}\right)\left(\frac{3\times10^3\,\text{g cm}^{-2}}{\sigma_s}\right)\left(\frac{r}{15R_J}\right)^{3/2} \qquad [A.6]$$

where the numerical form is for the accretion of Ganymede in a minimum mass disk of particles. The surface mass density σ_s is estimated by spreading Ganymede's mass over an annulus extending from the midpoint between Ganymede's and Europa's orbits to the midpoint between Ganymede's and Callisto's orbit to yield $\sigma_s = 3300\,\text{g cm}^{-2}$. With $\rho_p \approx 2\,\text{g cm}^{-3}$ and an orbital radius of $15R_J$, we arrive at $\tau_A \sim 50$ years when $F_g = 10$. This is a lower bound on the timescale for the growth of Ganymede, since σ_s is reduced as the growth proceeds, but it is indicative of the very short timescales for accretion in minimum mass disks.

Safronov (1969), by transforming from relative to random velocities and assuming the vertical and horizontal velocity dispersions are equal, found $K=\pi/4\sqrt{2}$. Safronov also assumed that the velocity dispersion of the accreting particles remained comparable to the escape velocity of the largest embryos as R_1 increased. In this case, $F_g=O(3)$, and R_1 increases linearly with time if the surface mass density σ_s is maintained in the vicinity of m_1. This linear increase in the radius of an accreting body is called orderly growth. $F_g \approx 3$ is not that much smaller than our choice of $F_g=10$ in eqn [A.6]. Runaway growth can make these accretion timescales even shorter.

The assumption by Safronov that the velocity dispersion of the smaller particles was always near the escape velocity of the largest bodies proved to be incorrect in numerical simulations by Wetherill and Stewart (1989). As long as most of the mass of the disk was in the smaller bodies, the velocity dispersion was nearly the escape velocity of the smaller particles. Increases in the velocities of small particles by close encounters with the

larger bodies were damped by interactions with members of the swarm. F_g is thereby increased by orders of magnitude from that assumed in orderly growth and led to what is called runaway growth. For v fixed near the escape velocity of the smaller bodies, the rate of growth in eqn [A.5] becomes proportional to v_e^2, which, for constant density, increases as R_1^2. The change in scaling results in the largest planetesimal growing much faster than any other, and it 'runs away.' For the two largest planetesimals of the swarm of radii $R_1 > R_2$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{R_1}{R_2}\right) = \frac{R_1}{R_2}\left(\frac{\dot{R}_1}{R_1} - \frac{\dot{R}_2}{R_2}\right) \approx \frac{R_1}{R_2}(R_1 - R_2) \qquad [A.7]$$

shows that if initially $R_1 > R_2$, the ratio R_1/R_2 grows as long as the mass available for accretion has not decreased substantially.

The timescale for accretion in eqn [A.6] is reduced by the larger value of F_g. Both orderly growth and runaway growth timescales depend on the maintenance of the surface mass density of the disk near the accreting satellite and that most of the disk mass is in the small particles. These timescales increase as the nearby material is exhausted and must be eventually governed by how rapidly particles can be brought into the so-called feeding zone of the growing satellite. Still, numerical simulations of lunar accretion in a particle disk verify the rapid accretion timescales even while accounting for the growth of the average particle size during the process (Ida et al., 1997; Kokubo et al., 2000). Mosqueira and Estrada (2003a,b) determined accretion timescales governed by how rapidly gas drag can bring larger embryos to the feeding zone of the satellite.

Although some stages of the accretion process in disks remain unclear, once small solid objects have formed or are deposited in a flat dissipative medium, their accumulation into a coplanar system of satellites seems reasonably well understood in spite of continued haggling over details. The timing of the formation depends on the temperature history of the disk when ices are the predominant constituents of the forming satellites. Once formed, the satellites will spiral toward the primary because of gas drag and interaction with density waves in the gaseous part (type I drift) (Ward, 1997). It is thus likely that at least the large regular satellites formed during the last stages of accretion of their host planet as the gas in the disk and the solar nebula was being dissipated. The small equatorial satellites residing close to their primaries have most likely been repeatedly disintegrated and reformed in a gas-free environment by planetesimals remaining in the heliocentric swarm. Instabilities in the distribution of large objects lead to mergers and eventual separation of the remaining objects by more than several Hill sphere radii, where the Hill sphere radius (sphere of influence) is defined as the distance from the satellite to its inner Lagrange point ($R_H \approx r(M_s/3M_P)^{1/3}$).

Refinements to the accretion process in disks take account of the effect of the primary and depletion of accreting particles in the feeding zone of a growing object (Greenzweig and Lissauer, 1990, 1992; Lissauer, 1987; Wetherill and Cox, 1984, 1985), where an upper bound on the gravitational enhancement factor of about 1000 is determined. Gas drag replenishes the feeding zone and thereby prolongs the accretion of a body in a disk, but only a fraction of such particles (10–40%) brought into the feeding zone by gas drag are actually accreted (Kary and Lissauer, 1995; Kary et al., 1993).

The previously mentioned discussion is focused on gas-free accretion of solids. However, particles near meter size do not tend to stick to one another during collisions, and they tend to spiral into the planet (or star) because of the head wind created by the less than Kepler speed of orbiting by the gas. Youdin and Goodman (2005) described a streaming instability that can concentrate boulders into quite large gravitationally unstable collections. The streaming instability arises because a concentration of boulders can force the gas within the concentration to orbit closer to the Kepler velocity. The interaction with the surrounding gas streaming by, also containing isolated boulders that are spiraling in, causes the concentration of boulders to increase and become gravitationally bound and collapse to large objects (planetesimals in circumstellar disks) as the relative kinetic energy of the boulders within the swarm is dissipated. In the solar nebula, these objects can exceed the size of the dwarf planet Ceres (Johansen et al., 2007, 2011, 2012). The streaming instability appears to be crucial in the accretion of solids in accretion disks to greater than kilometer size.

A.2 Viscous Spreading

An inherent property of disks orbiting a primary is that they tend to spread as angular momentum is exchanged between adjacent regions because of the Kepler shear. Gravitational, magnetic, and viscous torques and wave transport with shock dissipation are all possible candidates for angular momentum transport (Balbus, 2003). Viscous interchange results from the Kepler shear in the motion of the material orbiting the primary. If we represent the shear stress as due to a viscosity η, we can write the shear stress at a distance r from the primary $\omega_{r\phi} = \eta|\mathrm{d}v_\phi/\mathrm{d}r|_{\mathrm{rot}} = \eta r|\mathrm{d}\Omega_K/\mathrm{d}r| = 3\eta\Omega_K/2$, where $|\mathrm{d}v_\phi/\mathrm{d}r|_{\mathrm{rot}}$ is the radial gradient of the azimuthal velocity in the frame rotating at the Kepler angular velocity at distance r. For a gas,

$$\eta = \frac{m\vec{v}}{3A} \approx \frac{mc_s}{3A} \qquad [A.8]$$

where m is the mean molecular mass, $\vec{v} = \sqrt{8kT/\pi m} \approx c_s$ is the mean molecular speed with k being Boltzmann's constant, T is the temperature, A is the collision cross section of the molecules, and c_s is the sound speed (e.g., Sears and Salinger, 1975). Most of the regular satellites around the major planets have a substantial fraction of ice. So, if ice is to be in solid form as satellitesimals, disk temperatures must be $\lesssim 200$ K (depending on the pressure), so for molecular hydrogen, $c_s \approx 10^5$ cm s^{-1}. The kinematic viscosity $\nu = \eta/\rho_g = 2H_g\eta/\sigma_g \approx c_s H_g m/(A\sigma_g)$, where ρ_g is the gas density, σ_g is the surface mass density of the gas, and H_g is the half thickness of the gas disk.

For the gaseous disk, we choose H_g to be the scale height of the disk that is determined by isostasy in the direction perpendicular to the disk, $\mathrm{d}P/\mathrm{d}z = -\rho_g g_z = -mPg_z/kT = -mPz\Omega_K^2/kT$, where P is the pressure and $g_z = GMz/r^3 = z\Omega_K^2$ is the component of gravity in the z direction. The solution of this equation gives $P = P_0 \exp -z^2/H_g^2$ where $H_g = \sqrt{2kT/m}/\Omega_K \approx c_s/\Omega_K$ is the isothermal scale height. As an example, we can estimate the timescale for viscous transfer of angular momentum in a disk surrounding Jupiter that has the minimum mass for accreting

Ganymede at Ganymede's distance from Jupiter augmented with volatiles to reach solar composition. The amount of solids in the disk necessary to make Ganymede corresponds to a surface density of 3300 g cm^{-2} spread from the midpoint between Ganymede and Europa, and the midpoint between Ganymede and Callisto is thereby increased to $\sim 10^5$ g cm^{-2} such that the kinematic viscosity $\nu \approx 3 \times 10^5$ cm^2 s^{-1}. The timescale for viscous transfer of angular momentum at Ganymede's distance from Jupiter ($\sim 10^{11}$ cm) is $r^2/\nu = 1.2 \times 10^9$ years. This time is so long compared with other timescales associated with a circumplanetary disk that molecular viscosity cannot be important in the disk evolution.

If the gas is turbulent, a turbulent viscosity is invoked to increase the efficiency of angular momentum transport. In this approximation, the molecular mass in eqn [A.8] is replaced by the mass of a typical turbulent eddy $\sim \rho_g l^3$ and the cross section A by $\sim l^2$ where l is a typical eddy size. Finally, $\bar{v}$ is replaced by the mean random velocity of the turbulent eddy v_t, so $\eta_t = \rho_g l v_t$. Next, $v_t = \alpha c_s$, where α is a free parameter, $l \sim H_g = c_s/\Omega_K$, so that the kinematic viscosity appropriate for a turbulent medium is (Shakura and Sunyaev, 1973)

$$\nu_t = \frac{\alpha c_s^2}{\Omega_K} \qquad [A.9]$$

The free parameter α is used to indicate the strength of the non-molecular viscous coupling, and the models are often called 'α disks.' The choices of α are usually based on unsupported assertions about the strength of the turbulence. Lower bounds on the magnitude of angular momentum transport follow from the masses of the giant planets. An equivalent viscosity must be sufficient to prevent the forming planet from opening a gap in the protoplanetary disk before it has acquired a significant fraction of its observed mass (Lin and Papaloizou, 1985). Typically, assumed values of $\alpha = O(10^{-3})$ in applications. For shear stress $w_{r\phi}$, the torque across a cylindrical surface of radius r centered on the primary is $T_\nu = w_{r\phi} 2\pi r^2 2H_g = 6\pi\eta\Omega_K r^2 H_g = 3\pi\alpha\sigma_g c_s^2 r^2$ for an α disk. For the example of a minimum mass disk at Ganymede's distance from Jupiter with $c_s = 10^5$ cm s^{-1} and $\alpha = 10^{-3}$, $\nu_t \approx 10^{12}$ cm^2 s^{-1} and the timescale for viscous spreading $\sim$400 years.

If we consider the mass dm in the cylindrical region of radial extent dr with specific angular momentum h, we have $D(h\mathrm{d}m)/Dt = -(\mathrm{d}T_\nu/\mathrm{d}r)\mathrm{d}r$ to balance the net torque on the cylinder with the change in the angular momentum, where $D/Dt \equiv \partial/\partial t + \mathbf{v}\cdot\nabla$ is the total derivative. In a steady-state disk,

$$\nu_r \frac{\mathrm{d}m}{\mathrm{d}r}\frac{\mathrm{d}h}{\mathrm{d}r} = F_r \frac{\mathrm{d}h}{\mathrm{d}r} = -\frac{\mathrm{d}T_\nu}{\mathrm{d}r} \qquad [A.10]$$

where F_r is the radial mass flux. For the general case where $T_\nu = 0$ at $r = 0$ and as $r \to \infty$ and with $\mathrm{d}h/\mathrm{d}r > 0$ as for Kepler motion, we see that $\mathrm{d}T_\nu/\mathrm{d}r$ must be positive at small r and negative at large r so that mass moves inward for small r and outward for large r. Angular momentum always moves outward.

Particle disks also spread from angular momentum transfer via particle collisions. For a disk of particles of mass m_p and velocity dispersion $\bar{v}$ about the Kepler velocity at distance r from the primary, the equivalent kinematic viscosity is given by $\nu_s = \eta_s/\rho_s = m_p\bar{v}/(3A\rho_s) = 2m_p\bar{v}H_s/(3A\sigma_s) = 4H_s\bar{v}\rho_p R_p/(9\sigma_s)$ (Daisaka et al., 2001), where σ_s is the surface mass density of particles in the disk, R_p is the particle radius, and ρ_p is the particle density (distinguished from the spatial mass density of particles ρ_s). For a disk of 100 m particles corresponding to the minimum mass particle disk at Ganymede's distance from Jupiter and the assumption $\bar{v} = v_{esc}$ of two touching particles, $H_s = Kv_{esc}/\Omega_K$ and $\rho_p = 1$ g cm^{-3}, ν_s is only a little over 80 cm^2 s^{-1}. So, low dispersion particle disks spread very slowly with timescale $r^2/\nu = 4.5 \times 10^{12}$ years. But inside the Roche radius in the lunar case, gravitational instabilities cause patches of higher-density material that are repeatedly sheared apart, thereby yielding enhanced collisional dissipation with an effective viscosity of $\nu \sim (\pi G\sigma_s)^2/\Omega_K^3$ and a resulting timescale $r^2/\nu_t \sim 1$ year (Ward and Cameron, 1978). This rapid spreading has been confirmed by N-body simulations (Takeda and Ida, 2001). But self-heating during this short timescale spreading is so intense, at least for the protolunar disk, that more silicates are vaporized, thereby decreasing the effective viscosity and allowing longer timescales for spreading (Thompson and Stevenson, 1988). So, the long timescales for spreading of particulate disks from the simple molecular viscosity analogy are not likely to prevail (see Salmon et al., 2010, for a thorough treatment of viscous spreading in particle disks).

A.3 Gas Drag

A forming satellite assumes a Kepler orbit about the primary, but the gas in the disk has its central acceleration reduced by a radial pressure gradient and thereby orbits slower than the satellites. The satellite thus experiences a continuous head wind that causes it to spiral toward the primary (Weidenschilling, 1977; Whipple, 1964). The gas motion is governed by the equation

$$\rho_g \frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t} = -\rho_g \nabla\Phi - \nabla P \qquad [A.11]$$

where Φ is the gravitational potential per unit mass and P is the pressure. In a steady state, cylindrical coordinates $\ddot{r}, \ddot{\phi}, \ddot{z}, \dot{r}$ and $\dot{z}$ are all zero, and the r component of eqn [A.10] is

$$-\rho_g r\dot{\phi}^2 = -\rho_g \frac{\partial\Phi}{\partial r} - \frac{\partial P}{\partial r} \qquad [A.12]$$

Now, $P = \rho_g kT/m = \sigma_g c_s^2/2H_g = \sigma_g c_s \Omega_K/2$ (m = mean molecular mass). Often, the surface mass density and midplane temperatures are represented by power laws (e.g., Weidenschilling, 1977) like $\sigma_g = \sigma_{g0}(r_0/r)^p$ and $T = T_0(r_0/r)^q$, where σ_{g0} and T_0 are values at distance r_0 from the primary. Then, $\partial P/\partial r = -K\sigma_g\Omega_K c_s/r$, where $K = O(1)$ depends on the choices for p and q. With $\Phi = -GM_p/r$, the solution of eqn [A.11] yields the gas angular velocity

$$\dot{\phi}^2 \equiv \Omega^2 = \frac{GM_p}{r^3} - \frac{K\sigma_g\Omega_K c_s}{\rho_g r^2} = \Omega_K^2 - \frac{2Kc_s^2}{r^2} \qquad [A.13]$$

from which

$$\Omega_K - \Omega \approx \frac{Kc_s^2}{r^2\Omega_K} \qquad [A.14]$$

where $\Omega_K + \Omega \approx 2\Omega_K$ has been used.

For circularly orbiting material, the gas drag force is given by

$$F_d = -C_d \pi R^2 \rho_g v_{rel}^2 \qquad [A.15]$$

where C_d is the drag coefficient, which depends on the Reynolds number $\mathcal{R} = 2v_{re1}R\rho_g/\eta$, where η is the molecular viscosity,

and $v_{rel} = r(\Omega_K - \Omega) = Kc_s^2/r\Omega_K$ is the relative velocity between the forming satellite and the gas, that is, the head wind. The Reynolds number dependence of C_d (e.g., Prandtl, 1952) leads to $C_d = 20/\mathcal{R}$ (Stokes drag) for $\mathcal{R} \lesssim 0.5$ and $C_d \approx 0.43$ for $\mathcal{R} \gtrsim 500$ (see Peale (1993) for an application of gas drag with full Reynolds number dependence for C_d). The torque on the satellite is rF_d, which when equated to the time derivative of the angular momentum given by $m_p\sqrt{GM_p r}$ yields an expression for $\dot{r}$. The timescale for gas drag changes in the orbit is then

$$\tau_{GD} \equiv \frac{r}{\dot{r}} = \frac{4}{3K^2}\frac{1}{C_d}\frac{\rho_p R}{\Omega_K \sigma_g}\left(\frac{r\Omega_K}{c_s}\right)^3 \sim 10^3 \text{ years}\left(\frac{10}{C_d}\right)\left(\frac{R}{2500\text{km}}\right)\left(\frac{\rho_p}{2\text{gcm}^{-3}}\right) \times \left(\frac{0.1}{c_s/r\Omega_K}\right)^3\left(\frac{3\times 10^5 \text{gcm}^{-2}}{\sigma_g}\right)\left(\frac{r}{15R_J}\right)^{3/2} \quad [A.16]$$

where we have used $K = 3/4$ for $p = q = 1$, and the numerical form is for Ganymede (Canup and Ward, 2002), where the minimum mass particle disk has been augmented by ~30 times as much gas to yield solar composition.

A.4 Migration from Density Waves

Satellites also interact with disks by creating spiral density waves at the commensurabilities of the mean motions in the disk with that of the satellite (e.g., Ward, 1997). The resulting distribution of mass in the density waves exerts gravitational torques on the satellite that tend to push the satellite away from the site of the density wave. Hence, the density waves generated inside the satellite orbit tend to increase its angular momentum, whereas those outside tend to decrease it. Simultaneously, the ring material receives or gives up angular momentum, which tends to push the ring material away from the satellite. The distribution of the resonances outside the satellite versus those inside leads to the outside density waves dominating, such that the net effect is for the satellite to spiral toward its primary, called type I drift, with a timescale given by (Canup and Ward, 2002; Ward, 1997)

$$\tau_I \equiv \frac{r}{\dot{r}} \approx \frac{1}{C_a\Omega_K}\left(\frac{M_p}{M_s}\right)\left(\frac{M_p}{r^2\sigma_g}\right)\left(\frac{c_s}{r\Omega_K}\right)^2 \sim 10^2 \text{ years}\left(\frac{3}{C_a}\right)\left(\frac{2500\text{km}}{R}\right)^3\left(\frac{2\text{gcm}^{-3}}{\rho_p}\right)\left(\frac{c_s/r\Omega_K}{0.1}\right)^2 \left(\frac{3\times 10^5 \text{gcm}^{-2}}{\sigma_g}\right)\left(\frac{15R_J}{r}\right)^{1/2} \quad [A.17]$$

where C_a is a torque asymmetry parameter that is a function of the disk's radial surface density and temperature profiles (e.g., Tanaka et al., 2002; Ward, 1997); M_p and M_s are the planet and satellite masses, respectively; and r is the distance from the M_p center of mass. The last term in eqn [A.17] is $(H_g/r)^2$. The numerical representation is that centered on Ganymede in a minimum mass Jovian disk. Recent works (e.g., Kley and Crida, 2008; Paardekooper and Mellema, 2006a,b) have developed revised type I torque formula for the case of non-isothermal, adiabatic disks, which depend on local disk properties. These are discussed in the Jupiter section.

The repulsion of the gas disk by the satellite can eventually open a gap in the disk if (e.g., Ward and Hahn, 2000)

$$\frac{M_s}{M_p} > c_v\sqrt{\alpha}\left(\frac{c_s}{r\Omega_K}\right)^{5/2} \sim 10^{-4}c_v\left(\frac{\alpha}{10^{-3}}\right)^{1/2}\left(\frac{c_s/r\Omega_K}{0.1}\right)^{5/2} \quad [A.18]$$

where $c_v = O(1\text{–}10)$. This form of the criterion comes from Ward and Canup (2002), where they pointed out that the limiting mass is just above Ganymede's mass for $c_v = 1$ and $\alpha = 10^{-3}$. If a gap is opened, the type I drift is replaced by type II, whose timescale is now the disk viscous timescale (Ward, 1997)

$$\tau_{II} = \frac{r^2}{\nu_t} = \frac{(r/H_g)^2}{\alpha\Omega_K} \sim 300 \text{ years}\left(\frac{10^{-3}}{\alpha}\right)\left(\frac{0.1}{H/r}\right)^2\left(\frac{r}{15R_J}\right)^{3/2}\left(\frac{M_J}{M_p}\right)^{1/2} \quad [A.19]$$

where again the numerical representation is centered on Ganymede and M_p is normalized by the Jupiter mass M_J. Whether or not a gap is opened by a satellite depends on the value of α and the scale height of the disk at the satellite location. For an alternative gap-opening criterion also depending on these two parameters, see Crida et al. (2012).

A.5 Thermodynamics

The temperature distribution in the disk is of fundamental importance in determining nearly all of the parameters associated with accretion within the disk and whether or not the accreted particles survive migration toward the primary. The growing satellites will be near the midplane of the disk, so the midplane temperature T_c must be known. This in turn is determined by an energy balance equation in steady-state disks, where sources of energy include the gravitational energy deposited by the flux of incoming material, the viscous dissipation within the disk, radiation from the still warm primary, and radiation from the surrounding solar nebula. The sink is radiation from the upper and lower surfaces of the disk at some effective temperature, T_e. If the accretion of the satellites is assumed to take place in a disk with no accretion from the solar nebula, the gravitational source of energy now comes from the redistribution of mass during viscous evolution, and the internal energy of the disk is reduced as it cools.

For optically thick disks, $T_e^4 = 2T_c^4/(1 + 3\tau/2) \approx 4T_c^4/3\tau$, whereas for optically thin disks, $T_e^4 \approx 4\tau T_c^4$ (e.g., Shapiro and Teukolsky, 1983), where $\tau = \int_0^{H_g} \kappa\rho_g dz \approx \overline{\kappa}\sigma_g/2$ is the optical depth from midplane to the surface, with κ being the Rosseland mean opacity ($\text{cm}^2\,\text{g}^{-1}$) (e.g., Schwarzschild, 1958). An example of a surface mass distribution in a steady-state disk from Canup and Ward (2002) (Lynden-Bell and Pringle, 1974) is

$$\sigma_g(r) \approx \frac{4\dot{M}}{15\pi\nu_t}\left[\frac{5}{4} - \sqrt{\frac{r_c}{r_d}} - \frac{1}{4}\left(\frac{r}{r_c}\right)^2\right] \text{ for } r < r_c \approx \frac{4\dot{M}}{15\pi\nu_t}\left[\sqrt{\frac{r_c}{r}} - \sqrt{\frac{r_c}{r_d}}\right] \text{ for } r \geq r_c \quad [A.20]$$

where the kinematic viscosity $\nu_t = \alpha c_s^2/\Omega_K$ is the approximation of Shakura and Sunyaev (1973) for a turbulent medium discussed in the preceding text, r_c is the radius inside of which the mass flux $\dot{M}$ is deposited uniformly, and r_d is the edge of the

disk. Another example is a disk with constant mass flux toward the primary throughout the region where the satellites are forming (e.g., Lynden-Bell and Pringle, 1974):

$$\sigma_g(r) = \frac{\dot{M}}{3\pi\nu_t}\left[1-\sqrt{\frac{R_P}{r}}\right] \qquad [A.21]$$

if the viscous couple vanishes at the primary's surface of radius R_P.

Figure 4 shows the Rosalind mean opacities appropriate for low temperatures in an accretion disk. The opacity due to Bell and Lin (1994) accounts for ice grains at low temperatures and 'metallic' grains at high temperatures. Ice particles dominate the opacity up to temperatures slightly above 160 K with approximately a T^2 power law dependence. Above this temperature, the ice evaporates with a sharp drop in opacity and 'metallic' grains dominate the opacity for larger T. The Pollack et al. (1994) opacities include a distribution of organic particles that maintain a high opacity in the region beyond the ice point. These opacities can be modeled by writing $\kappa = \kappa_0 T^{\xi}$, but different values of the exponent ξ apply in different parts of the disk. There have been no studies of the formation of icy satellites with this accounting of the variations in the disk opacities. An example of the energy balance equation for a steady-state disk at distance r from the primary is

$$\sigma_{SB}T_P^4\left[\frac{2}{3\pi}\left(\frac{R_P}{r}\right)^3+\frac{1}{2}\left(\frac{R_P}{r}\right)^2\frac{H}{r}\left(\frac{d\ln H}{d\ln r}-1\right)\right] + F_{grav}(r)+F_{vis}(r) = 2\sigma_{SB}\left(T_e^4-\frac{\beta_n}{4\pi}T_{neb}^4\right) \qquad [A.22]$$

where the first bracketed term on the left is the radiation deposited per unit area from the warm planet (Ruden and Pollack, 1991), $F_{grav}(r)$ is the energy deposited due the accretion, and $F_{vis}(r)$ is the energy deposited per unit surface area from viscous interactions. The fraction of solid angle subtended by the solar nebula is $\beta_n/4\pi$. The most extreme model dependences are in the terms F_{grav} and F_{vis}. There are no constraints on F_{grav} from simulations, and F_{vis} depends on the unknown value of α. The importance of the opacity κ for the midplane properties cannot be overemphasized.

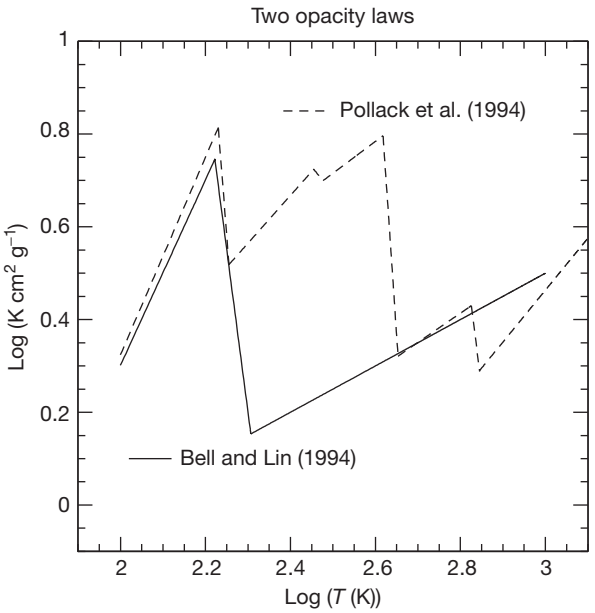

Figure 4 Power law approximations to the Rosseland mean opacities for a cold accretion disk. Appendix B Tides

Tidal dissipation can drastically change the orbital configuration and the thermal state of the regular natural satellites from the time of their formation. So, it is imperative to understand this evolution, which puts constraints on the conditions of satellite formation. We therefore outline a theory of tidal effects on satellite orbits (and rotations) in this appendix. The potential of mass element dm_0 at $\mathbf{r}$ (within m_0) due to a mass M located at $\mathbf{R}$ relative to a coordinate system fixed in the body m_0 is given by

$$dV = -\frac{GM\,dm_0}{|\mathbf{R}-\mathbf{r}|} = -\frac{GM\,dm_0}{R}\left[1+\frac{r}{R}P_1(\cos S)+\left(\frac{r}{R}\right)^2P_2(\cos S)+\left(\frac{r}{R}\right)^3P_3(\cos S)\ldots\right] \qquad [B.1]$$

where G is the gravitational constant, P_i are the Legendre polynomials, and $\cos S = \mathbf{r}\cdot\mathbf{R}/rR$. The first two terms in the expansion combine to yield an acceleration parallel to $\mathbf{R}$, so the lowest-order tide-raising potential per unit mass in m_0 due to M is given by the second harmonic term

$$W_2 = -\frac{GMr^2}{2R^3}\left[3\cos^2 S-1\right] \qquad [B.2]$$

Typically, $r/R \ll 1$ allows neglect of higher-order terms, but if a satellite is close to a primary (e.g., Phobos), higher-order terms contribute significantly to the total tidal interaction (Bills et al., 2005).

For a homogeneous sphere, Love (1944) showed that for a small distortion, the displacement of the surface due to the disturbing potential W_2 is a small factor ϵ_2 times a surface harmonic S_2 of the same degree:

$$\epsilon_2 S_2 = \frac{5}{2g}\frac{W_2(r=a_e)}{[1+19\mu/(2\rho g a_e)]} \qquad [B.3]$$

where g is the surface gravity acceleration on m_0, μ is the rigidity, ρ is the density, and a_e is the radius of the sphere. The potential per unit mass at $r > a_e$ due to this spherical surface harmonic mass distribution is then

$$-\frac{3}{5}\left(\frac{a_e}{r}\right)^3\epsilon_2 S_2 = -\frac{3}{2[1+19\mu/(\rho g a_e)]}\frac{GM}{2R^3}\times\frac{a_e^5}{r^3}\left(3\cos^2 S-1\right) \qquad [B.4]$$

such that if we place a mass m at $\mathbf{r}$,

$$V_T = -\frac{k_2 GMma_e^5}{2R^5r^5}\left[3(\mathbf{R}\cdot\mathbf{r})^2-r^2R^2\right] \qquad [B.5]$$

is the potential of m at $\mathbf{r}$ due to a tide raised by M on m_0 or the potential of M at $\mathbf{R}$ due a tide raised by m on m_0. The potential Love number $k_2 = 1.5/[1+19\mu/(2\rho g a_e)]$ refers to the body on which the tide is raised. For centrally condensed bodies, k_2 is

reduced. For example, the fluid Love number for the Earth is 0.934 instead of 1.5 (Lambeck, 1980, p. 29).

Now, consider M and m to be the same body. We model the effects of the dissipation by assuming the equilibrium response of m_0 to the tidal stress applied by m lags by some time Δt by analogy to the damped harmonic oscillator forced at a frequency that is small compared to the natural frequency of oscillation. Then, $\mathbf{R}(t)=\mathbf{r}(t-\Delta t)$ is the simplest representation of the effects of dissipation of tidal energy in m_0, that is, $\mathbf{R}$ is the position of m a short time in the past relative to a coordinate system fixed in m_0, where $\mathbf{r}$ is defined in the same coordinate system. The components of $\mathbf{R}=\mathbf{r}(t-\Delta t)$ are not to be included in differentiations of V_T in determining the tidal forces on m. We distinguish these coordinates with a * and write the coordinates of m considered the tide-raising body as

$$\mathbf{r}^*(t-\Delta t)=\mathbf{r}^*(t)-\left.\frac{d\mathbf{r}^*}{dt}\right|_t\Delta t=\mathbf{r}^*+\Delta\mathbf{r}^* \qquad [B.6]$$

If we substitute the right-hand side of eqn [B.6] into eqn [B.5] and expand to the first order in Δr^*, the results were

$$V_T=-k_2Gm^2a_e^5\left(\frac{1}{r^3r^{*3}}+\frac{3\mathbf{r}\cdot\Delta\mathbf{r}^*}{r^4r^{*4}}-\frac{6\mathbf{r}^*\cdot\Delta\mathbf{r}^*}{r^3r^{*5}}\right) \qquad [B.7]$$

where

$$\Delta\mathbf{r}^*=-\left.\frac{d\mathbf{r}^*}{dt}\right|_{body}\Delta t=-\Delta t\left(\frac{dx^{*'}}{dt}\mathbf{e}'_1+\frac{dy^{*'}}{dt}\mathbf{e}'_2+\frac{dz^{*'}}{dt}\mathbf{e}'_3\right) \qquad [B.8]$$

and the time derivative is relative to the $x'y'z'$ system of coordinates fixed in the rotating body m_0. With the generic relation for a vector $\vec{D}$, $\left(d\vec{D}/dt\right)_{body}=\left(d\vec{D}/dt\right)_{space}-\vec{\omega}\times\vec{D}$ and with $\vec{D}\to\mathbf{r}^*$ and $\vec{\omega}\to\vec{\dot{\psi}}$, where $\vec{\dot{\psi}}$ is the angular velocity of m_0, we can write $d\mathbf{r}^*/dt|_{body}=d\mathbf{r}^*/dt|_{space}-\vec{\dot{\psi}}\times\mathbf{r}^*$ and

$$\Delta\mathbf{r}^*\cdot\mathbf{r}^*=-\mathbf{r}\cdot\dot{\mathbf{r}}\Delta t \qquad [B.9]$$

where the derivative on the right-hand side is now relative to inertial space.

As an example, we assume m_0 is rotating about the z' axis at angular velocity $\dot{\psi}$ relative to the xyz axes fixed in inertial space with the xy and $x'y'$ planes being coincident, so that $\psi=\psi_0+\dot{\psi}t$ is the angle between the x and x' axes. Then,

$$\Delta\mathbf{r}^*=-\left(\dot{\psi}y+\dot{x}\right)\Delta t\mathbf{e}_1+\left(\dot{\psi}x-\dot{y}\right)\Delta t\mathbf{e}_2-\dot{z}\Delta t\mathbf{e}_3 \qquad [B.10]$$

The force on m due to the tide it raises on m_0 is found from the negative gradient of V_T in eqn [B.7] with respect to the unstarred coordinates, after which we can set $r^*=r$ and substitute eqns [B.9] and [B.10] into the gradient so obtained to yield

$$\begin{aligned}
-\frac{\partial V_T}{\partial x}&=-k_2Gm^2a_e^5\left[\frac{3x}{r^8}+\frac{6\mathbf{r}\cdot\dot{\mathbf{r}}x\Delta t}{r^{10}}+\frac{3\left(\dot{\psi}y+\dot{x}\right)\Delta t}{r^8}\right]\\
-\frac{\partial V_T}{\partial x}&=-k_2Gm^2a_e^5\left[\frac{3y}{r^8}+\frac{6\mathbf{r}\cdot\dot{\mathbf{r}}y\Delta t}{r^{10}}+\frac{3\left(-\dot{\psi}x+\dot{y}\right)\Delta t}{r^8}\right]\\
-\frac{\partial V_T}{\partial z}&=-k_2Gm^2a_e^5\left[\frac{3z}{r^8}+\frac{6\mathbf{r}\cdot\dot{\mathbf{r}}z\Delta t}{r^{10}}+\frac{3\dot{z}\Delta t}{r^8}\right]
\end{aligned} \qquad [B.11]$$

The gradient $-\nabla V_T$ from eqn [B.11] is the force on m due to tides raised on m_0 by m. If the orbital angular velocity of m is always less than and in nearly the same direction as the spin angular velocity of m_0 (prograde), this force will increase m's orbital semimajor axis and eccentricity and decrease the orbital inclination relative to m_0's equatorial plane. Here, $k_2\to k_2^{m_0}$, the Love number for m_0; $a_e\to R_{m_0}$, the equatorial radius of m_0; $\dot{\psi}\to\dot{\psi}_{m_0}$, the angular velocity of m_0; and $\mathbf{r}\to\mathbf{r}_{m_0m}$, the vector from the center of m_0 to the center of m with corresponding components in inertial space of x, y, and z.

The force on m_0 due to tides raised on m by m_0 has the same form as eqn [B.11] with now $k_2\to k_2^m$, the Love number for m, $m\to m_0$; $a_e\to R_m$, the radius of m; and $\mathbf{r}=\mathbf{r}_{mm_0}=-\mathbf{r}_{m_0m}$. To convert this force to the force on m due to tides raised on m by m_0, the change in sign of the force expressions by Newton's third law is canceled by the change in the sign of the coordinates effected by setting $\mathbf{r}=\mathbf{r}_{\mathbf{m_0m}}$ instead of $-\mathbf{r}_{m_0m}$. So, eqn [B.11] expresses the force on m due to tides raised on m by m_0 with $k_2\to k_2^m$, $m\to m_0$, $a_e\to R_m$ and $\mathbf{r}\to\mathbf{r}_{m_0m}$.

The torque on m due to tides raised by itself on m_0 is $T_T=\mathbf{r}\times(-\nabla V_T)$, and the torque retarding m_0's spin is the negative of this, where $\mathbf{r}=\mathbf{r}_{m_0m}$. Similarly, the torque retarding m's spin due to tides raised on m by m_0 has the same form, but with $\mathbf{r}=\mathbf{r}_{mm_0}$ and $m\to m_0$, $a_e\to R_m$ and $k_2\to k_2^m$. This latter torque on m can be represented by

$$\boldsymbol{T}_T=\frac{3k_2Gm_0^2R^5}{r^6}(\hat{\mathbf{r}}\cdot\hat{\mathbf{r}}_T)(\hat{\mathbf{r}}_T\times\hat{\mathbf{r}}) \qquad [B.12]$$

where we have omitted the sub- and superscripts but remember that the variables apply to m. $\hat{\mathbf{r}}$ is a unit vector toward the tide-raising body m_0, and $\hat{\mathbf{r}}_T$ is a unit vector toward the tidal maximum, which is the subprimary position on m a short time Δt in the past as in the preceding text. Equation [B.12] is valid for arbitrary inclination of the orbit and equatorial planes. Similar to the earlier-mentioned analysis,

$$\hat{\mathbf{r}}_T=\hat{\mathbf{r}}-\frac{d\hat{r}}{dt}\Delta t \qquad [B.13]$$

where the time derivative is relative to the body system of coordinates. Replacement of $\hat{\mathbf{r}}_T$ with eqn [B.13] yields

$$\boldsymbol{T}_T=\frac{3k_2Gm_0^2R^5\Delta t}{r^6}\hat{\mathbf{r}}\times\dot{\hat{\mathbf{r}}} \qquad [B.14]$$

where we have set $\hat{\mathbf{r}}\cdot\hat{\mathbf{r}}_T=1$. So, with the generic relation between the derivatives of a vector relative to body and space coordinates described previously with $\hat{\mathbf{r}}=\cos f\mathbf{e}_1+\sin f\mathbf{e}_2$ and $\boldsymbol{\dot{\psi}}=\dot{\psi}(\sin i\sin\Omega'\mathbf{e}_1-\sin i\cos\Omega'\mathbf{e}_2+\cos i\mathbf{e}_3)+\dot{\Omega}'\mathbf{e}_3$, it is easy to obtain

$$\begin{aligned}
\hat{\mathbf{r}}\times\dot{\hat{\mathbf{r}}}=&\dot{\psi}\sin i\cos(f-\Omega')(-\sin f\mathbf{e}_1+\cos f\mathbf{e}_2)\\
&+\left(\dot{f}-\dot{\Omega}'-\dot{\psi}\cos i\right)\mathbf{e}_3
\end{aligned} \qquad [B.15]$$

where i and Ω' are inclination and longitude of the ascending node of the $x'y'$ (equator) plane on the xy (orbit) plane. Equation [B.15] is substituted into eqn [B.14] and averaged over the orbit period. Useful averages are

$$\begin{aligned}
\left\langle\frac{a^6}{r^6}\dot{f}\right\rangle&=n\left(1+\frac{15}{2}e^2+\frac{45}{8}e^4+\frac{5}{16}e^6\right)/(1-e^2)^6=nf_1(e)\\
\left\langle\frac{a^6}{r^6}\right\rangle&=\left(1+3e^2+\frac{3}{8}e^4\right)/(1-e^2)^{9/2}=f_2(e)\\
\left\langle\frac{a^6}{r^6}\cos 2f\right\rangle&=\left(\frac{3}{2}e^2+\frac{1}{4}e^4\right)/(1-e^2)^{9/2}=f_3(e)\\
\left\langle\frac{a^6}{r^6}\cos^2 f\right\rangle&=\frac{f_2(e)+f_3(e)}{2}\\
\left\langle\frac{a^6}{r^6}\sin^2 f\right\rangle&=\frac{f_2(e)-f_3(e)}{2}
\end{aligned} \qquad [B.16]$$

where $\dot{f} = n\left(a^2\sqrt{1-e^2}\right)/r^2$ has been used in the first of eqn [B.16] with a and e being the orbital semimajor axis and eccentricity, respectively. The averaged tidal torque on m due to tides raised by m_0 on m is thus

$$\langle \boldsymbol{T}_T \rangle = \frac{3k_2 G m_0^2 R^5 \Delta t}{a^6}\left\{-\dot{\psi}\sin i \sin\Omega'\left(\frac{f_2(e)-f_3(e)}{2}\right)\boldsymbol{e}_1 + \dot{\psi}\sin i\cos\Omega'\left(\frac{f_2(e)+f_3(e)}{2}\right)\boldsymbol{e}_2 + \left[nf_1(e) - f_2(e)\dot{\psi}\cos i\right]\boldsymbol{e}_3\right\} \quad [B.17]$$

where we have neglected $\dot{\Omega'}$ compared to n and $\dot{\psi}$.

As an example, consider the retardation of the rotation of a satellite in a circular ($e=0$) and equatorial ($i=0$) orbit from the tidal torque. The time rate of change of the angular momentum of the satellite $C\left(\mathrm{d}\dot{\psi}/\mathrm{d}t\right) = \langle T_T \rangle$, where C is the moment of inertia of m about its spin axis and where only the $\mathbf{e}_3$ term remains in eqn [B.17]. So,

$$\frac{\mathrm{d}\dot{\psi}}{\mathrm{d}t} = -\frac{3k_2 G m_0^2 R^5}{C a^6}\Delta t\left(\dot{\psi}-n\right) = -\frac{15}{2}k_2\frac{m_0}{m}\frac{R^3}{a^3}\frac{n}{Q_0}\left(\dot{\psi}-n\right) \quad [B.18]$$

where $\Delta t = 1/(Q_0 n)$, $C = 2mR^2/5$, and $n^2 = Gm_0/a^3$ have been used. The expression for Δt follows from the discussion in the succeeding text with Q_0 being the dissipation function at frequency n. The solution of eqn [B.18] is a decaying exponential for $\dot{\psi} - n$ (if n is nearly constant) with time constant

$$\tau_T = \frac{2}{15}\frac{1}{k_2}\frac{m}{m_0}\frac{a^3}{R^3}\frac{Q_0}{n} \quad [B.19]$$

where $k_2 = 0.05$ and $Q_0 = 100$, $\tau_T \approx 4300$ years for Ganymede and 57 000 years for Callisto at their current distances from Jupiter. Note that for $e=0$, the asymptotic tidal state is $\dot{\psi} = n$ (i.e., rotation synchronous with the orbital mean motion), but for $e \neq 0$, the asymptotic tidal state is $\dot{\psi} > 0$ determined by the vanishing of $\langle T_T \rangle$ in eqn [B.17]. Satellites with $e \neq 0$ are able to maintain synchronous rotation if the torque on the permanent axial asymmetry dominates $\langle T_T \rangle$ and forces the axis of minimum moment of inertia to librate about the direction to the primary whenever the satellite is at periapse.

The relationship between the dissipation function Q and Δt follows from a simple example. The dissipation parameter Q for a system oscillating at frequency ω is defined by (e.g., Lambeck, 1980, p. 14)

$$\frac{1}{Q} = \frac{\oint \frac{\mathrm{d}E}{\mathrm{d}t}\mathrm{d}t}{2\pi E^*} = \omega\Delta t \quad [B.20]$$

where the numerator is the energy ΔE dissipated during a complete cycle of oscillation and E^* is the maximum energy stored during the cycle. For a tidally distorted, nearly spherical body with the disturbing body in a circular equatorial orbit, a cycle would consist of half a rotation of the distorted body relative to the body causing the tide. For a complex tide generated by a noncircular, nonequatorial orbit of the disturbing body, each periodic term in a Fourier decomposition of the tide would have its own maximum stored energy and dissipation over a complete cycle of oscillation. The response of an oscillator with forcing function $F = A'\sin\omega t$ when $\omega \ll \omega_0$, with ω_0 being the lowest frequency of free oscillation, can be represented by $x = B'\sin\omega(t-\Delta t)$, where Δt is the phase lag in the response due to the dissipation as was assumed in the preceding text for the tidal response. The rate at which the forcing function does work is $\mathrm{d}E/\mathrm{d}t = F\dot{x} = A'B'\omega\sin\omega t\cos\omega(t-\Delta t)$. Then,

$$E(t) = \int_{t_1}^{t} F\dot{x}\,\mathrm{d}t = A'B'\omega\left[\frac{-\cos(2\omega t - \omega\Delta t)}{4\omega} + \frac{\sin\omega\Delta t}{2}t\right]_{t_1}^{t} \quad [B.21]$$

The first term in eqn [B.21] is the periodic storage of energy in the oscillator, and the second is the secular loss of energy. The energy dissipated in a period $2\pi/\omega$ is $\Delta E = A'B'\pi\sin\omega\Delta t$. The peak energy stored is found by integrating $\mathrm{d}E/\mathrm{d}t$ from a value of t where $x=0$ to a value of t where $x = x_{max}$. Since $x \propto \cos(\omega t - \omega\Delta t)$ and $\dot{x} \propto -\omega\sin(\omega t - \omega\Delta t)$, $x=0$ when $\omega t - \omega\Delta t = (2n-1)\pi/2$ and $x = x_{max}$ when $\dot{x} = 0$ or $\omega t - \omega\Delta t = n\pi$. If we choose the limits spanning $t=0$, then the interval of integration is $-\pi/2 + \omega\Delta t \leq \omega t \leq \omega\Delta t$, where $x=0$ at the lower limit and $x = x_{max}$ at the upper limit. Applying these limits to the first term in eqn [B.21] to get the stored energy yields

$$E^* = A'B'\left[\frac{\cos\omega\Delta t}{4} - \frac{-\cos\omega\Delta t}{4}\right] = \frac{A'B'}{2}\cos\omega\Delta t \quad [B.22]$$

Substitution of the expressions for E^* and ΔE into eqn [B.20] yields $1/Q = \tan\omega\Delta t \approx \omega\Delta t$ when the dissipation is relatively small (large Q). Q is then proportional to $1/\omega$ for the assumption in this tidal model that Δt is constant.

The tidal effective Q of the solid Earth has been estimated from satellite observations to be 280 ± 70 (Ray et al., 2001), which is close to the value obtained by the attenuation of normal modes of the Earth (Widmer et al., 1991). For Mars, $Q \approx 100$ from the secular acceleration of the satellite Phobos (Bills et al., 2005; Smith and Born, 1976). For Mars, the dominant frequency is $\dot{\omega} = 2\left|\dot{\psi} - n_P\right|$, where $\dot{\psi}$ is Mars' rotational angular velocity and n_P is Phobos' mean orbital motion. The factor 2 follows from there being two tidal cycles for each synodic period. With a rotation period of 24 h 37 min 23 s and an orbital period of 0.319 days, $\omega = 3.14 \times 10^{-4}$ rad s^{-1} leading to $\Delta t \approx 32$ s for $Q = 100$. For Mercury, the fundamental tidal period is the orbit period, since Mercury rotates 180° relative to the Sun for each orbit. For the attenuation of seismic waves in the Earth and from laboratory experiments on Earth-like materials, Q is proportional to frequency raised to a small, positive fractional (0.2–0.4) power with nominal values near $Q = 100$ (e.g., Shito et al., 2004), but to avoid an infinite discontinuity in the torque whenever a tidal frequency passes through zero while changing sign, an alternative behavior must be invoked (see the discussion on Andrade and Maxwell tidal models).

For energy dissipation within a satellite, the approach of Peale and Cassen (1978) is simplified by Wisdom (2004). The rate at which work is done on a satellite by the tide is given by

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\int_{\mathrm{body}} \rho\mathbf{v}\cdot\nabla W_2\,\mathrm{d}V \quad [B.23]$$

where W_2 is the previously mentioned tide-raising potential and $\mathbf{v}$ is the velocity of a volume element $\mathrm{d}V$ of density ρ. If we

can assume the satellite is incompressible, then $\nabla\cdot\mathbf{v}=0$, and from $\nabla\cdot W_2\mathbf{v}=\mathbf{v}\cdot\nabla W_2+W_2\nabla\cdot\mathbf{v}$, we can write

$$\frac{dE}{dt}=-\int_{body}\rho\nabla\cdot(W_2\mathbf{v})\,dV=-\rho\int_{surface}W_2\mathbf{v}\cdot n\,dS \qquad [B.24]$$

where the last form follows from divergence theorem. In eqn [B.24], $\mathbf{n}$ is the normal to a surface element dS, and we have taken ρ outside the integral by assuming a uniform density.

The rate at which the height of the surface changes is $\mathbf{v}\cdot\mathbf{n}=d\Delta R/dt\approx h_2 dW_2'/dt/g$ (eqn [B.3]), where $h_2=5\,k_2/3$ is the second degree displacement Love number (Love, 1944) and g is the surface gravity acceleration of the satellite. The prime on W_2 indicates the time delay in the response of the body to the forcing function. Then,

$$\frac{dE}{dt}=-\frac{\rho h_2}{g}\int_{surface}W_2\frac{d}{dt}(W_2')\,dS \qquad [B.25]$$

If higher-order terms are necessary in the tidal potential for close satellites, eqn [B.25] would be a sum of terms involving the Love numbers h_3, h_4, etc.

If we consider the case where the satellite equatorial and orbital planes are coincident, $\mathbf{r}=(r\cos f,\ r\sin f,\ 0)$, and $\mathbf{R}=\left(R\cos\left(\phi+\dot\psi t\right),\ R\sin\left(\phi+\dot\psi t\right),\ 0\right)$, where R and ϕ are the ordinary spherical radial and azimuthal coordinates of a point on the surface in a coordinate system fixed in the satellite, and the $\dot\psi t$ accounts for the rotation of the satellite relative to an inertial system. For small eccentricities, we can write $a/r\approx 1+e\cos nt$, $\cos f\approx\cos nt+e(\cos 2nt-1)$ and $\sin f=\sin nt+e\sin 2nt$ to the first order in eccentricity e (e.g., Murray and Dermott, 1999). For the time-lagged potential W_2', t is replaced by $t-\Delta t$ and for a satellite rotating synchronously with its orbital motion, $\dot\psi=n$. With these substitutions, the average rate of energy dissipation is found by performing the surface integral and averaging over an orbit period:

$$\frac{dE}{dt}=-\frac{42}{5}\frac{\pi\rho h_2}{g}\frac{G^2m_p^2R^6}{a^6}e^2n\sin n\Delta t\approx-\frac{42}{19}\frac{\pi\rho^2n^5R^7e^2}{\mu Q} \qquad [B.26]$$

where $h_2\approx 5\rho gR/(19\mu)$ from the definition of k_2, $n^2=Gm_p/a^3$ has been used, and $\sin n\Delta t\to n\Delta t=1/Q$. The last form in eqn [B.26] agrees with that in Peale et al. (1979) as corrected in Peale (2003). Equation [B.26] is the lowest-order approximation for the tidal dissipation in a synchronously rotating satellite with orbital eccentricity e. For very large eccentricities, higher-order terms must be included.

The tidal dissipation in a synchronously rotating satellite will tend to reduce the eccentricity as $e\neq 0$ is the cause of the dissipation. The spin angular momentum of the satellite is conserved because of the synchronous lock. The specific orbital angular momentum $[G(m_p+m_s)a(1-e^2)]^{1/2}$ can thus not gain angular momentum from the satellite spin. The orbital energy $-Gm_pm_s/2a$ must decrease if energy is dissipated in the satellite, and a must thereby decrease. But the conserved angular momentum means e must decrease if a decreases. At the same time, the tide raised on the planet by the satellite tends to increase the eccentricity if the spin angular velocity $\dot\psi_p$ exceeds a value near $1.5n$ for small eccentricity (depending on the tidal model). The rate of change of the eccentricity of a satellite orbit due to tides raised on the primary by the satellite can be determined from the Lagrange planetary equations as expressed in terms of the perturbing accelerations S, T, and W (radial, tangential, and perpendicular to the orbit) (e.g., Plummer, 1960 (1918), p. 151). For the tidal model adopted herein, S, T, and W can be determined from the xyz components given in eqn [B.11]. Substitution of the required S and T components into the Lagrange equation for de/dt averaged over an orbit period yields

$$\frac{de}{dt}=\frac{k_{2p}}{Q_p}\frac{m_s}{m_p}\frac{R_p^5}{a^5}\frac{ne}{(1-e^2)^{13/2}}\left[\frac{\dot\psi_p(1-e^2)^{3/2}}{n}\left(\frac{33}{2}+\frac{99e^2}{4}+\frac{33e^4}{16}\right)-\left(27+\frac{405e^2}{4}+\frac{405e^4}{8}+\frac{135e^6}{64}\right)\right] \qquad [B.27]$$

where Q_p is the value of Q corresponding to frequency of the orbital mean motion n and the subscripts s and p refer to the satellite and planet, respectively. The value of the planetary angular velocity $\dot\psi_p$ above which $de/dt>0$ increases with eccentricity, which follows because the planet has to be rotating sufficiently faster than the orbital motion at periapse to give it the kick that increases the eccentricity. Otherwise, tides raised on the primary will reduce the eccentricity. In the limit of small eccentricity, $\dot\psi_p\gtrsim 1.64n$ for $de/dt>0$. In a model where the tidal potential is separated into its component frequencies with individual phase lags, Goldreich (1963) found that $\dot\psi_p\gtrsim 1.5n$ for positive de/dt.

The magnitude of the rate of decrease in the eccentricity due to tides raised on the satellite can be found in the same way by interchanging the satellite and planetary parameters as discussed in eqn [B.11], where now $\dot\psi_s\equiv n$ leads to $de/dt<0$ for a satellite rotating synchronously with its orbital mean motion for all values of e. The variation in the eccentricity to lowest order in e from tidal dissipation in the planet and the satellite is thus

$$\frac{de}{dt}=\frac{k_{2p}}{Q_p}\frac{m_s}{m_p}\frac{R_p^5}{a^5}e\left(\frac{33}{2}\dot\psi_p-27n\right)-\frac{21}{2}\frac{k_{2s}}{Q_s}\frac{m_p}{m_s}\frac{R_s^5}{a^5}ne \qquad [B.28]$$

where $\dot\psi_p$ and n are the spin angular velocity and orbital mean motion, respectively, and subscripts p and s refer to planet and satellite. (This equation replaces the erroneous eqn [B.21] of this chapter in the first edition of this volume of the *Treatise on Geophysics*.) Whether eccentricity of a satellite orbit increases or decreases as the orbit evolves under tidal evolution depends on the relative magnitude of the two terms in eqn [B.28].

The reader should be aware of the uncertainty and somewhat arbitrariness of tidal models. Our analysis of tidal dissipation using a constant time lag in the response of a planet or satellite to the forcing function leads to $Q\propto 1/\omega$, where ω is a tidal frequency, is the simplest. It has the most straightforward development while yielding relatively intuitive tidal evolution. It has the advantage of being applicable for arbitrary eccentricities, whereas most other models require an expansion in eccentricity (e.g., Kaula, 1964), which must be truncated. Each of the periodic terms in the Kaula expansion is lagged in phase from the same term in the tide-raising potential with the phase lag having the same sign as the frequency of the term. The magnitude of the phase lag is $1/Q$ and one can assume various frequency dependencies for the value of Q to represent different tidal models. Our constant Δt model would have $Q\propto 1/\omega$ where ω is the frequency of the term. A tidal

model often used is Q = constant, which has the nonphysical characteristic that each term in the expansion changes sign abruptly without reducing its magnitude as the frequency of that term passes through zero. Other frequency dependencies for Q can be substituted into the Kaula expansion to represent other assumptions about the dissipative properties of the material.

The major disadvantage of the constant Δt model for solid bodies is that it does not account for creep or residual distortion after the perturbing force is removed. A discussion of how creep is handled is given in Karato's (2008) book, where quite complicated frequency dependencies for Q may result. Some researchers now favor the empirically determined Andrade tidal model (Castillo-Rogez et al., 2011), but it mimics the $Q \propto 1/\omega$ model at very low frequencies and thereby no longer represents real materials. There is some evidence favoring the Maxwell model at very low frequencies, and Efroimsky (2012) had formulated a tidal model with the empirical Andrade model used for normal frequencies but transitioning to the Maxwell model for very low frequencies. All of these manipulations are for solid materials. Although it is usually inferred that partially molten bodies, as in our discussion of the Earth–Moon system, have a high dissipation compared to the completely solid or completely fluid bodies, there is no detailed tidal model to represent this state. The frustration of model dependence of all conclusions regarding the outcome of tidal dissipation persists.

We have seen in the preceding text that nominal values of Q (or Q_0 in the model detailed earlier in the text) are near 100 for Mars and for the damping of seismic waves in the Earth's mantle and near 300 for satellite determinations of the solid Earth response to the Moon and for the damping of seismically excited normal modes of the Earth. $Q = 100$ is an often adopted value representing Earth-like materials. However, the damping of seismic waves in the Moon's upper layers leads to $Q \approx 4000$ at 4 Hz and $Q \approx 7000$ at 8 Hz (Nakamura and Koyama, 1982), but the monthly tidal $Q \approx 37$ and the annual $Q \approx 60$ (Williams et al., 2001). The widely varying values of Q reflect the nature of the materials where the dissipation is taking place, where the dryness of the surface layers of the Moon may lead to the high values of Q, and partial melts in the interior may yield the low tidal Qs. Efroimsky (2012) pointed out the uncertainties in comparing seismic Qs with tidal Qs. Finally, a totally different procedure is needed for the unsolved problem of determining effective Qs of gaseous planets (and stars), where resonances of tidal frequencies with normal modes of oscillation of the gaseous body become important. In summary, the uncertainty of the proper tidal model to use in various circumstances persists, but the simplest tidal theory described previously in the text can be used to determine qualitative constraints on the origin of the natural satellites from their inferred evolutions.

10.18.1 Introduction

The icy moons of the outer solar system are numerous and diverse in their properties. Although none of these objects approach the size of Earth, three – Ganymede, Callisto, and Titan – are larger in diameter than the planet Mercury. In this chapter, we focus on the large regular satellites thought to have coaccreted with their parent planets. An exception is Triton, which is a large satellite thought to have been captured by Neptune. The small irregular satellites (~60 known objects orbiting Jupiter and several tens of objects in orbit around the other giant planets) are not discussed here. Most of the latter are thought to have been captured by the giant planets.

Internal pressures for the large moons approach several GPa, sufficient to yield phase changes and significant compression in the water ice component – but not the rock. Water ice being among the major constituents of these bodies implies that the interior physics, in terms of the effect of the phase diagram and equation of state of water ice, is as complex as for the Earth, where analogously, megabar pressures compel rock to undergo compressive and phase change effects. The addition of soluble and generally more volatile compounds to the water ice lowers the melting temperature, yields partial melts, and greatly complicates the treatment of the interiors of icy satellites. As was first discussed by Lewis (1971), the large icy satellites may contain global liquid layers underneath their icy surfaces. The presence and the extent of such liquid layers will depend on the thermal state and composition of the H_2O layer in the outer part of the satellite. Since the solar insolation is only of minor importance for the internal heat budget of the satellites in the outer solar system, the energy required to form and maintain liquid layers has to be provided from the interior. Radiogenic heating in the rock component and – in some cases – tidal friction are the main heat sources for satellites. The presence of volatiles such as ammonia, significantly reducing the melting temperature of ice, will be crucial for the existence and maintenance of these internal oceans. Lewis (1971) used an equilibrium condition with the heat production due to radioactive nuclides being equal to the heat loss through the ice shell. However, the assumption of equilibrium may not be valid throughout the satellite's history, especially at the early stages of evolution. Time-dependent thermal histories and the

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00178-0

consequences for internal structure were calculated by Consolmagno and Lewis (1976, 1978) for the icy Galilean satellites and for several size classes of model satellites, respectively. These models, however, suffered from the lack of reliable data, especially for the mean densities deduced from the masses and the radii, of the outer planet satellites.

With the *Voyager* flybys (1979 Jupiter, 1981 Saturn, 1986 Uranus, and 1989 Neptune), data on the physical properties and images of the surfaces of the satellites improved significantly. The new constraints led to refinements of the then-available models (Ellsworth and Schubert, 1983; Lupo, 1982; Schubert et al., 1981, 1986) and, due to the observed diversity of surface features of the satellites, to the development of more complex models for individual satellites. By the end of the 1970s, the significance of tidal heating for some of the outer planet satellites became apparent (Peale et al., 1979), leading to considerable interest in thermal and interior structure models of Io, Europa, Ganymede, and Enceladus, the satellites for which tidal heating was considered to be the cause of volcanic activity (Io) and intense resurfacing in the satellites' history.

The *Galileo* mission (Jupiter orbiter, 1995–2003) has significantly improved our knowledge on the internal structure of the Galilean satellites (for a post-*Galileo* review, see Schubert et al., 2004). Until recently, the Galilean satellites were the only satellites in the outer solar system for which higher gravitational moments were determined from spacecraft flybys. Potential theory and the theory of equilibrium figures in combination with the acquired data allow for a more detailed inference of the internal structure of satellites if their rotational state and the tidal potentials are known (Dermott, 1979; Zharkov et al., 1985). *Galileo* data have been used to construct models of the four Galilean satellites (Anderson et al., 1996, 1998, 2001a,b; Schubert et al., 2004; Sohl et al., 2002), consisting of ice, rock, and metals. The data provide evidence for a considerable degree of internal differentiation for the three inner Galilean satellites. Callisto, however, is only partially differentiated (Anderson et al., 2001b), which may be a consequence of different accretion scenarios (Canup and Ward, 2002; Estrada and Mosqueira, 2006) and orbital evolution of Ganymede into the Laplace resonance, an orbital commensurability between the three inner Galilean satellites, Io, Europa, and Ganymede (Peale and Lee, 2002; Showman and Malhotra, 1997). Barr and Canup (2010) suggested different impact rates during late heavy bombardment (about 700 Ma after planet formation) as an alternative scenario to explain the differences between Ganymede's and Callisto's interior structure.

The acquisition of similar data has been under way since 2004 from the *Cassini*/*Huygens* mission for some of the icy satellites of Saturn. At the time of this writing, gravity data have been obtained from flybys at Titan, Enceladus, and Rhea. Among the results is an evidence for a liquid water ocean beneath Titan's crust (Iess et al., 2012) and partially differentiated structures for both Rhea and Titan (Iess et al., 2007, 2010), while the data for Enceladus do not as yet constrain the internal structure beyond the bulk density (Ducci et al., 2012; Rappaport et al., 2007). A handful of further gravity flybys are planned for the remainder of the solstice extended mission set to end in 2017. In addition, important information on the spin state of Titan has been laboriously obtained through *Cassini* RADAR data (Meriggiola and Iess, 2012) and will continue to be obtained up to the end of the mission.

In this chapter, we review the composition of icy satellites, describe the construction of interior structure models, present recent models composed of rock (including iron) and ice, describe how other materials affect the interior, and close with recent discoveries and key issues. We focus generally on the larger moons (**Figures 1** and **2**), those for which compression is important but porosity is not (**Figure 3**), and will briefly discuss some smaller moons, for example, Enceladus, where recent *Cassini* data have constrained particular properties of the interior.

10.18.2 Spectroscopic Constraints on Composition

With the exception of Enceladus, an active satellite, space probes do not have access to subsurface material of the icy moons. However, close inspection of surface materials by

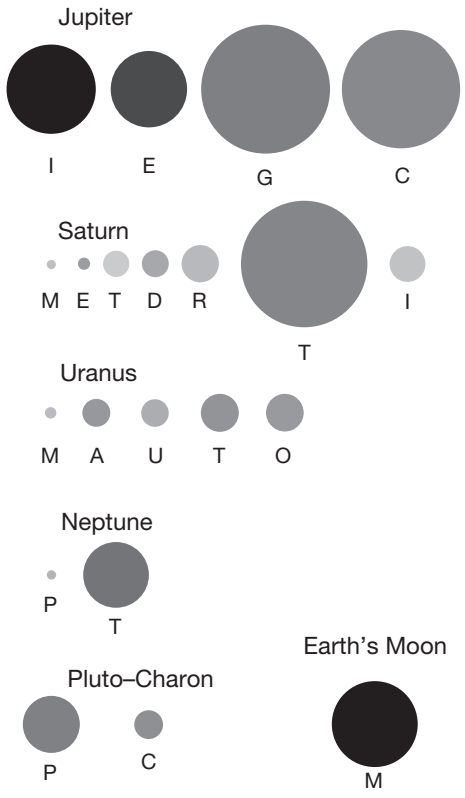

Figure 1 The largest moons of the solar system. Shown are the satellite systems of Jupiter, Saturn, Uranus, Neptune, and the Pluto–Charon system, including all moons with a radius larger than about 200 km. The smallest included here is Mimas with a radius of 198.8 km. Within each system, the satellites are ordered by the distance from the planet (distances are not to scale). The shading illustrates the mean density relative to each other, with Io being the densest (~3500 kg m^{-3}) and Tethys the one with the smallest density (956 kg m^{-3}). Pluto and the Moon, which is slightly smaller than Io, are included for comparison. From left to right and top to bottom: Io, Europa, Ganymede, Callisto; Mimas, Enceladus, Tethys, Dione, Rhea, Titan, Iapetus; Miranda, Ariel, Umbriel, Titania, Oberon; Proteus, Triton; Pluto, Charon; the Moon.

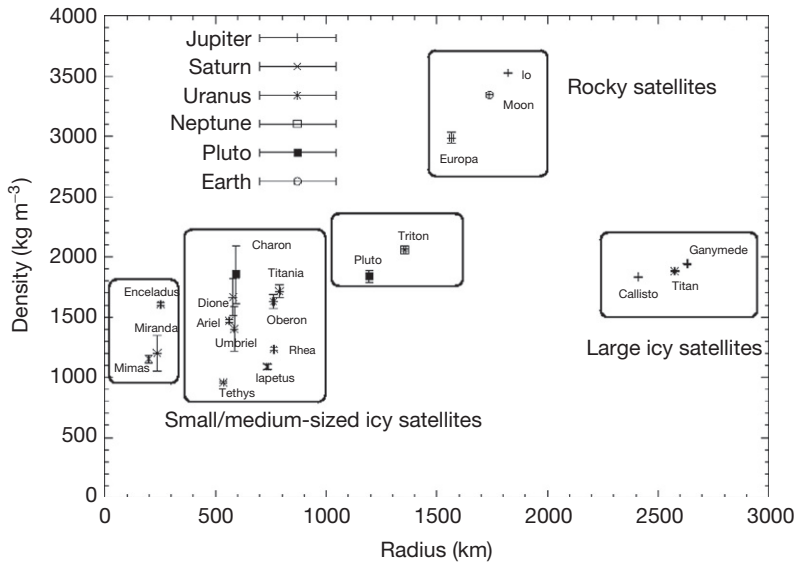

Figure 2 Mean density as a function of radius for all satellites larger than about 200 km and Pluto. Different symbols represent the respective primary planets. Several groups can be distinguished with respect to size and rock content. The small, medium-sized, and large icy satellites all contain substantial amounts of ices. Pluto and Triton are distinct from the medium-sized icy satellites with respect to size and their relatively high rock content. Europa, the Moon, and Io are dominated by rock. Modified from Hussmann H, Sohl F, and Spohn T (2006) Subsurface oceans of medium-sized outer planet satellites and large trans-Neptunian objects. *Icarus* 185: 258–273.

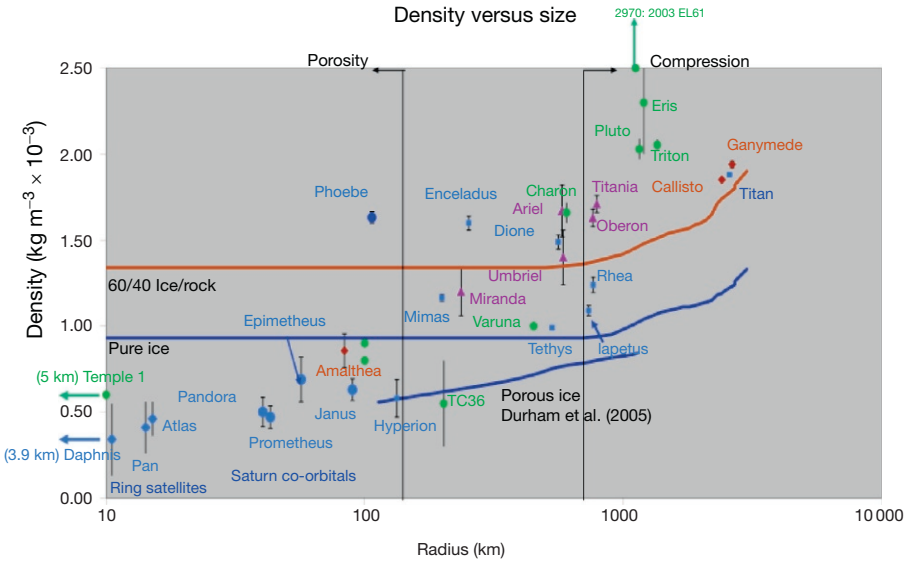

Figure 3 Bulk (measured) density of icy satellites and selected Kuiper belt objects versus radius. Shown also as vertical lines are rough limits on the size above which compressional effects alter the bulk density from the material density of the objects and below which porosity becomes potentially important in lowering the density. The two approximately horizontal lines show run of model density versus radius for water ice and silicate bodies containing 60% water ice (top line) and 100% water ice (bottom line). Reproduced from Johnson TV and Estrada PR (2009) Origin of the Saturn system. In: Dougherty M, Esposito LW, and Krimigis SM (eds.) *Saturn from Cassini-Huygens*, pp. 55–74. Dordrecht: Springer.

remote-sensing instruments can reveal the nature of physical and chemical processes involving the surface, subsurface, and the satellite's environment. In this section, we briefly review the constraints on the composition of icy satellite surfaces derived from spectroscopy.

Water ice is the major carrier of oxygen in the solid material of the outer solar system and is abundant in the moons of the giant planets. Spectroscopic observations, mostly in the near-infrared, constrain the presence and amount of water ice at the surface and therefore also in the crust. Callisto's surface contains 20–45% by weight water ice (Calvin and Clark, 1991), while Ganymede's surface ice content is even larger at upward of 90%, and Europa's approaches 100% (Clark, 1980). Other oxygen-bearing compounds are present or suspected as well, such as hydrogen peroxide on Europa (Hand and Brown, 2013) and CO_2 on Ganymede (Hibbits et al., 2003). In the

Saturn system, the intermediate-sized satellites Mimas, Enceladus, Tethys, Dione, Rhea, and Hyperion show water ice absorption features on their surface (Filacchione et al, 2013), as does Phoebe (Clark et al., 2005), as the major – but not sole (Brown et al., 2006) – spectroscopically active component of their surfaces. *Cassini* measurements of plume material coming from the subsurface of Enceladus show strong evidence for subsurface liquid water (Postberg et al., 2011), a variety of non-water ice species including methane and CO_2 (Waite et al., 2006), and it is thus unclear whether the methane was present at the time of Enceladus' formation or formed from CO_2 (Mousis et al., 2009b). Titan's surface, beneath its haze-shrouded atmosphere, also contains water ice (Tomasko et al., 2005) but mostly covered with organic material (Clark et al., 2010). In the Uranian system, water ice is present on the five major satellites, and carbon dioxide has been detected on Ariel, Umbriel, and Titania (Cartwright et al., 2013). Water ice has been detected on Neptune's moon Triton along with nitrogen, methane, carbon dioxide, and carbon monoxide (Brown et al., 1995); Pluto; and its moon Charon (see **Chapter 10.20**).

10.18.3 Elemental Abundance from Density

The major solid-forming materials in the outer solar system, based on simple solar elemental abundance considerations of the relevant elements, are water ice, silicates, and iron compounds. These are the materials that we will call, for brevity's sake, respectively, 'ice' and 'rock.' Where we consider 'ices' other than water ice, for example, solid carbon dioxide or ammonia–water mixtures, we will specifically call these out. Likewise, we will consider the rock phase to explicitly include the corresponding solar abundances of iron and nickel, the primary metals. Only where required (specifically in the case of Ganymede, with its metal core distinct from the silicates), we will consider these separately. To first order, then, our models of icy satellites consist of ice and rock, including the iron component. Chondritic abundances are assumed for the composition of the rock and iron component.

The significance of the densities of the icy satellites lies in the constraints they impose on interior models, and in turn (for satellites that are subjected to strong compressional effects), these models are the intermediary between the measured densities and the corresponding rock-to-ice ratios within the satellites. Whether water dominates over rock, or vice versa, is a strong function of whether carbon is mostly locked up in oxidized or reduced molecules, because the solar elemental C/O ratio is close to one-half according to the most recent determinations (**Table 1**). The revised solar abundances reviewed in Asplund et al. (2009) render the ice-to-rock ratio fairly sensitive to the molecular state of the carbon compared to previous tabulations. However, a number of processes can alter the rock-to-ice ratio in outer planet satellites from the value predicted by solar abundance and a particular assumed value of oxidized carbon (which would be mostly carbon monoxide, but including carbon dioxide as well). The process of satellite disk formation may alter molecular abundances and selectively remove either ice or rock (Canup and Ward, 2006; Estrada and Mosqueira, 2006; see also **Chapter 10.17**). If the abundance of organics of high carbon number (and thus mostly refractory) is large enough to remove carbon from the system, then the relationship between water abundance and oxidized carbon species weakens considerably, as **Figure 4** shows.

This last case is particularly interesting because a variety of high-carbon-number organics were likely present in condensed phases in the solar system. Moderate reductions in the oxygen abundance in the inner part of the solar nebula, for example, associated with diffusive redistribution of water vapor and cold trapping of water ice (Stevenson and Lunine, 1988) will result in the gas-phase thermochemical production of acetylene, hydrogen cyanide, and other light organics (Cyr et al., 1999). Chemistry in nebular shocks, photochemistry on the surface of disks, or particle chemistry associated with cosmic rays that penetrate the disk will produce a variety of organic molecules with higher carbon-to-hydrogen ratio than methane. It is possible that we are seeing evidence of this chemistry in the detection of higher hydrocarbons in comets and organic phases in Phoebe, likely an object captured by Saturn from solar orbit (Clark et al., 2005; Johnson and Lunine, 2005). The large amount of carbon dioxide seen in each does not

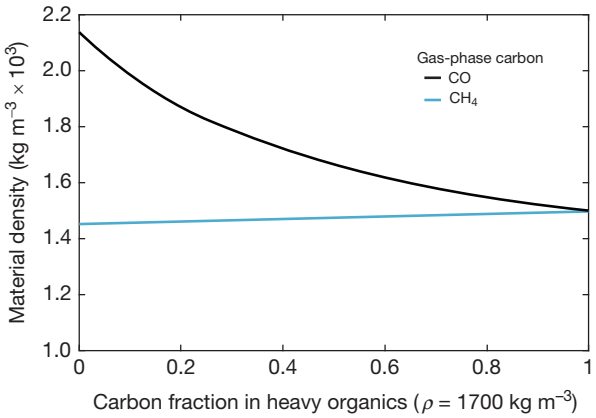

Figure 4 Plot of density of an uncompressed (small) rock–ice moon versus amount of carbon present in refractory organics. The refractory organics are assumed to have a mean density of 1700 kg m^{-3}, equivalent to amorphous carbon. The black line illustrates the case in which the rest of the carbon is in the form of carbon monoxide, while the shaded line illustrates the case in which it is in the form of methane. For a heavy organics fraction in excess of 0.5, the difference in density between the two cases is $<10\%$. Reproduced from Wong M, Lunine JI, Atreya SK, et al. (2008) Oxygen and other volatiles in the giant planets and their satellites. *Reviews in Mineralogy and Geochemistry* 68: 219–246.

necessarily mean that the latter dominated in abundance over carbon monoxide but may reflect instead the vast difference in volatility between the two. The effect of the presence of more refractory (carbon-rich) organics is to lower the sensitivity of the bulk density to the ratio of carbon monoxide (which consumes water) to methane.

In sum, while it is clear from spectroscopic data, chemical considerations, and satellite bulk densities that water ice is the dominant solid-forming material in the outer solar system, the relative abundances of other species – particularly carbon-bearing ones – remain uncertain and may be highly variable from object to object and from one satellite system to another (Dodson-Robinson et al., 2009). Densities and hence rock-to-ice ratios do not provide a direct one-to-one correspondence with particular carbon compositions and hence formation conditions. Further progress will require detailed spectroscopy of surfaces and the ability to measure in detail – in extraordinary cases such as Enceladus – the chemistry of material emitted from the interiors.

10.18.4 Size, Shape, and Mass

Typical radii of the major satellites range between about 200 km (Mimas and Miranda) and a few thousand kilometers with Ganymede, Titan, and Callisto being the largest satellites in the solar system (see **Figure 1** and **Table 2** for comparison of the sizes and masses).

With the exception of Titan, satellite surfaces can be observed directly by spacecraft imaging systems and ground-based telescopes, yielding the physical size of these objects that is required to determine the density. The radius of Titan's solid surface, buried beneath hundreds of kilometers of opaque haze, was first revealed by a radio occultation performed by *Voyager* 1 (Lindal et al., 1983). For irregular objects, which include moons as large as Jupiter's Amalthea and Saturn's Phoebe and Hyperion (the last with a long dimension exceeding 200 km), the determination of the total volume is more difficult and typically requires spacecraft observations at reasonable spatial resolution over a significant fraction of the body (e.g., Saturn's moon Phoebe; Porco et al, 2005).

More subtle is determining the shapes of moons, which reflect the satellites' internal structure under certain conditions (Dermott, 1979; Hubbard and Anderson, 1978; Zharkov et al., 1985). Moons tend to relax to a triaxial ellipsoidal shape determined by hydrostatic equilibrium of the rotating and tidally deformed body. This refers to the long-term fluid relaxation of a tidally distorted body. It must be distinguished from the tidal deformations due to periodic forces varying on timescales of the orbital period due to the orbital eccentricity or inclination, nonnegligible obliquity, or of a nonsynchronous rotational state. Deviations from hydrostatic equilibrium may occur, for instance, due to internal activity, incomplete relaxation, or a 'frozen in' structure that has been adjusted to equilibrium conditions different from the present ones. Measurements by *Cassini* in the Saturn system reveal at least one case (Iapetus) where the shape of the body is best represented by an oblate spheroid (Thomas, 2010; Thomas et al., 2007) inconsistent with the satellite's present-day rotation. It has been suggested (Castillo-Rogez et al., 2007) that the observed bulge, which did not adjust to the present equilibrium conditions, is due to a faster rotation rate in the satellite's past. In general, the shape of a satellite provides important clues to the orbital history of the body and to the rigidity over time of its internal layers.

Density and radial mass distribution inferred from the moment of inertia factor (see also **Chapter 10.02**) are the key parameters that constrain interior structure models. The mass of a satellite may be determined from two fundamentally different types of observations (Jacobson, 2004): visual (astrometric) observations of satellite motions from Earth-based telescopes or imaging systems on spacecraft and tracking via radio signal of the path of a spacecraft as it flies close by a moon and experiences the effect of the gravitational pull on its

Table 2 Characteristics of the largest icy satellites and Io

		ρ (kg m^{-3})	Radius (km)	Mass (10^{22} kg)	Eccentricity	P_{rot} (days)	Silicate mass (10^{22} kg)	%mass of ice	Power (TW)	MoI factor

P	Charon	1759	603.6	0.162	<0.001	6.39	0.0976	40	0.005	?

The first column gives the planet (J for Jupiter, S for Saturn, U for Uranus, N for Neptune, and P for Pluto). To assess the radiogenic power at present time, we assume that the density of silicates is 3525 kg m^{-3}, a value equal to Io's density, an ice density of 1000 kg m^{-3}, and a radiogenic heating rate in the silicates of 5×10^{-12} W kg^{-1}, respectively. P_{rot} is the rotational period that is equal to the period of revolution for all the major satellites (synchronous state). In the case of Triton, 'r' indicates the retrograde orbit. Values for the Galilean satellites are taken from Schubert et al. (2004) and for Rhea from Iess et al. (2007). For Rhea, however, Schubert and Anderson (2007) derive an MoI value of 0.391. Values for Titan are taken from Iess et al. (2010). For the other satellites, see Hussmann et al. (2010). Mean densities, silicate mass fraction, and radiogenic heat production rate are calculated from the given values.

[a]Based on different analyses of the flyby data, there remains a discrepancy in the derived values for the moment of inertia of Rhea (see Anderson and Schubert, 2007, 2010; Iess et al., 2007).

trajectory. The latter is straightforward in terms of the nature of the effect: the stronger the satellite mass for a given flyby distance, the greater the effect on the spacecraft trajectory (measured in terms of the velocity perturbation). The astrometric observations depend on identifying mutual gravitational interactions among satellites or between satellites and the parent planet. The simplest effect – observing the wobble of a planet around the center of mass of a binary planet–moon system – provided the mass ratio of Pluto's moon Charon relative to Pluto (Olkin et al., 2003) and the system mass (Tholen and Buie, 1990). For giant planet systems, one looks for orbital commensurabilities that lead to orbital changes sensitive to satellite mass. For example, in the Saturn system, Mimas–Tethys and Enceladus–Dione resonances provide masses of these satellites, while small satellites at Lagrange points of larger moons also provide mass information on the latter (see Jacobson, 2004 for more details). Not all satellite masses can be well determined in this way, and tracking of spacecraft during close flybys remains the definitive mass-determination technique. Values for the Saturnian satellite system, for which four spacecraft have been used to determine densities, are given in Table 4 of Jacobson et al. (2006) and **Table 2**.

10.18.5 Modeling the Interior Structure

Due to the lack of measurements obtained by a seismic network, by deep surface penetration, or by ground-penetrating radar, interior structure models of the icy satellites are based on indirect evidence. The following characteristics are the main clues to investigate the structure of these moons: (1) radius and mass, (2) gravity field, (3) rotational state and shape, (4) magnetic field, (5) surface temperatures and heat flow, (6) composition of surface and atmosphere, and (7) activity at the surface. In addition to these features characterizing mainly a satellite's present state, knowledge on its evolution helps constrain possible internal states. This includes (1) surface geology and tectonics, which are telltale signs of present or past energetic processes; (2) orbital dynamics, being important for satellites evolving due to tides or in resonances; and (3) the chemical environment during accretion, that is, the composition and physical state of the solar nebula and planetary subnebula. The relevance of the items listed earlier varies for each individual satellite. However, in the following, we will illustrate how the combination of certain aspects can be used to gain a broad picture of the interiors of the icy moons.

10.18.5.1 Density and Composition

The satellite's radius R and its density ρ (or equivalently its radius and mass M if the shape is known or if spherical symmetry is assumed) are the basis of the models. To determine the distribution of mass within the icy satellites requires close spacecraft flybys, sometimes repeatedly, in order to resolve more precisely a body's gravitational field. The spacecraft will move along a trajectory that is perturbed by the various components of the body's gravitational field expressed as a spherical harmonic series (Hubbard and Anderson, 1978; Rappaport et al., 2001; Zharkov et al., 1985).

Assuming that the icy moons consist of rock (including iron) and nonporous ice, an assumption that is to first order reasonable on the basis of the compositional abundances of the outer solar nebula, the rock and ice mass fractions can be inferred from the mean density. Whereas the ice density is well constrained ($\sim$920 kg m^{-3}), the rock density may vary between about 2500 kg m^{-3} for hydrated rock (Schubert et al., 1986) and 8000 kg m^{-3} for pure iron. A typical value of nonhydrated silicate rock is 3500 kg m^{-3}, which will be used in the following as a reference value whenever we refer to rock. This value is close to the mean density of Io that is composed of rock and iron only, lacking a major component of volatiles. It is therefore used as a typical value for the rock/iron component of the other satellites.

For most of the satellites, it is unclear if they are differentiated into several distinct layers or homogeneous. Even for the same material, the density is pressure- and thus depth-dependent. In contrast to the larger terrestrial planets, however, compression within the rocky layers can be neglected and the rock densities can be regarded as constant. As shown by Sohl et al. (2002), even for the largest satellite, Ganymede, the density variations within each layer are small if self-compression is taken into account. However, the internal pressures can be sufficient to cause phase transitions from ice-I to high-pressure ice phases ice-II, ice-III, ice-V, and ice-VI, the densities of which (up to 1300 kg m^{-3}) significantly exceed the ice-I density (e.g., Schubert et al., 1986; Sotin et al., 1998).

10.18.5.2 Gravity

Besides the possibility to exactly determine the mass and radius of a satellite, close spacecraft flybys can provide measurements of the gravitational moments J_2 and C_{22}. The coefficient J_2 describes the polar oblateness mainly caused by the satellite's rotation and can best be determined with a polar flyby; C_{22} describes the equatorial bulge that is – in case of synchronous rotation – pointing toward the primary due to tidal interaction. It can best be determined with an equatorial flyby. According to first-order potential theory, these coefficients completely determine the satellite's moment of inertia C about the rotational axis, provided that the satellite is in hydrostatic equilibrium. C is defined as

$$C = \frac{8\pi}{3}\int_0^R \rho(r) r^4 \mathrm{d}r \qquad [1]$$

where $\rho(r)$ is the run of density with radial distance from the interior. **Table 2** gives basic parameters of selected icy moons, including C/MR^2. The determination of the dimensionless moment of inertia factor MoI $= C/MR^2$ yields an additional equation to infer the internal structure of a satellite that can be solved simultaneously with the mass balance equation. The lower the MoI factor is, the greater is the concentration of mass toward the center. For a homogeneous sphere, MoI $= 2/5$. In case of large satellites and planets, the MoI factor is slightly smaller than 2/5 even for homogeneous composition due to compression and phase changes at depth. The MoI factors of the Galilean satellites (see **Table 2**) were determined from flybys of the *Galileo* spacecraft and imply considerable degrees

of differentiation for Io (Anderson et al., 2001a), Europa (Anderson et al., 1998), and Ganymede (Anderson et al., 1996). Callisto, however, is regarded as partly differentiated (Anderson et al., 2001b).

Measurements of Titan's gravity field have been obtained by the *Cassini* spacecraft from various flybys. The mass (or more precisely the *GM* value), higher moments of the gravity field, the moment of inertia about the rotational axis, and the tidal potential Love number k_2 have been derived from Doppler tracking data (Iess et al., 2010, 2012). In a similar way, *Cassini* flybys were used to determine the static gravity fields of Rhea (Iess et al., 2007) and Enceladus (Ducci et al., 2012). In the case of Enceladus, data analysis from the flybys is still ongoing (as of August 2013).

Spacecraft flybys can be used to infer whether hydrostatic equilibrium is attained. The hydrostatic first-order theory yields $J_2 = 10/3\ C_{22}$, which can be verified if J_2 and C_{22} were independently determined from at least two close flybys. A ratio of 10/3 would be a strong argument in favor of hydrostatic equilibrium, although a combination of nonhydrostatic contributions resulting in the same ratio cannot be ruled out entirely.

In case of hydrostatic equilibrium, C_{22} is related to the moment of inertia through the secular (fluid) Love number k_f (e.g., Schubert et al., 2004) depending on the internal density distribution. k_f describes the complete relaxation of the body on long timescales (i.e., the fluid response) adjusting to the given tidal and rotational potentials. For a homogeneous body, $k_f = 3/2$, independent from its density. The relation of k_f, generally depending on the density distribution within the satellite, to the gravitational coefficient C_{22} can thus be used to constrain the satellite's internal structure. For a synchronously rotating satellite, to first order (e.g., Schubert et al., 2004),

$$C_{22} = \frac{1}{4} k_f \frac{\omega^2 R^3}{GM} \qquad [2]$$

where ω is the angular frequency of the orbital and rotational period and G is the gravitational constant. For the satellite's axial moment of inertia C, it follows (e.g., Kaula, 1968)

$$\frac{C}{MR^2} = \frac{2}{3}\left[1 - \frac{2}{5}\left(\frac{4 - k_f}{1 + k_f}\right)^{1/2}\right] \qquad [3]$$

In hydrostatic equilibrium, the extent of the satellite's internal differentiation – whether the ice has separated from the rock or the rock from the metal, thereby segregating into layers according to the density – can be thus obtained from C_{22}. Using eqn [1] and the value of C, the density distribution within a satellite can be constrained. However, due to the inherent ambiguity of the gravity data, such solutions are not unique (see **Chapters 10.02** and **10.05**).

Albeit not proving it, the ratio of C_{22} and J_2 may provide strong evidence if a moon actually is in hydrostatic equilibrium. Such measurements were successfully performed by the *Galileo* spacecraft at Io, the only Galilean satellite where the tidal and rotational responses could clearly be separated. Satisfying the $J_2 = 10/3\ C_{22}$ constraint, Io is very likely in hydrostatic equilibrium (Anderson et al., 2001a). The results are less conclusive for the other Galilean satellites, in particular for Callisto. As a consequence of the equatorial flyby, geometries J_2 and C_{22} could not be determined independently (Schubert et al., 2004). In the cases of Titan and Rhea, the quadrupole moments are consistent with a hydrostatic state (Iess et al., 2007, 2010). Although nonhydrostatic contributions cannot be ruled out completely (even when $J_2 = 10/3\ C_{22}$), the hydrostatic theory is frequently used as a first approach to construct interior structure models of the icy satellites, especially for the large ones.

The moments of inertia about the principal axes can also be derived from the rotational state of a satellite. One way suitable for rapidly rotating bodies is to determine the precession of the spin pole. The precession rate depends on all three moments of inertia and can be used to further constrain the principal moment about the rotation axis in combination with the quadrupole moments of the gravity field. In this case, the assumption of hydrostatic equilibrium is not needed. However, the precise determination of the precession rate is difficult because of the long timescales of precession. In case of synchronously rotating satellites, the determination of the satellite's obliquity can also be used to determine the moments of inertia. In case the satellite obtains a so-called *Cassini state*, the spin pole adjusts its angular separation from the orbit pole so that it remains coplanar with the orbit pole and the invariant pole, as the former precesses about the latter (Bills and Nimmo, 2008). If both the gravity parameters J_2 and C_{22} and the obliquity are known, then the moment of inertia can be determined without the assumption of hydrostatic equilibrium. However, to apply this theory, it has to be shown that the satellite actually has obtained one of the equilibrium states, known as *Cassini states*.

10.18.5.3 Two- and Three-Layer Structural Models

As an illustration, the two-layer model, consisting of a rock core and a H_2O layer, will be discussed (see also **Chapter 10.02**). Such a model may be a reasonable approach for the medium-sized satellites of Saturn and Uranus, in case of full differentiation. Larger satellites will undergo phase transitions from ice-I to high-pressure ice phases. It should also be noted that even for the medium-sized satellites, for example, for Rhea, the phase transition from ice-I to ice-II can occur in the central region, if the satellite is not fully differentiated in ice and rock (Anderson and Schubert, 2007; Castillo-Rogez, 2006; Schubert et al., 1986). However, in case of full differentiation, the pressures in the outer ice layer are sufficiently small for the ice-I phase to remain stable.

From a simple mass balance equation for a spherical body, the radius R_c and the mass M_c of the core can be directly obtained if the densities are known:

$$R_c = R\left(\frac{\rho - \rho_m}{\rho_c - \rho_m}\right)^{1/3}, \quad M_c = 4/3\pi R_c^3 \rho_c \qquad [4]$$

where ρ_c and ρ_m are the densities of the core and mantle (in this case ice-I), respectively. Results for possible core sizes are shown in **Figure 5** for the medium-sized satellites of Saturn and Uranus. Strikingly, there is no decrease of rock content with increasing distance from the planet in the Saturnian system. This stands in contrast to the Jovian system, in which the observed density gradient is consistent with a radial

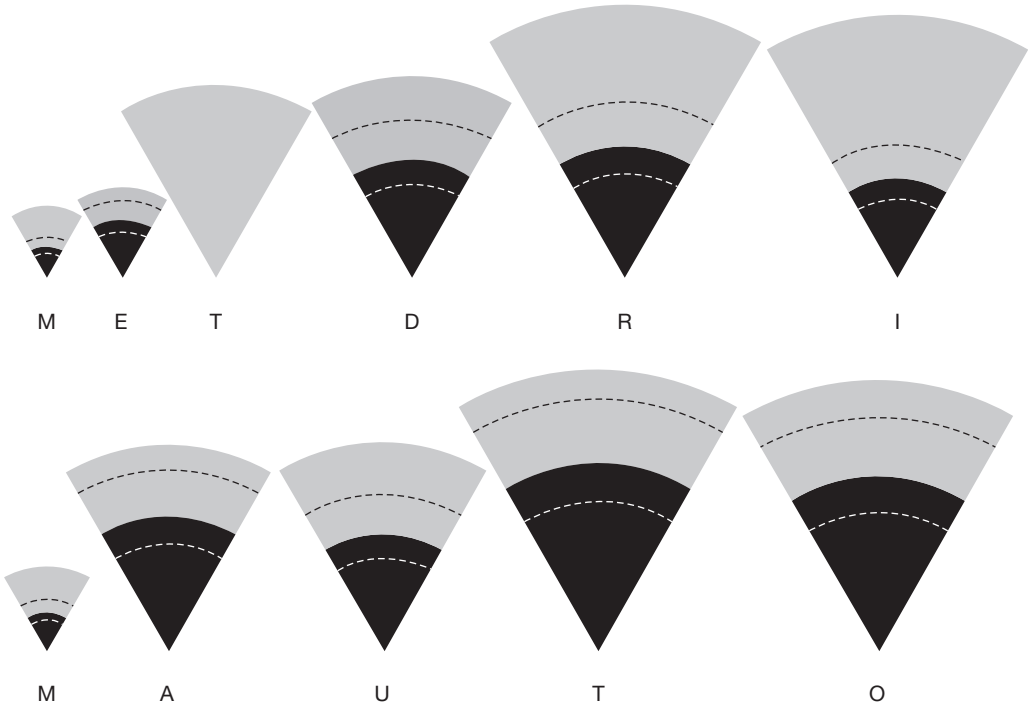

Figure 5 Possible internal structures of the midsized icy satellites of Saturn and Uranus consistent with the mean density are shown assuming complete differentiation into a rock core ($\rho_c = 3500$ kg m^{-3}) and an icy mantle ($\rho_m = 960$ kg m^{-3}). Complete differentiation is assumed here, only to illustrate the rock content. Whether differentiation was actually completed or if the satellites consist of homogeneous ice–rock mixtures has to be inferred from spacecraft flybys. For Rhea, for instance, complete differentiation can be ruled out on the basis of *Cassini* data (Anderson and Schubert, 2007; Iess et al., 2007). From left to right and bottom to top: Mimas, Enceladus, Tethys, Dione, Rhea, Iapetus; Miranda, Ariel, Umbriel, Titania, and Oberon. Sizes are to scale. The dashed lines show the possible range of core sizes for a variation of the rock density between 2000 and 6000 kg m^{-3}, corresponding to hydrated rock (larger cores) and iron-rich rock (smaller cores), respectively. The strong variation of rock content in the Saturnian system is remarkable. Tethys is essentially an icy sphere, whereas the rock-mass fraction and thus core sizes differ considerably for the other satellites. Additionally, there is no obvious correlation of rock content with increasing distance from Saturn. It should be noted that prior to the determination of the higher moments of the gravitational fields, homogeneous ice–rock mixtures cannot be ruled out. The latter would imply ice-II phases in the central regions of the largest of the midsized satellites, Titania, Oberon, and Rhea.

temperature distribution in the Jovian subnebula. It is also noteworthy that with a mean density of only 956 kg m^{-3}, Tethys is lacking a substantial rock-mass fraction, whereas the moons in its vicinity, Enceladus and Dione, contain the highest rock-mass fractions (55% and 48%, respectively) of the midsized Saturnian satellites. The origin of such an irregular distribution that may imply collisional disruption in the inner part of the Saturn system (Mosqueira et al., 2010) is still an open question. In the Uranian system, variations in the rock content are smaller, ranging between 40% (Ariel) and 60% (Titania). An exception is Miranda (23%), which, however, is significantly smaller than the other satellites of Uranus and had a unique origin (Greenberg et al., 1991). The bulk rock-mass fraction is increasing as we go outward from Saturn to Uranus, a trend that continues if the Neptunian satellite Triton (74%) and the Pluto–Charon system (70% and 63%, respectively) are included.

For the two-layer model and more generally for the N-layer model, we may additionally use the moment of inertia (provided it is determined from flybys) to constrain the internal structure. Counting the layers from inside out, the mass balance equation and the equation for the moment of inertia have to be solved simultaneously:

$$\begin{aligned} M &= 4/3\pi\left[\rho_1 R_1^3 + \sum_{j=2}^{N}\rho_j\left(R_j^3 - R_{j-1}^3\right)\right] \\ \mathrm{MoI} &= 2/5\frac{1}{\rho R^5}\left(\rho_1 R_1^5 + \sum_{j=2}^{N}\rho_j\left(R_j^5 - R_{j-1}^5\right)\right) \end{aligned} \quad [5]$$

In this set, the density and the radius of each layer are in principle unknown, except for the outermost layer for which the radius coincides with the total radius ($R_N = R$). Thus, only two of the $2N-1$ unknown quantities can be obtained from eqn [5], implying an inherent ambiguity of multilayered interior structure models. Further assumptions, for example, on the layer densities are thus required to construct the models. In eqn [5], we assumed that the density within each layer is constant and thus neglected compressional effects – an assumption justified even for the largest icy satellites (Sohl et al., 2002).

The Jovian satellite Europa is a three-layer-type example, consisting of an iron core, a rocky mantle, and an outer H_2O layer (Anderson et al., 1998; Kuskov and Kronrod, 2005; Schubert et al., 2009; Sohl et al., 2002). For Europa, the moment of inertia was determined from *Galileo* flybys (see **Table 2**) using the assumption of hydrostatic equilibrium,

and thus, the set of equations mentioned earlier can be fully applied. Provided that the densities of the H_2O layer and the rocky layer are known, the set of eqn [5] can be solved, yielding the density and the radius of the core, respectively. Depending on its composition and thus density, the core can be as large as about 50% of Europa's total radius. The outer H_2O shell can have an extension of about 80–170 km (Anderson et al., 1998). A typical result for Europa's structure is shown in Figure 6. However, on the basis of the current data, an H_2O shell on top of a uniform mixture of rock and metals, although more unlikely, cannot be ruled out completely (Anderson et al., 1998; Schubert et al., 2009).

10.18.5.4 Pressure-Induced Phase Transitions

For a given density profile of a spherical satellite, it is straightforward to calculate the pressure $P(r)$ as a function of the radial distance r from the satellite's center solving the hydrostatic equation:

$$dP = -g(r)\rho(r)dr \qquad [6]$$

where g is the gravitational acceleration. Besides compression effects, which are of minor importance, the internal pressure is crucial for the possible occurrence of phase transitions within the ice or rock layers.

The internal structures of the largest icy satellites, Ganymede, Titan, Callisto, Europa, and Triton are complex because (1) there is evidence at least for the Galilean satellites that they contain iron cores, (2) pressures are sufficiently high for phase transitions of water ice to occur (at least for Ganymede, Callisto, and Titan), and (3) internal heat sources may be sufficient to maintain liquid water oceans underneath the ice-I shell (Spohn and Schubert, 2003).

Up to a pressure of about 0.2 GPa, ice-I will be stable, transforming into ice-III, ice-V, and ice-VI with increasing pressure. In Figure 7, the phase diagram for pure H_2O is shown. For a comprehensive discussion on high-pressure polymorphs of ices and their physical properties, see, for example, Hobbs (1974). A typical interior structure considering the phase transitions and corresponding densities of the high-pressure ice phases is shown as an example in application to Ganymede in Figure 8.

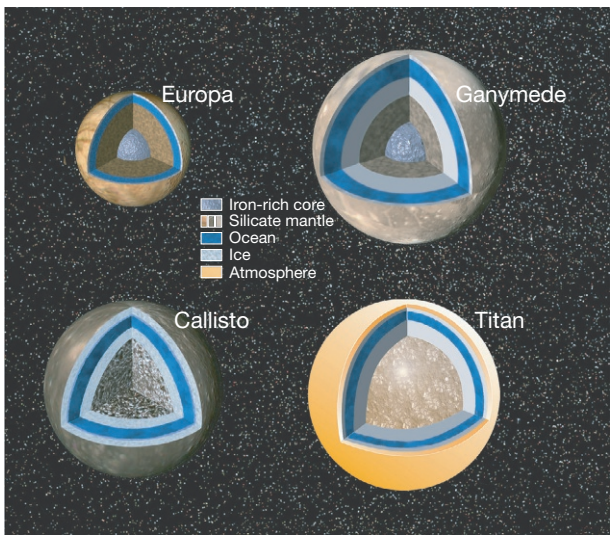

Figure 6 Models of the internal structures of large icy satellites and Europa (adapted from Sotin C and Tobie G (2004) Internal structure and dynamics of the large icy satellites. *Comptes Rendus De L'Academie Des Sciences Physique* 5: 769–780.)

10.18.5.5 Oceans

The fact that the ice-I melting temperature decreases with increasing pressure allows for the existence of liquid layers between the ice-I shell and the high-pressure ice phases, if the internal temperature is in the right range (see Figure 9). Volatiles, like ammonia (NH_3), are important because even small amounts substantially reduce the melting temperature of water ice (Figure 10).

Since the early work of Lewis (1971), the existence of subsurface water oceans in icy satellites and the relevance of ammonia (or other volatiles) were discussed, especially for the largest satellites. Because of possible tidal heating, the Jovian satellite Europa has been investigated in substantial detail. No concurrence with respect to the existence of an ocean was reached in the earlier models (Cassen et al., 1979, 1980; Ojakangas and Stevenson, 1989; Ross and Schubert, 1987; Squyres et al., 1983b) because of the unknown efficiency of convection in the ice shell. However, the existence of such an ocean is presently considered as the most likely case for Europa. It is consistent with thermal modeling (Hussmann et al., 2002; McKinnon, 1999; Mitri and Showman, 2005; Spohn and Schubert, 2003; Tobie et al., 2003, 2005) and with the geologic record (Carr et al., 1998; Pappalardo et al., 1998, 1999, and references therein), it explains the formation of cycloidal features on the surface (Hoppa et al., 1999), and it is consistent with the induced magnetic field detected at Europa (Kivelson et al., 2000).

Induced magnetic fields are generated, because the moons, which revolve around Jupiter in the planet's equatorial plane, are subject to the time-varying magnetic field of Jupiter. At the

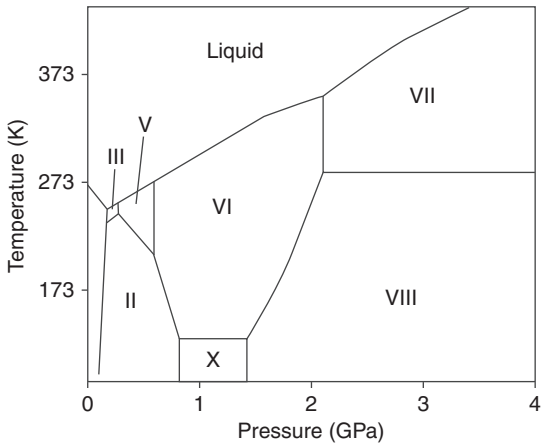

Figure 7 Phase diagram of pure water ice. The different high-pressure ice phases are shown. Most relevant for the icy satellites are ice-I, ice-II, ice-III, ice-V, and ice-VI.

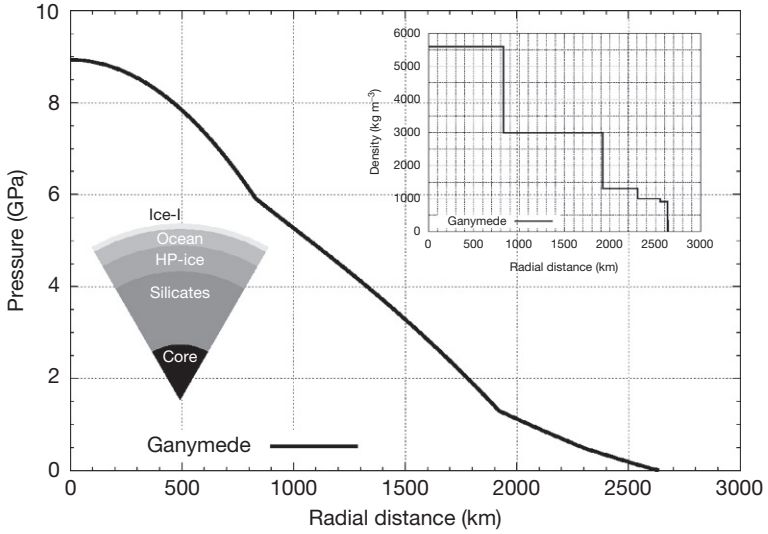

Figure 8 Interior structure model of Ganymede as a type example for a large icy satellite. Shown is the pressure and corresponding density (upper right) as a function of the radial distance from the planetary center. Based on the moment of inertia and mass balance constraints, the internal structure is calculated assuming hydrostatic and thermal equilibrium (equivalent to the Titan models described in Sohl et al., 2003). Further evidence for the differentiation of an iron core comes from the proof of Ganymede's intrinsic magnetic field during the *Galileo* mission.

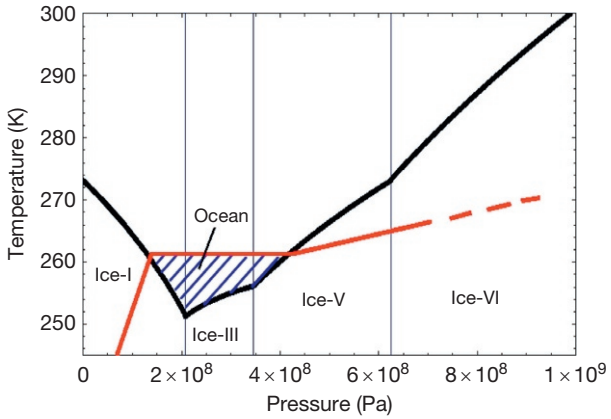

Figure 9 Conceptual sketch of oceans in icy moons. The melting curve of ice-I is shown in black (compare also with **Figure 7**) as a function of internal pressure (and thus with increasing depth). The red curve, representing a possible temperature profile, intersects the melting curve at two points. In between, the solid ice phase will not be stable and a liquid layer will form, in this case between the ice-I and the ice-V layers. The blue area shows the range where oceans are possible, even for lower temperatures. The higher the temperatures, the greater is the vertical extension of the ocean. The minimum temperature allowing for oceans is about 250 K in case of pure water ice. It may be substantially smaller with the presence of ammonia in the ocean (not shown here). The vertical lines mark the locations of the phase transitions.

location of the moons, the amplitude and the direction of the components of the Jovian field vary on a timescale of Jupiter's rotational period (9.925 h), because of an angle of about 9° between Jupiter's rotation axis and the axis of the Jovian magnetic field. Due to these variations, an electric current and consequently a secondary (or induced) magnetic field will be generated in electrically conducting regions within the moons. The amplitude and the direction of the induced field will be correlated with the variations of the Jovian principal field. Such fields were detected at Callisto, Europa, and possibly at Ganymede (Khurana et al., 1998; Kivelson et al., 2000, 2002; Neubauer, 1999; Zimmer et al., 2000). For Ganymede, the data analysis is more complicated because Ganymede additionally has an intrinsic magnetic field (Kivelson et al., 2002). The data analysis shows that the induced fields are generated close (a few hundred kilometers or less) to the surface, ruling out the possibility of currents in the deep interior (e.g., within metallic cores) as a cause for the induced fields (Zimmer et al., 2000). The most probable explanation for the induced fields being generated close to the surface is the electrolytic conductivity due to the presence of salts within a liquid water layer (Khurana et al., 1998; Neubauer, 1999). The induced magnetic fields are extremely important because it is so far the only observational evidence for the present-day existence of oceans. Surface features, for instance, may have an age of several My or more and may thus not necessarily represent the ocean's present state. The magnitude of the induction response is proportional to the product of electrical conductivity and thickness of the ocean. Estimates of the salinity of the ocean could therefore be used to constrain the ocean thickness (e.g., Hand and Chyba, 2007).

Liquid layers can also be expected in other large icy satellites (Lewis, 1971), especially at Titan (Grasset et al., 2000; Sohl et al., 1995, 2003), Ganymede, Callisto (Spohn and Schubert, 2003), and Triton (Hussmann et al., 2006; Lewis, 1971; Ruiz, 2003), provided that there are antifreezes, for example, ammonia, present reducing the melting temperature of water ice. The presence of ammonia can be expected on the basis of models of the solar nebula and condensation temperatures and theories of satellite formation at least for the Saturn system and beyond (Lewis, 1972). The abundance expected for the icy satellites, based on models for the Saturnian subnebula and on data obtained from the composition of comets and clouds around young stellar objects, is of the order of a few percent (Bockelée-Morvan, et al., 2004; Dartois and d'Hendecourt, 2001; Lunine and Stevenson, 1987; Mousis et al., 2009a).

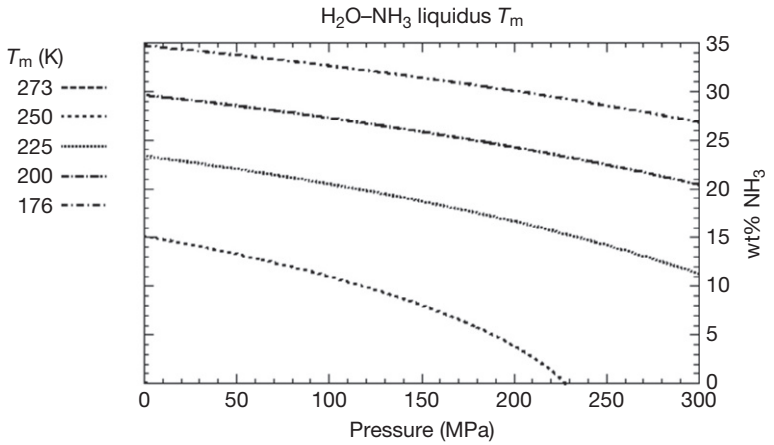

Figure 10 Contours of the melting temperature as a function of ammonia concentration and pressure for an H_2O–NH_3 mixture according to the parameterization of Leliwa-Kopystyński et al. (2002). Reproduced from Hussmann H, Sohl F, and Spohn T (2006) Subsurface oceans of medium-sized outer planet satellites and large trans-Neptunian objects. *Icarus* 185: 258–273.

For the largest satellites, Ganymede, Titan, and Callisto, internal oceans are expected to be located between the ice-I layer and the high-pressure ice layers. Differentiated Triton and Pluto models imply a pressure regime where the presence of high-pressure phases can be neither ruled out nor confirmed because of the inherent ambiguity of the models. A structure similar to the one of Europa, with a water–ammonia ocean being in direct contact with the silicate layer, is, however, conceivable for Triton and Pluto.

For the midsized satellites, present-day oceans could only exist in the largest members of this class of objects under certain conditions. Besides Ganymede, Titan, Callisto, and Europa, the best candidates for present-day subsurface oceans are Triton, Pluto, Titania, Oberon, and Rhea, provided that they are differentiated and contain ammonia (Hussmann et al., 2006). However, modeling based on gravity data from the *Cassini* mission suggests that Rhea is not fully differentiated (Anderson and Schubert, 2007; Iess et al., 2007) ruling out the possibility of an internal ocean. Rhea's structure is then likely to be an ice–rock mixture including ice-II in its central region (Castillo-Rogez, 2006). Although it is substantially smaller, Enceladus may also be added to the list of possible ocean candidates because of its strong endogenic and surface activity (Porco et al., 2006; see also details in **Section 10.18.7.4**).

The precise determination of the gravity field may provide an indirect way to detect subsurface oceans, due to the greater deformation of the outermost ice-I layer as a response to tidal forces, in case of an ocean. For a moon on an eccentric orbit, the gravitational force exerted by the parent planet varies in a predictable way and it is possible, with flybys at apoapsis and periapsis (farthest and closest distance to the parent planet) or in orbit, to obtain the time-varying tidal potential. The latter is a combination of the external tidal potential (caused by the planet) and the internal or secondary tidal potential caused by the redistribution of mass inside the satellite (i.e., due to the formation of a tidal bulge). The amplitude and phase lag of the satellite's tidal bulge as a response to the periodic external force can be used to determine the overall rigidity of the interior – which in turn constrains the possible presence of interior liquid layers. A liquid layer will decouple the outer ice shell from the deep interior, allowing for larger deformation rates of the ice shell due to the tidal forcing as compared to the case where an entirely solid ice shell is directly connected to the rock. Generally, tidal amplitudes will be about an order of magnitude larger in the presence of a liquid layer (Moore and Schubert, 2000, 2003; Sohl et al., 1995). The tidal potential and the tidal deformation of a satellite surface can tell whether a subsurface exists. Due to the linear dependence of the tidal response on the ice rigidity, a combination of independent measurements would be desired to constrain the ice thickness further. Promising strategies would be to combine measurements of the tidal potential, the tidal deformation, and the magnetic induction response in orbit around the satellite. In addition the determination of libration amplitudes (small periodic changes in the rotation rate due to tidal torques) can constrain the ice thickness in case of a de-coupling ocean layer (e.g., Van Hoolst et al. (2008) in application to Europa). The impact of the liquid layer on the tidal response of Titan's ice shell has provided indirect evidence for a subsurface ocean during the *Cassini* mission (Iess et al., 2012). If, and how, the tidal response of the ice shell can be used to infer the thickness of the ice shell and therefore the depth in which liquid water may be present has been investigated for possible future Europa missions (Wahr et al., 2006).

10.18.5.6 Thermal State

The interior structure is linked to a satellite's thermal state via the heat production rate in the rock component due to long-lived radiogenic isotopes (see also **Chapter 10.08**) and – in some cases – tidal heating. Assuming an elementary abundance of uranium, thorium, and potassium, consistent with the chondritic composition, the heating rate can be obtained from the laboratory-derived half-lives and the energy release per decay of the individual isotopes. The specific present-day heating rate H in the rocky component of the icy satellites is of the order of several 10^{-12} W kg^{-1}, which is roughly one order of magnitude less than the heating rate at the very beginning of the solar system. Here, and in the following, we neglect short-lived

isotopes that may have played a role at the early stages of solar system evolution, especially for planetesimals and their remnants, the asteroids and other small objects (Merk et al., 2002). The role of short-lived isotopes (mainly ^{26}Al, ^{60}Fe, and ^{53}Mn) has been recognized in various applications for the early evolution of satellites as a means of initiating phases of geologic activity (e.g., Barr and Canup, 2008; Castillo-Rogez et al., 2009).

From a satellite's rock-mass fraction m_{rock}, its overall present-day heat production is given by $H_{\text{total}} = Hm_{\text{rock}}$ (see Table 6 in Hussmann et al., 2010 for radiogenic heat production rates of solar system satellites). Since the heat transfer rate Q through the ice shell will depend on its thickness and physical state, the latter can be related to the heat production rate, determined by the chosen density and size of the rock core, if a steady-state $H_{\text{total}} = Q$ is assumed. Although such an equilibrium state may not be exactly matched, it is a reasonable approach for the icy satellites at late stages of their evolution, after primordial heat sources due to accretion, core formation, or early tidal heating have become negligible. However, it should be noted that for the Earth – the only planetary body for which reliable data have been obtained – only 50% of the surface heat flux can be attributed to radiogenic heating. The corresponding values are unknown for other planets and satellites, and therefore, the equilibrium condition must be regarded as a first assumption. Because of their small size and therefore greater surface to volume ratio (in comparison with the Earth and other terrestrial planets), the icy satellites cool faster and approximation to equilibrium is more likely for their present states. Deviations due to additional contributing heat sources, and possible disequilibrium between internal heating and the output of heat through the surface, however, cannot be ruled out completely.

The conductive heat flow through an ice shell of thickness D and temperatures T_0 and T_s at the base and the surface of the ice shell, respectively, are given by

$$Q = 4\pi R^2 k \frac{T_0 - T_s}{D}(1 - D/R) \qquad [7]$$

assuming a constant value for the thermal conductivity, generally being temperature-dependent. Considering a wide temperature range of 40–273 K, k varies for ice-I between 14 and 2 $\text{Wm}^{-1}\,\text{K}^{-1}$, according to the parameterization of Klinger (1981), $k(T) = 567/T$, which is valid for temperatures above 30 K. Similar values are obtained using the parameterization of Hobbs (1974). The factor $(1 - D/R)$ takes into account the spherical geometry and may be neglected for large satellites. The corresponding temperature profile is given by

$$T(r) = T_s + \frac{T_0 - T_s}{1 - R_0/R}\left(\frac{R_0}{r} - \frac{R_0}{R}\right) \qquad [8]$$

with $R_0 = R - D$ the radius of the base of the ice shell. Both equations are connected through Fourier's law. Here, the thermal conductivity and the surface temperature are taken to be constant with the latter ranging from about 100 K for the Jupiter system to about 40 K for Triton and the Pluto–Charon system. The values for individual satellites depend on surface characteristics, for example, albedo, or the presence of an atmosphere (e.g., Titan's surface temperature = 94 K, significantly exceeding the value (about 80 K) expected without an atmosphere). Setting the heat production into equilibrium with the heat flow, $Q = H_{\text{total}}$, the temperature at the base of the ice shell is given by

$$T_0 = T_s + \frac{DH_{\text{total}}}{4\pi R^2 k(1 - D/R)} \qquad [9]$$

The equations mentioned earlier are valid for purely conductive shells, only. The heat transfer through a thick and relatively warm ice shell, however, may be dominated by the much more efficient process of subsolidus convection. Whereas, at present, heat is mainly transferred by conduction in small-sized and midsized icy satellites, thermal convection can be the dominant process in large icy satellites.

10.18.5.7 Heat Transfer

Thermal convection is discussed in detail in **Chapter 10.08**. Whereas the basic equations describing convection in an ice shell are the same as for mantle convection, the physical properties, especially the temperature range in which ices are subject to viscous flow, are completely different as compared to rock. The viscosity, which is difficult to describe by first principles or by parameterizations based on laboratory measurements, is a key parameter controlling convection. It is strongly temperature-dependent, and different parameters have to be applied for various creep mechanisms operating in specific temperature and stress regimes. Furthermore, the viscosity is pressure- and grain size-dependent. The physical properties for H_2O ice, creep mechanisms, and laboratory data with regard to the dynamics of icy satellites are discussed, for example, in Weertman (1983), Durham and Stern (2001), Goldsby and Kohlstedt (2001), Sotin et al. (1998), McKinnon (2006), and Durham et al. (2010).

Due to the large viscosity contrast between the base of the ice shell and the surface, the icy satellites are thought to operate in the stagnant-lid regime (Solomatov, 1995; see also **Chapter 10.08**), characterized by a convective region and a relatively thick lid, in which the viscosity is too large for flows to occur. In the lid, the heat transfer is purely conductive and can be calculated by the equations given earlier. In cases of high heat flux, icy satellites may also operate in a 'mobile-lid' regime where convective plumes can rise close to the surface. These exceptional cases, characterized by a high heat flux, may be relevant for present Enceladus (Barr, 2008; Han et al., 2012). A schematic temperature profile for a satellite in the stagnant-lid regime is shown in **Figure 11**. The convective region is characterized by a small temperature drop, corresponding to a viscosity contrast of about an order of magnitude only. Since pressure changes are small within the ice shell, adiabatic temperature changes can be neglected, and except for the boundary layers, the temperature T in the well-mixed convective region can be regarded as constant. Several scaling laws, based on laboratory data and numerical experiments, have been proposed to describe both the heat flow and the onset of convection (Davaille and Jaupart, 1993; Deschamps and Sotin, 2001; Grasset and Parmentier, 1998; Solomatov, 1995). Non-Newtonian viscosities and the dependence on grain sizes for strongly temperature-dependent convection

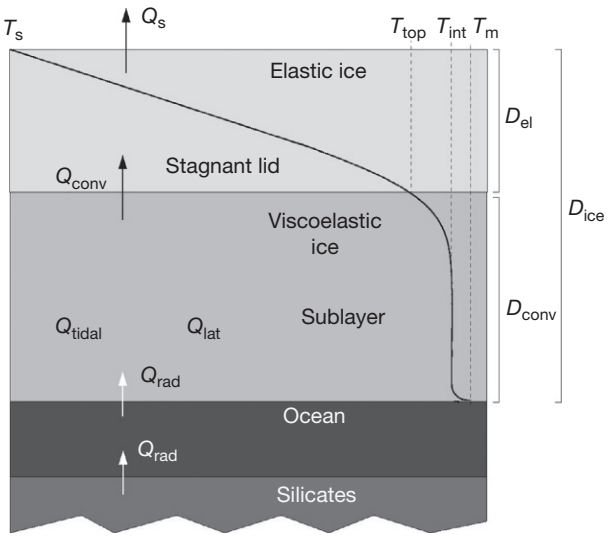

Figure 11 Schematic sketch of a convective ice-I layer at the surface of an icy satellite. Q_{rad} is the radiogenic heating rate from the silicate mantle. Q_{conv} is the heat flow out of the convective region, and Q_s the surface heat flow. Q_{lat} and Q_{tidal} may be additional heat sources in the ice if latent heat is released due to crystallization or in cases where tidal dissipation is an important factor. The ice-I layer is divided in the convective sublayer and the stagnant lid. The temperature (black curve) is high and, apart from the boundary layers at the very top and bottom, almost constant within the convective region. In the stagnant lid, the temperature is decreasing strongly corresponding to the conductive heat transport. The temperature profile can be constructed if the melting temperature T_m, that is, the temperature at the base of the ice shell and the surface temperature T_s, as well as material parameters, for example, the thermal conductivity, are known. Such a structure (not to scale) with a rocky mantle and an H_2O layer on top of it would be appropriate for the satellite Europa. Modified from Hussmann H, Spohn T, and Wiezcerkowski K (2002) Thermal equilibrium states of Europa's ice shell: Implications for internal ocean thickness and surface heat flow. *Icarus* 156: 143–151.

have been discussed, for example, by Barr et al. (2004), McKinnon (2006), and Barr and McKinnon (2007).

The thickness of the stagnant lid (and implicitly the thickness of the convecting sublayer) depends very sensitively on the value of the derivative of viscosity as a function of temperature, evaluated at the interior temperature in the sublayer, and on the value of the local Rayleigh number evaluated at the sublayer temperature (Solomatov and Moresi, 2000). This implies that in contrast to previous models (e.g., Schubert et al., 1979), the upper bound of the convective region is not determined by a fixed isotherm, but is found to be dependent on the temperature within the convective region itself (Davaille and Jaupart, 1993; Grasset and Parmentier, 1998). Using such an approach, the temperature at the top of the convective layer can be calculated as a function of the internal temperature determining also the corresponding heat flow out of the convective region if a viscosity law and an appropriate Rayleigh number are defined. In a steady state, the heat flow out of the convective region will be equal to the purely conductive heat flow through the stagnant lid, which can be used to determine the thicknesses of the individual layers. The more vigorous the convection, the thicker will be the convective region and the thinner the stagnant lid (for fixed temperatures at the surface and the base of the ice shell). At present, convection is expected to play a major role in the ice shells of the largest satellites, for example, Ganymede, Titan, Callisto, and Europa.

10.18.5.8 Effect of Volatiles

Independent of the mode of heat transport (convection or conduction), it has to be verified whether a solid ice shell could be stable under the given circumstances, that is, whether T_0 is above or below the melting temperature of ice-I. The determination of the pressure P_0 at the base of the shell is straightforward since the mass of the latter is known for a specified thickness D with the remaining mass being included in the sphere below the ice shell. The melting temperature $T_m(P_0)$ can then be determined from the laboratory-derived parameterizations for the given pressure. The reduction of the melting temperature due to a specified small amount of ammonia may be taken into account at this stage (see **Figure 10**). Parameterizations are given by Chizhov (1993) for pure H_2O and by Hogenboom et al. (1997), Leliwa-Kopystyński et al. (2002), Grasset and Pargamin (2005), and Choukroun and Grasset (2010) for H_2O–NH_3 mixtures. If T_0 exceeds the melting temperature, the solid ice-I phase will not be stable and a liquid water layer (ocean) will form underneath the ice shell (**Figure 9**). The upper bound of the ocean will be determined by the melting curve and can be calculated from the corresponding pressure. If T_0 is smaller than the melting temperature, the ice-I layer will be stable. In this case, it has to be verified whether or not the pressure of the ice-I/ice-III or ice-I/ice-II phase transition is reached. If not, the ice shell will consist of ice-I only, and the remaining bulk composition of the satellite will be rock, including the iron-rich components. If the pressure is sufficiently high for the phase change to occur, the lower part of the H_2O layer will consist of high-pressure ice covering the rocky interior.

As mentioned earlier, a liquid layer may form between the ice-I shell and the high-pressure phase. Such an ocean is assumed to be isothermal because the adiabatic temperature increase with increasing pressure is small for the icy satellites. Some applications, however, require that the adiabatic increase in ocean temperature (and density) be included to properly calculate radial expansion of icy satellites (e.g., Bland et al., 2009; Showman et al., 1997 in application to Ganymede). In a simple approach, the temperature at the base of the ocean can be equated with the temperature at the base of the ice shell, and the corresponding pressure (and hence depth) at the base of the ocean can again be calculated from the melting curve, this time for the high-pressure phase. Assuming a mean density of the high-pressure ice phase and the rock core, the extension of the latter is determined from the mass balance constraints. By varying the core size, and thus the heat production in the satellite's deep interior, an equilibrium model can be derived by an iterative process.

Depending on the number of available constraints, there may be some ambiguity inherent in the model results, and equilibrium may be attained for various core sizes, densities, and ice thicknesses. In **Figure 8**, the interior structure of Ganymede is shown as a typical example of a class of models consistent with the mass balance and moment of

inertia constraints assuming thermal equilibrium. Further constraints, for example, the presence of a magnetic field, can be used to restrict possible values of core sizes and densities (e.g., assuming the density of the Fe–FeS eutectic for the core).

10.18.6 Evolution of Satellite Interiors

The presence of subsurface oceans could have been an important factor in the satellites' histories, even for the smaller satellites, because of the greater radiogenic heating rate in the past. Thermal evolution models can be calculated from heat balance equations applying the same fundamental principles as for the terrestrial planets (see **Chapter 10.08**). The major modification in application to the icy satellites is the replacement of the physical properties of mantle rock by those of ice. Further complexity arises in models in which subsurface oceans play a role. Additional factors, for example, the release of latent heat due to crystallization of an ice layer and the increase of ammonia concentration in the subsurface ocean due to freezing of pure ice, have to be taken into account.

10.18.6.1 Tidal Heating

Besides radiogenic heating, additional heat sources are relevant especially at the beginning of satellite evolution. The most important ones are accretional heating, release of potential energy due to differentiation, and tidal heating (e.g., Hussmann et al., 2010; Schubert et al., 1986). The latter has been very efficient during the phase in which the satellites were not yet in a synchronous rotation state. This state was obtained later in the evolution by all large and midsized icy satellites. For synchronously rotating satellites, tidal heating will be most effective for (1) large satellites on (2) eccentric orbits (3) close to the primary with (4) high internal temperatures (see eqn [10] in the succeeding text). These conditions are best fulfilled by the Jovian satellite Io, for which tidal friction still is the dominating heat source (see **Chapter 10.08**). At present, tidal heating significantly contributes to the heat budget of Europa and Enceladus. The example of Enceladus shows that the internal composition and the thermal state of a satellite could be crucial for tidal effects. With respect to size, distance from the planet, and orbital eccentricity, we would expect tidal heating of Mimas instead of Enceladus. That Enceladus, and not Mimas, is internally active may be due to the higher rock content – and thus larger radiogenic heating – or due to different thermal–orbital histories of the two satellites (see **Section 10.18.7.4**).

Tidal heating may additionally have played a significant role in the early stages of evolution for several other moons involving highly eccentric orbits or nonsynchronous rotation. Ganymede and Triton, both showing a great diversity of surface terrain and tectonic features, are prominent examples for a specific orbital history, most likely involving strong tidal heating (McKinnon and Leith, 1995; Showman and Malhotra, 1997).

Even for synchronously rotating satellites, tidal friction plays a crucial role for the histories of some moons because it provides a link between the orbital evolution (because tidal friction in the satellite implies a loss in orbital energy and reduces the eccentricity) and the thermal state of a satellite (internal heating because of friction within the satellite). For a satellite in synchronous rotation with negligible inclination and obliquity, the tidal heating rate is given by (Segatz et al., 1988)

$$H_{\text{tidal}} = -\frac{21}{2}\frac{R^5 n^5 e^2}{G}\text{Im}(k_2) \qquad [10]$$

where n and e are the mean motion and orbital eccentricity of the satellite, respectively. $\text{Im}(k_2)$ is the imaginary part of the second-degree potential Love number that depends on the structure (density profile), tidally effective rheology (e.g., temperature-dependent viscosity of the planetary material), and frequency of the forcing (i.e., the mean motion n). Here, k_2 describes the viscoelastic response of the satellite to the external periodic forcing on the timescale of the orbital period – it has to be distinguished from the previously introduced fluid Love number, which describes a completely relaxed state of a planetary body on long timescales.

The complex body tide Love numbers are obtained by numerical integration of the linearized field equations for small viscoelastic deformations in a spherical and self-gravitating body subject to specific boundary and continuity conditions (e.g., Segatz et al., 1988). The correspondence principle that relates the viscoelastic problem to the well-known elastic problem permits to solve the resultant set of differential equations for the complex radial functions k_2(r) (potential), h_2(r) (radial displacement), and l_2(r) (tangential displacement) in the frequency domain (Zschau, 1978). In application to the deformation problem of satellites under periodic tidal forcing, layers with constant density and constant material parameters are usually assumed. The rheological model describes the relation between stress and strain taking into account the deformation of ice and rock as a function of frequency. The simplest assumption is the Maxwell model in which the deformation is elastic (i.e., energy-conserving) on timescales shorter than the Maxwell time, the ratio of tidally effective viscosity and rigidity. On timescales on the order of the Maxwell time, the deformation is viscoelastic and highly dissipative. On timescales significantly exceeding the Maxwell time, the response can be regarded as fluid. The Maxwell model is completely determined by two material parameters, viscosity and rigidity, that are generally temperature-dependent. More realistic rheological models (e.g., the Burgers model) include also transient parameters that are, however, difficult to constrain for the tidal problem by laboratory measurements. Equation [10] is independent from the rheological model chosen. This approach links the dissipation rate to the rheological model in a consistent way, and it is thus more general than the often used approximation of $\text{Im}(k_2) \sim k_2/Q$, where Q is a constant quality factor describing the ratio of the maximum elastic energy stored in one tidal cycle over the energy dissipated in that cycle. Tidal dissipation can be extremely relevant for the evolution of satellites because it connects the thermal state with the orbital and/or rotational state.

The link between tidal heating and thermal evolution has been intensely investigated in application to the Galilean satellites because of Io's thermal activity and the resonance locking of the inner three satellites (Fischer and Spohn, 1990; Greenberg, 1982; Ojakangas and Stevenson, 1986; Peale, 1986; Peale et al., 1979; Spohn, 1997; Squyres et al., 1983a; Yoder, 1979; Yoder and Peale, 1981; see also **Chapter 10.08**).

With respect to the icy satellites, tidal heating has been considered mainly in application to Europa to infer the thermal state and thickness of the ice shell (Cassen et al., 1979, 1980; Hussmann et al., 2002; Mitri and Showman, 2005; Ojakangas and Stevenson, 1989; Ross and Schubert, 1987; Sotin et al., 2009; Tobie et al., 2003; see also the details in **Section 10.18.7.2**) and in application to Enceladus to explain the tectonic surface features (Peale, 2003; Poirier et al., 1983; Ross and Schubert, 1989; Squyres et al., 1983a).

Thermal–orbital models have also been applied to explain Ganymede's tectonic surface features by an evolution into the Laplace resonance (Showman and Malhotra, 1997) and to investigate the thermal–orbital history of Europa and its ocean over long timescales (Hussmann and Spohn, 2004). The relation between the orbital history and tidal dissipation in Titan has been discussed by Sohl et al. (1995) and Tobie et al. (2005, 2006).

10.18.6.2 Heat Balance

The evolutionary paths of the icy moons are as diverse as is the appearance of their surfaces and their bulk structure. It is therefore impossible to describe all aspects by a simple set of governing equations. However, the basis of all evolution models is an energy balance between the internal heat sources and the heat transport equations depending on viscosity (in case of convection) and material parameters. The distribution of heat sources will depend on the state of differentiation and, in case of tidal heating, on the orbital state of the satellite. The initial conditions will furthermore depend on accretional processes and the thermal environment due to solar insolation. The heat balance equation for a spherical shell with density ρ, heat capacity c, temperature T, and volume V, bounded by the surfaces S_1 and S_2 ($S_1 > S_2$), is given by (Schubert et al., 1986)

$$\int_V \left(\frac{\mathrm{d}}{\mathrm{d}t}(\rho c T) - H_V \right) \mathrm{d}V = \int_{S_2} q_2 \mathrm{d}S - \int_{S_1} q_1 \mathrm{d}S \qquad [11]$$

where H_V is the total heat production rate per unit volume and q_1 and q_2 are the heat fluxes (power per unit surface) into the shell (through surface S_1) and out of the shell (through surface S_2), respectively. Appropriate equations describing the convective or conductive heat flows have to be applied to calculate q_1 and q_2. Both parameterized convection models and numerical approaches solving directly the Navier–Stokes equations for the convective ice shell subject to certain boundary conditions have been applied to investigate the evolution of icy satellites. Two-dimensional numerical models were extensively developed in application to the ice shells of the Galilean satellites (Barr and Showman, 2009; Showman and Han, 2004). The disadvantage of such an approach, in which fewer parameters are required, is an immense increase in computational time (further more for three-dimensional models) and the greater effort that is required to couple such models with other theories, for example, tidal heating and orbital evolution. Additionally, in some specific problems where the information on flow patterns as a result of numerical models is not needed, parameterized models may be preferred.

An integration of eqn [11] can be done for several shells with different material parameters or heat sources, describing the individual layers of the satellite. The initial temperature profile required for the integration is usually given by an assumed accretional profile of the satellite (e.g., Schubert et al., 1986).

10.18.6.3 Thermal Histories

Thermal histories have been calculated mainly in application to the Galilean satellites and the satellites of Saturn (Consolmagno and Lewis, 1976, 1978; Ellsworth and Schubert, 1983; Lupo, 1982; Multhaup and Spohn, 2007; Schubert et al., 1981, 1986). Typical evolution scenarios of homogeneous midsized icy satellites can be divided into four phases (Ellsworth and Schubert, 1983; Multhaup and Spohn, 2007; Schubert et al., 1986): (1) the initial accretional state is characterized by a cold interior, a temperature increase with radial distance from the center, and a steep thermal gradient at the very surface due, in part, to impact heating (e.g., Schubert et al., 1986); (2) the satellite is then heated from within due to radioactive decay of long-lived isotopes. The internal temperature increases and, after a typical time of the order of several tens of My, the temperature profile is reversed, with the central region being warmer than the outer part of the satellite; (3) depending on the heat sources available and the size of the satellite, convection may start while the satellite heats up. In this phase, maximum temperatures will be reached, with the satellite being in its most dynamic phase, characterized by a maximum surface heat flow and internal activity. Convection leads to more efficient cooling of the satellite whose temperature then again decreases with time for several Gy; (4) at a certain time, convection will stop due to the generally decreasing radiogenic heating rate, and the satellite will further cool conductively up to 4.5 Gy, that is, the present time.

According to such a scenario, all the small and midsized satellites are expected to be in the fourth, relatively cold phase, cooling conductively. However, further modifications of that scenario can arise if the internal temperatures exceed the melting temperature of ice-I or ice-I/volatile mixtures within the satellite. In that case, liquid layers may form and the satellite will differentiate, forming a rock core and an outer ice layer, possibly contaminated with rocks. A liquid layer may persist enclosed between the rock and the ice layers. Whether these layers can survive up to the present time will depend on the rock content (and thus heating rate of the satellite) and on the amount of volatiles included in the liquid. Because of freezing of pure ice at the top of the liquid layer, the volatile content in the liquid will increase, thereby impeding crystallization until the eutectic composition is reached. Further cooling will lead to the crystallization of the eutectic mixture. Lewis (1971) noted the significance of ammonia as the most important antifreeze component for icy satellites and concluded that the largest objects still may contain liquid layers in their interiors, a result that is consistent with more recent models of icy satellites (Hussmann et al., 2006; Spohn and Schubert, 2003).

It should be noted that in these evolution models, additional heat sources, like tidal heating, that may have been important for individual satellites are neglected. The enormous internal heating and activity of Enceladus (Porco et al., 2006;

see also the details in Section 10.18.7.4) shows that individual satellite histories may be completely different from the general scenario described here. However, most of the midsized satellites' surfaces are heavily cratered showing only little or no signs of recent activity, which is consistent with the general concept of evolution of this class of objects.

The importance of tidal heating for satellites was realized prior to the *Voyager* arrivals at Jupiter (Peale et al., 1979). Whereas radiogenic heating is the major heat source in the inner solar system, tidal heating has been recognized as an important driver for the evolution of satellites in the outer solar system in various applications. A notable difference to radiogenic heating is the strong feedbacks that can be initiated by tidal heating. Through the temperature-dependent rheological parameters, both the dissipation rate itself and the efficiency of heat transport can be affected by tidal heating. Furthermore, the energy that is dissipated comes from orbital and/or rotational energy of the satellite. Therefore, tidal heating connects the thermal evolution with the orbital and rotational histories of the satellites. In addition, it may have played a crucial role for geologic processes that have shaped the satellite surfaces. Thus, processes like tidal heating, convection, orbital evolution, geologic activity, and furthermore formation, differentiation, and later evolution of satellites are interrelated and interdependent. In case of orbital resonances, even the evolution of different satellites and their respective energy budgets are related to each other. We will discuss examples in applications to specific satellites further below.

For the large icy satellites, more complex evolution scenarios, including core formation or the segregation of rocks within the ice shells, have been applied to understand their physical characteristics. This includes models of the incomplete differentiation of Callisto to explain the substantial differences between Ganymede and Callisto (Barr and Canup, 2010; Kirk and Stevenson, 1987; McKinnon, 2006; Mueller and McKinnon, 1988; Nagel et al., 2004) or the differentiation and evolution of Titan (Fortes, 2012; Grasset and Sotin, 1996; Grasset et al., 2000). The three large icy satellites Ganymede, Callisto, and Titan are further discussed in the following section.

Besides the physical evolution described so far, the chemical history of the icy satellites, which is directly linked to the composition (including minor components) of the nebula in which the satellites accreted, plays an important role (e.g., Kuskov and Kronrod, 2005; Lunine and Stevenson, 1982). Models have been developed mainly in application to Titan to understand the unique coupling between interior, surface activity, and atmosphere of this icy moon (Lunine and Stevenson, 1987; Tobie et al., 2006; see also **Section 10.18.7.3**).

10.18.7 Interior Structure of Selected Icy Satellites

While the densities of the Galilean satellites and Titan were determined to high accuracy during the *Voyager* flybys, it was the *Galileo* spacecraft that obtained most of the information on the interior structure of the Galilean satellites as it orbited around Jupiter between 1995 and 2003. *Cassini* has provided important data during a set of dedicated 'radio science' flybys of Titan and other satellites in the Saturn system. In the following, we discuss a selection of the icy satellites in detail, focusing on results from the *Galileo* and *Cassini* missions with respect to internal structure. For the Saturn system, we discuss the largest satellites, Titan, Rhea, and Iapetus, as well as the presently active satellite Enceladus. Saturn's midsized satellites are also discussed by Matson et al. (2009). In addition to the satellites of Jupiter and Saturn, we discuss Neptune's moon Triton, for which activity at the surface has been revealed by the *Voyager* 2 spacecraft.

10.18.7.1 Ganymede and Callisto

Ganymede is the largest satellite in the solar system with a radius of 2634 km. Its density of 1940 kg m^{-3} lies in between the densities of silicates and that of water. The observation that Ganymede has its own intrinsic magnetic field and forms a small magnetosphere inside Jupiter's vast magnetosphere was a major discovery of the *Galileo* mission. Ganymede has a clear signature of a permanent dipole (Kivelson et al., 1998). As pointed out by Stevenson (2003), a permanent magnetism explanation is conceivable (Crary and Bagenal, 1998) but unlikely, and the most reasonable interpretation is a dynamo in the metallic core (Schubert et al., 1996). Kivelson et al. (2002) suggest a dipole moment equal to 1.32×10^{20} A m^2. The dipole is tilted by 176°, almost antiparallel to the spin axis. The few flybys allow only for the determination of the degree 1 and 2 coefficients of the spherical harmonic decomposition of the magnetic field. By determining the loss of power between degrees 1 and 2, the radius of a liquid iron core has been evaluated around 200 km (Kivelson et al., 2002). By comparison with Earth, a liquid Fe–S core is expected although the nature of the light element in Earth's core is still debated. Because of the self-sustained magnetic field, we can assume that within Ganymede, the metal-rich component has separated from the rock, forming an iron core, surrounded by a silicate mantle. The outer layers consist of H_2O, which will be present in the form of high-pressure ice, ice-I, or liquid water, depending on internal pressure, temperature, and composition as a function of depth.

A dipolar field cannot fully explain the magnetic data. Two models have been proposed by Kivelson et al. (2002) in order to explain the remaining signal: quadrupole terms resulting from the dynamics of the core dynamo and an induced magnetic dipole driven by the time-varying component of the externally imposed magnetic field of Jupiter's magnetosphere. Both models give equally satisfactory fits to the data although the inductive field is favored (Kivelson et al., 2002) due to its presence within Europa and Callisto (see the succeeding text).

The gravity data alone can provide the moment of inertia assuming hydrostatic equilibrium. A value of 0.3115 ± 0.0028 has been obtained (Anderson et al., 1996; Schubert et al., 2004), implying that Ganymede is strongly differentiated (**Figures 6** and **8**). A two-layer model (silicate core and H_2O mantle) cannot explain this very small moment of inertia if reasonable values are taken for the densities of silicate and H_2O (Anderson et al., 1996). It should be noted that there are nonhydrostatic contributions to the gravity field of Ganymede. Those contributions can be explained by mass anomalies that might correlate with the geologic units (dark vs. bright terrain) on Ganymede (Palguta et al., 2009).

An iron-rich core that is required to explain the small value of the moment of inertia is in complete agreement with the interpretation of the magnetic data (Bland et al., 2008; Kimura et al., 2009). However, the radius of each interface cannot be precisely determined since it depends on the choice made for the densities (see also **Chapter 10.02** on the inherent ambiguity of such models). The thickness of the H_2O layer is in the range between 600 and 900 km (Deschamps and Sotin, 2001; Sohl et al., 2002). Due to the high-pressure value reached at the bottom of the H_2O layer, high-pressure ice phases must exist below depth of roughly 150 km. The H_2O layer is subdivided into ice-Ih, ice-III, ice-V, and ice-VI sublayers (**Figure 8**).

The state of the H_2O outer layer is a subject of debate. If a liquid layer exists, as suggested by the induced magnetic field (Kivelson et al., 2002), it should be located between the ice-I and the ice-V layers (**Figures 6** and **8**). If the liquid layer is pure water, and if there is no other internal heating source than the radiogenic decay in the silicates (0.6 TW, **Table 2**), then the scaling laws describing stationary convection suggest that the ice viscosity should have a value around 10^{15} Pa s (**Figure 12**). Such a value is much larger than the viscosity of ice measured on terrestrial glaciers. If the melting-point viscosity is comparable with that of terrestrial glaciers (5×10^{13} Pa s), then the amount of heat that can be removed is on the order of 1.5 TW. Another source of heat, for example, tidal heating, is required to explain such a large value. According to simulations (Showman and Malhotra, 1997; Sotin and Tobie, 2004; Tobie et al., 2005), present-day tidal heating cannot be larger than radiogenic heating and cannot explain such a large value. Another explanation invokes the presence of antifreeze materials that would lower the temperature (increase the viscosity) at the solid–liquid interface (Spohn and Schubert, 2003). But this is clearly not proven.

The differentiation of the metallic (largely iron, based on solar abundances) core may have been a late episode in the evolution of the icy satellites (Deschamps and Sotin, 2001; Grasset and Sotin, 1996). This hypothesis presumes that the outer ice layer acts as an insulator that cannot release all the heat produced by the decay of the radiogenic elements. How the internal dynamics and evolution scenarios, including core formation, are related to Ganymede's geology – characterized by two types of terrain, the heavily cratered dark terrain and the less cratered bright terrain (e.g., Patterson et al., 2010) – is still an open question. Images obtained by *Voyager* and *Galileo* suggest that Ganymede experienced some resurfacing events at about 3.5 Ga. In the case of Ganymede, the link between orbital evolution into the Laplace resonance and thermal evolution by heat pulses through enhanced eccentricities is a promising scenario (Showman and Malhotra, 1997). As suggested by Bland et al. (2009), this may also explain phases of global expansion that occurred during Ganymede's history as derived from extensional features on the surface.

Callisto's radius is about 200 km smaller than that of Ganymede and its mass is 70% that of Ganymede. The old, heavily cratered, and dirt-rich surface suggests that endogenic resurfacing has never happened since the satellite completed its accretion. The post-*Galileo* view of Callisto is surprising. If hydrostatic equilibrium is achieved, the *Galileo* gravity data suggest that the moment of inertia is equal to 0.3549 ± 0.0042 (Schubert et al., 2004). This value is not compatible with a fully differentiated Callisto (Anderson et al., 2001b). It should be noted, however, that the *Galileo* flybys were near equatorial, implying that the gravity field coefficients J_2 and C_{22} could not be determined independently. Furthermore, the derived S_{22} value is nonzero, suggesting deviations from the hydrostatic state. In the case of Callisto, relatively large uncertainties about the internal structure and hydrostaticity remain that could best be addressed by tracking polar (or highly inclined) flybys and orbits of future missions complementing the *Galileo* data.

The magnetic data suggest that an ocean is present at depth around 150 km (Khurana et al., 1998; Zimmer et al., 2000). These two interpretations of geophysical data seem contradictory since the presence of an ocean would probably lead to differentiation. In order to reconcile these two observations,

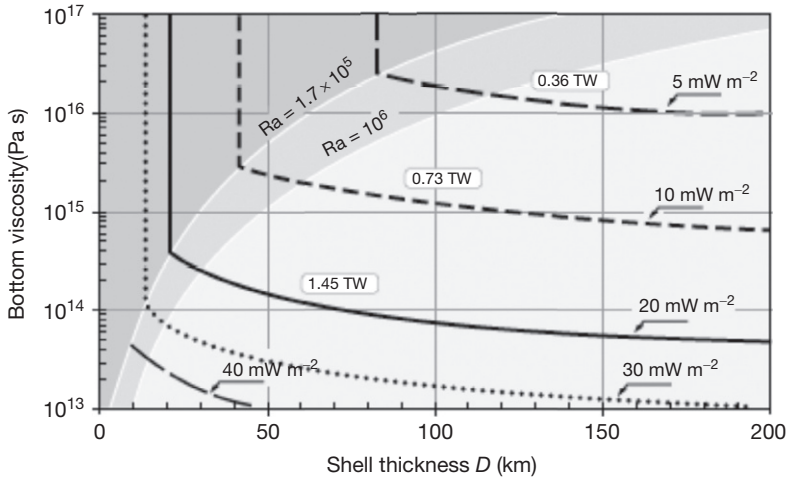

Figure 12 Amount of heat transferred by conduction or by convection within the ice-I shell of a large icy satellite, plotted as bottom viscosity, required to match a given heat flux versus thickness of the shell. Lines of constant total power and surface heat flow (power per unit area) are shown. Parameters for Callisto have been used.

Nagel et al. (2004) propose that Callisto's core is a mixture of ice and rock with the rock concentration near the close-packing limit.

Models of heat transfer in the ice-I outer layer of Callisto vary in their results. One model suggests that convection is not possible, which explains the presence of the ocean (Ruiz, 2001). McKinnon (2006) suggests that the cooling from above of the ice-I shell leads to subsolidus convection. This latter work confirms the results of previous modeling studies (e.g., Deschamps and Sotin, 2001). The amount of heat that can be removed by subsolidus convection is the same whether one uses the scaling laws proposed by Dumoulin et al. (1999) or those described in Deschamps and Sotin (2001). The amount of heat transferred depends strongly on the viscosity and weakly on the thickness (**Figure 12**). This amount is much larger than the heat released by the decay of the radiogenic elements at present time (0.4 TW, **Table 2**) unless the viscosity of ice near its melting point is larger than 10^{15} Pa s. Convection is able not only to remove the radiogenic heat but also to freeze the ocean very quickly unless some antifreeze contaminants like ammonia are present (Deschamps and Sotin, 2001; McKinnon, 2006; Spohn and Schubert, 2003).

The comparison between Ganymede and Callisto is interesting since these two satellites have mass and radius that are fairly similar but their internal structure is apparently quite different. Ganymede is fully differentiated with a liquid iron core generating a magnetic dynamo, whereas Callisto is only partially differentiated. Another difference is their surfaces. Ganymede's surface was tectonically active, whereas Callisto's surface does not show any sign of late activity. More information about their interiors is needed to understand why they are so different. The lower radiogenic power within Callisto may be one explanation. Alternatively, different accretion scenarios, due to different locations in the Jovian subnebula (Barr and Canup, 2008; Canup and Ward, 2002; see also **Chapter 10.17**), may be considered. This would be closely connected with the evolution of Ganymede into the Laplace resonance locking. Callisto has not been captured in resonance with the other satellites, and tidal heating never has played a significant role in its evolution. Both a primordial origin (Peale and Lee, 2002) and an evolution into resonance at a later stage (Bland et al., 2008; Showman and Malhotra, 1997) may have caused a difference between the two satellites with respect to internal structure and geology. Barr and Canup (2010) suggest different impact rates and thus higher amounts of energy provided to Ganymede's surface and interior (as compared to Callisto) during late heavy bombardment as a driving factor for the different evolutionary paths.

The example of Ganymede and Callisto shows that not only the bulk composition but also the interaction with other satellites or with the subnebula during the phase of accretion determines the satellite evolution. Evolution scenarios of icy moons in many cases cannot be considered separated from each other but must be seen in the context of the whole satellite system.

10.18.7.2 Europa

With respect to the distance from Jupiter, Europa is the second of the Galilean moons (note that there are additionally four small satellites, Metis, Adrastea, Amalthea, and Thebe inside Io's orbit, which is the innermost of the Galilean satellites), orbiting around the giant planet at a period of 3.55 days. Its density of 3018 kg m^{-3} lies between that of Io (3530 kg m^{-3}) and those of Ganymede (1936 kg m^{-3}) and Callisto (1851 kg m^{-3}). The mass fraction of ice on Europa is only about 6–9% based on the mean density. Thus, Europa is a fundamentally rocky body with only small amounts of H_2O. The characteristics of the gravity field have been measured during several Europa flybys in the course of the *Galileo* mission (Anderson et al., 1998; Schubert et al., 2004). Unfortunately, the flybys were not with a geometry that allowed J_2 and C_{22} to be determined independently from each other. Assuming hydrostatic equilibrium ($C_{22} = 0.3\ J_2$), it is possible to determine the value of the hydrostatic Love number k_f, which is related to the moment of inertia C about the rotation axis by the Radau formula (eqn [3]). The value of 1.048 ± 0.020 found for Europa suggests that it is fully differentiated including an iron-rich core, a silicate mantle, and an H_2O shell (Anderson et al, 1998; Schubert et al., 2004, 2009; Sohl et al, 2002). Another way to interpret the density data, which cannot be completely ruled out on the basis of the MoI value, is that Europa would be made of a large core not separated in metal and rock overlaid by a layer of H_2O (e.g., Schubert et al., 2009). However, such a structure is unlikely because the required mean density of the rock/iron mixture would exceed the mean density of Io. Enrichment in heavy elements in Europa would, however, be difficult to understand for a satellite smaller than Io that has formed further away from Jupiter in a colder region of the Jovian subnebula. Typical density models of Europa assume three-layer structures with core sizes ranging roughly between 300 and 700 km and thicknesses of the H_2O layer between 80 and 170 km. The values depend on the assumed core and silicate densities (Anderson et al, 1998; Schubert et al., 2009; Sohl et al., 2002). The core density would be significantly reduced by volatiles, for example, sulfur. The mantle density is likely to range between 3000 and 3500 kg m^{-3} constrained by Io's density (upper bound) and likely lacks hydrated silicates (lower bound). Under given pressure conditions on Europa, hydrated rock would release its water at temperatures as low as 500–800 °C (Schubert et al., 2004), which are difficult to avoid in Europa's evolution, especially in the view of tidal heating and differentiation processes that have occurred on Europa.

Additional information about the internal structure of Europa comes from magnetometer measurements during the *Galileo* mission. Europa has a strong inductive magnetic field (see also **Section 10.18.5.5**) consistent with an electrically conducting interior with an outer radius equal to nearly the entire radius of the moon (Khurana et al., 1998; Zimmer et al., 2000). However, it does not show any evidence of a permanent dipole. The induction field can be explained by a water ocean of similar conductivity to the Earth's oceans, provided this ocean has a thickness exceeding 10 km (Kivelson et al., 2000). These measurements of an induced magnetic field provide the strongest observational evidence for the present-day existence of an ocean.

The high-resolution images obtained during the *Galileo* mission provide some clues about Europa's internal structure and evolution. Compared to the other icy Galilean satellites,

Europa's surface displays intriguing tectonic features, such as domes, disrupted blocks, chaotic terrains, and fractures (Carr et al., 1998; Collins and Nimmo, 2009; Collins et al., 2000; Doggett et al., 2009; Greeley et al., 1998, 2004; Greenberg et al., 1998; Kattenhorn and Hurford, 2009; Pappalardo et al., 1998, 1999; Prockter and Patterson, 2009; Riley et al., 2000; Spaun et al., 1998). The small number of impact craters suggests that Europa's surface has undergone substantial resurfacing by either tectonic or cryovolcanic processes. It is younger than the surfaces of the two other icy Galilean satellites Ganymede and Callisto. However, it is difficult to obtain absolute ages of surfaces from the number of impact craters, because the cratering rate in the outer solar system is not well known. Models suggest for the surface of Europa ages between 10 million years and several hundred million years (Bierhaus et al., 2009 and references therein). Another possibility for assessing the age is the erosion rates by sputtering. The estimates of erosion rates by sputtering are constrained by the measurements of the H_2O escape rate during the *Galileo* mission. If sputtering has been operating for more than 1 billion years, it should have erased most of the topography; however, this is not the case for Europa. The remaining topography of Europa is consistent with an age of its surface in the range of some million years (Pappalardo et al., 1999).

The disrupted blocks, also called 'rafts,' have been interpreted by different models. Collins and Nimmo (2009) list the following models for formation of chaotic terrain: (a) melt through, (b) diapirism, (c) brine mobilization by diapirism, (d) brine mobilization driven by partial melt through, (e) sill formation, and (f) impacts. The melt-through and brine mobilization models can explain key features of chaos terrain. However, it is still not clear how both large ($\sim$1000 km) and small ($\sim$1 km) features can be generated by these processes.

In the thin-shell model, the outer solid layer is less than a few kilometers thick and the surface is constantly in contact with an ocean below due to tidal cracking and disruption. Small variations in the thermal gradient cause chaos and lenticulas (Carr et al., 1998; Greenberg et al., 1999). In another thin-shell model (Thomson and Delaney, 2001), the thin crust is periodically broken by faults that form in response to the tidal forces resulting from Europa's eccentric orbit around Jupiter. The blocks resulting from the faulting of the ice crust could then be entrained by the streams of the liquid ocean and could move relative to each other. Because the surface temperature is far below the freezing point, the displacement of the blocks would be limited by the rapid freezing of any liquid that would be present in between the blocks.

Schmidt et al. (2011) suggest that chaos terrain forms above liquid water lenses perched within the ice shell. By their model, topographic heights of chaos terrain, for example, *Conamara Chaos*, can be explained by refreezing of liquid reservoirs. Active melting would result in topographic depressions, as observed for *Thera Macula* a region potentially showing active resurfacing.

Another reason for the crust to be disrupted is the possibility for localized sources of heat in Europa's silicate layer (e.g., Goodman and Lenferink, 2012). It may be conceivable that tidal forces would lead to partial melting in Europa's silicate layer (e.g., Moore and Hussmann, 2009) and volcanism at the silicate–water interface. Such a scenario is inspired by Io's very active volcanism. In this case, the water would be very hot during a volcanic eruption and would rise to the surface, melting the ice crust and inducing strong displacements. However, the amount of heat dissipated in Europa's silicate shell and deep interior is not well constrained and whether it would allow for silicate volcanism is presently unknown.

It must be noted that volcanism is not necessarily required. Convection in Europa's silicate layer would create zones of higher temperature, and percolation of water within the silicates would create conditions favorable for hydrothermalism (Lowell and DuBose, 2005) and subsequent displacement of hot water to the surface. Such a scenario is appealing for exobiology because the conditions at the silicate–ocean interface would be very similar to those existing on Earth's seafloor.

An alternative model suggests that the blocks and domes are related to subsolidus (solid-state) convection in the lower part of the crust (McKinnon, 1999; Nimmo and Manga, 2002; Pappalardo and Barr, 2004; Pappalardo et al., 1998; Rathbun et al., 1998; Sotin et al., 2002). In this model, the domes are explained by the topography resulting from the rising of hot subsolidus icy plumes forming at the interface between the liquid layer and the icy shell. The topography of the domes is not well constrained and cannot be used to constrain the characteristics of the upwelling plumes. If this is the right explanation for the domes, it implies that the icy crust is at least 20 km thick. The chaotic terrain would form by the collapse of the upper crust as depressions form due to partial melt in the plume head induced by tidal heating (Sotin et al., 2002). Convection models that include surface weakening and compositional buoyancy are promising approaches in explaining some chaos terrains, pits, and uplifts (Barr and Showman, 2009). However, the current data are likely to be too limited to unambiguously determine the formation processes of the different features.

Europa is unique in displaying large-scale cycloidal fractures on its surface. The formation of these features is closely connected to the diurnal tides on Europa (Hoppa et al., 1999). As tidal stresses build up during one orbital cycle, cracking occurs when the tensile strength of the ice is reached. The opening crack would then propagate according to the time-dependent stress field dictated by the tidal potential. When the tensile stress becomes insufficient to continue crack propagation, it would stop at a certain point. After a few hours when the tensile stress has built up again, the crack would continue to propagate. However, the direction would be different because of the different tidal stress field. The resulting cracks form arcuate segments connected to a cycloidal chain with lengths of several hundreds or thousands of kilometers. The formation of these features requires sufficient tidal amplitudes that are only occurring when a thick fluid layer is present below the ice shell. The cycloidal features therefore provide strong evidence for a subsurface ocean on Europa at the time they formed. Further evidence for such a global decoupling layer comes from *Galileo* imaging analysis, suggesting nonsynchronous rotation of the ice shell on a timescale of $\sim$10 000 years (Geissler et al., 1998). By the analysis of orientation and distribution of lineaments on Europa, it was found that the ice shell rotates slightly faster than synchronous. Based on gravity data, it is inferred that the bulk of Europa is

rotating synchronous. Therefore, nonsynchronous rotation would imply a decoupling layer between the ice shell and the deep interior.

Albeit on a smaller level as compared to Io, Europa is subject to tidal heating (Cassen et al., 1979, 1980; Hussmann et al., 2002; Ojakangas and Stevenson, 1989; Ross and Schubert, 1987; Sotin et al., 2009; Squyres et al., 1983b; Tobie et al., 2003, 2005). The heat generated by tidal flexing can be more than one order of magnitude larger than radiogenic heating alone and could explain the presence of an ocean below the icy crust. Since the amount of ice is small, high-pressure phases cannot form and the ocean would be in contact with the silicate core, which makes Europa quite appealing from an astrobiology point of view.

There are also a few multiringed structures on Europa, such as Tyre and Callanish, which are interpreted as impact features. Studies of the morphology of impact craters suggest an ice thickness at the time and location of the impact of about 4–20 km, converging on the range of 15–19 km (Schenk and Turtle, 2009). This interpretation of the formation and relaxation of impact craters is a strong argument in favor of a deep liquid ocean below an icy crust. Although an entirely solid convecting layer of 'warm ice' may also be consistent with crater relaxation, such a structure is unlikely because a thick low-viscosity layer would lead to vigorous tidal heating exceeding by far the heat loss due to convection. The disequilibrium between heat production and heat flow would cause melting and thinning of the ice layer that would again imply an ocean layer at the base of the ice shell (Hussmann et al., 2002).

With the progress made in modeling thermal convection in planetary interiors, models describing Europa's thermal evolution have substantially improved in the last 20 years. The main important improvements are the description of convection with complex temperature and compositional dependencies (e.g., Barr and Showman, 2009 and references therein) and the coupling between orbital characteristics and tidal heating, originally proposed for Io (Fischer and Spohn, 1990; Greenberg, 1982; Yoder and Peale, 1981) and later applied to Europa (Hussmann and Spohn, 2004; Tobie et al., 2005).

As stated before, the amount of tidal heating is much larger for Europa than for the two Galilean satellites Ganymede and Callisto or for Saturn's moon Titan. It may be more than an order of magnitude larger than radiogenic heating. Tidal dissipation is mainly located in the convective layer of the ice shell, that is, in the region where the temperature is close to the melting point (see **Figure 11**). The very effective tidal heating within a thick high-temperature layer would prevent the ice layer from freezing because with increasing ice thickness, the heating rate will also increase significantly, exceeding the rate of heat transfer. The equilibrium thickness in which the tidal heating rate in the ice shell and the radiogenic heating from the rocky mantle are balanced by the convective heat flow is of the order of 30–40 km (Hussmann et al., 2002), which is less than the total thickness of 70–200 km of the total H_2O layer derived from the gravity data, therefore suggesting the presence of an ocean.

Tidal heating in a convective shell explains the presence of an ocean within Europa even without invoking the presence of antifreeze material such as ammonia. However, it does not mean that antifreezing materials are absent. The induced magnetic field indicates that the ocean contains ions, as electrical conductors, and therefore, a reduction of the melting point can be expected. Inferences about the composition and evolution of Europa's ice–ocean–rock system mainly rely on modeling and laboratory data (Zolotov and Kargel, 2009). Data from future space missions, in particular spectroscopic observations of the surface and the search for active plumes, would be required to further assess possible ocean composition and its astrobiological potential.

Consistent with geologic observations (e.g., Figueredo and Greeley, 2004), the thickness of Europa's ice shell additionally may be subject to considerable changes with time, adjusting to the corresponding heat budget (e.g., Nimmo and Manga, 2009). The latter varies not only due to the decay of radioactive isotopes, which would imply an increase of thickness due to the decreasing heat source, but also due to the orbital state and the resulting tidal heating. The tidal deformation and also the tidal dissipation rate will depend on the orbital eccentricity and mean motion (eqn [10]). Since Europa is locked in resonance with Io and Ganymede, its eccentricity is forced and oscillations in both the orbital state and the heat production rate may occur as a response to Io's thermal–orbital state, which is mainly controlled by tidal interaction between Io and Jupiter (Yoder, 1979; Yoder and Peale, 1981). Oscillatory phases have been proposed for Io by Ojakangas and Stevenson (1986) and by Fischer and Spohn (1990). As a consequence of such a thermal–orbital coupling, the thickness of Europa's ice shell may vary between a few kilometers and a few tens of kilometers on a timescale of the order of 100 Ma (Hussmann and Spohn, 2004). The observed diversity of geologic surface features on Europa may be partly explained by these time-dependent variations of ice thickness.

Because of the resonance locking, Europa's eccentricity is maintained on geologic timescales. Therefore, tidal heating would not cease, which is essential for any biological evolution that might have started at some point in Europa's history. Depending mainly on the tidal interaction between Jupiter and Io, tidal heating may operate on Europa for Gy preventing the ocean from freezing and adding heat to Europa's interior. Europa is therefore a very attractive body for exobiology (Greenberg et al., 2000; Hand et al., 2009; Reynolds et al., 1983), even more because the water layer is likely to be in contact with the silicate core, allowing for complex chemical processes (Kargel et al., 2000; Zolotov and Kargel, 2009). At this interface, hydrothermal systems similar to those at terrestrial seafloors may play a role (Lowell and DuBose, 2005). It has been envisaged that the conditions may be analogous to those existing at terrestrial black smokers where life develops without sunlight and where specific bacteria form. However, there is no evidence, yet, that Europa's silicate core is subject to volcanism and that tidal heating in the silicate shell is capable of producing zones of high heat flux as in the case of Io.

Recent numerical evolution models of Europa are also focusing on the dynamics within the ocean and its implications for heat generation and heat transport (Tyler, 2008; Chen et al., 2013) and on the salinity within the ocean (Travis et al., 2012; Vance and Goodman, 2009). Theoretic models of the rotation state of Europa (including small obliquities) have been investigated to infer possibilities to constrain the ice thickness above a decoupling ocean layer by measuring the libration amplitudes (Van Hoolst, 2008; Jara-Orue and

Vermeersen, 2014) and to understand the interplay between solid body-tides, the decoupling mechanisms, and the physical librations (Van Hoolst et al., 2013).

10.18.7.3 Titan

Titan, the largest satellite of Saturn, is unique among the moons in the solar system because of its substantial atmosphere and photochemically produced, dark orange stratospheric haze layer that precludes direct observations of the surface. Detailed information on the surface, however, was obtained from the landing of the *Huygens* probe (Lebreton et al., 2005) and by *Cassini* RADAR data collected over the course of the mission (Elachi et al., 2005; Stofan et al., 2006; Lopes et al., 2010). Titan's dense atmosphere that is dominated by molecular nitrogen with a substantial component of methane (Coustenis et al., 1989; Flasar et al., 2005; Owen, 1982) suggests that the satellite's interior is more enriched in volatile ices such as $NH_3 \bullet H_2O$ and $CH_4 \bullet nH_2O$, which have densities similar to that of water ice (Hunten et al., 1984). This is likely to be due to the lower temperature of the less massive proto-Saturnian nebula in comparison with the proto-Jovian nebula, which favors the incorporation of a larger amount of volatiles such as ammonia and methane at the distance of Titan (20.6 Saturn radii) without significantly affecting the satellite's mean density in comparison with Ganymede and Callisto.

The absence of rocky inner satellites in the Saturnian system may indicate lower temperatures of the nebula during the evolution of the gaseous and dusty accretion disk from which the satellite system formed by mutual collisions of icy and rocky planetesimals (Coradini et al., 1995; Owen, 2000). Based on the assumption that all nitrogen was originally supplied as NH_3, volatile components could appear in roughly cosmic abundances in the interior of Titan with ratios of $NH_3/H_2O \approx 1/6$ and $NH_3/CH_4 \approx 1$. Corresponding water ice–ammonia mixtures then have an ammonia content of 14 wt%, a composition more water-rich than the peritectic composition of about 32 wt% (Hunten et al., 1984; Lewis, 1972; Stevenson, 1992).

The presence and abundance of atmospheric methane that would be lost over the age of the solar system due to photolytic dissociation (Strobel, 1974) suggests that sources of methane must be present at the surface and possibly in Titan's interior (Sotin et al., 2005; Tobie et al., 2006). Such a connection between interior, surface, and the dense atmosphere allowing for Titan's methane cycle (Atreya et al., 2006) is unique for the icy satellites.

Titan is intermediate between the Jovian satellites Ganymede and Callisto with respect to its radius of 2575 km and mean density of 1881 kg m^{-3}. The mean densities of Ganymede, Callisto, and Titan indicate that their interiors are composed of ice and silicates in nearly equal amounts by mass (Lupo, 1982; see in the preceding text). The interior of Titan is likely to be differentiated at least into a rock + iron core and an icy mantle as a consequence of substantial accretional heating accompanied by partial outgassing and atmosphere formation (e.g., Grasset et al., 2000; Hunten et al., 1984). Based on *Cassini* flybys, Iess et al. (2010) have derived a moment of inertia of 0.3414, which is too high for fully differentiated models as obtained, for example, for Ganymede. Their interpretation is either an incomplete separation of rock from ice or a core in which a large amount of water remains chemically bound in silicates. Barr et al. (2010) suggested that a partial differentiation of Titan arises from undifferentiated accretion and impact-induced core formation permitting some of Titan's rock to consolidate into a core. Gao and Stevenson (2012) had argued that the actual moment of inertia may be less than the reported value because of possible nonhydrostatic effects that render invalid approximations used in Iess et al. (2010). If the maximum value of the MoI is used, then Titan has either a mixed rock–ice layer or a substantially hydrated silicate core (Castillo-Rogez and Lunine, 2010). The former is difficult to maintain (O'Rourke and Stevenson, 2013), while the latter requires substantial early leaching of radioactive isotopes into the overlying ocean (see the succeeding text) to avoid complete dehydration.

The orbital eccentricity of Titan causes tidal variations of the quadrupole moments from which the second-degree potential Love number k_2 has been derived (Iess et al., 2012). k_2 is related to the satellite's interior structure and rheological properties and reflects the gravitational signature of a substantial internal ocean. Indeed, the value of k_2 seems to be between 0.6 and 0.7 with the expected value of 0.45–0.5 about 2σ away from the mean. If further gravity flybys confirm the high value, then either Titan has solid layers that are highly compressible in addition to the ocean, or the ocean is substantially overdense compared to pure water, perhaps containing substantial amounts of sulfur as in Fortes (2012).

Evidence for subsurface oceans from induced magnetic fields as in the case of the Galilean moons could not be obtained in the Saturn system. The main reason is that the magnetic field axis of Saturn is not tilted significantly with respect to the rotational axis as it is the case for Jupiter. Therefore, variations in the field strength at the location of the moons are much smaller and could not be detected. Furthermore, Titan's orbit is relatively far away from Saturn. However, there is further evidence for a subsurface ocean on Titan based on the detection of the second harmonic of a Schumann resonance (Beghin et al., 2012) during the descent of the *Huygens* probe. The electric current sheets induced in Titan's ionosphere by Saturn's magnetospheric plasma flow could trigger electromagnetic waves in Titan's atmosphere that would be trapped in a Schumann resonance between two electrically conducting layers. The inner reflecting boundary is proposed to be a buried water–ammonia ocean lying at a likely depth of 55–80 km below a dielectric icy crust. The almost perfect electrical conductivity in the subsurface could be provided by such a global water ocean.

Further evidence for a subsurface ocean on Titan could be obtained by precisely determining the rotational state of the satellite. Current estimates of the moment of inertia from Titan's spin-pole orientation that are independent from the MoI determination from the gravity field differ from the latter. This discrepancy can be explained by a decoupling of the ice shell from Titan's deep interior, presumably by a subsurface ocean. However, the spin-pole orientation may also be affected by atmospheric excitations. To distinguish between these two models may be possible from further data analysis of *Cassini*'s extended mission (Bills and Nimmo, 2011).

Depending on the amount of volatiles incorporated into the icy mantle and depending on the satellite's thermal evolution, an ammonia-rich liquid water layer may be located between the near-surface ice-I layer and solid high-pressure ice layers at greater depth (Grasset and Sotin, 1996; Grasset et al., 2000; Sohl et al., 2003).

Because of Titan's close resemblance to Ganymede in mass and overall density, the evolution of the two bodies should be similar assuming identical compositions and boundary conditions. However, a number of arguments have been advanced that Titan incorporated some amount of ammonia in its interior during formation (e.g., Niemann et al., 2005) and might have also incorporated large amounts of methane (Tobie et al., 2006). The former implies a substantial liquid layer would exist throughout Titan's history, and the latter implies significant changes in the thermal properties of the upper ice-I crust if the methane were to force its conversion to methane clathrate hydrate (Lewis, 1971).

A pristine water-rich ammonia–water ocean may have formed as a consequence of the blanketing effect of a hot protoatmosphere, if accretion was completed within 10^4–10^5 years (Kuramoto and Matsui, 1994). This would freeze from top and bottom. It has been suggested that the ice-I layer on top of the ocean was initially cooling and thickening due to thermal conduction and became unstable to convection about 200 My after accretion (Grasset and Sotin, 1996). Some volatiles will presumably be present in the form of hydrates and clathrates, thereby affecting the rheological and thermal properties of the ice layers (Hunten et al., 1984; Stevenson, 1992; Tobie et al., 2006). The presence of volatiles tends to reduce the freezing temperature of the ocean, thereby lowering the temperature of the ice-I layer and increasing its viscosity. Larger viscosities due to temperatures far below the melting temperature then would retard convection and slow cooling of the ice-I layer, so that the subsurface ocean may have survived to the present day because of the progressing enrichment of ammonia as compared to the primordial ocean (Deschamps and Sotin, 2001; Grasset and Sotin, 1996).

Furthermore, during Ganymede's evolution into the Laplace resonance with Europa and Io, it may have been strongly heated, which possibly led to complete differentiation as described in the subsection earlier. Titan almost certainly experienced no such event though it is subject to periodically varying tidal distortions resulting from its significant orbital eccentricity of 0.0292 in addition to its permanent rotational flattening.

Evolution models instead are constrained to avoid excessive dissipation in Titan's interior throughout its history so as to maintain its observed present-day free eccentricity (Sohl et al., 1995; Tobie et al., 2005). There is considerable uncertainty in the initial eccentricity, both generally and specifically because Titan might have suffered collisions early on from one or more fragments from the breakup of proto-Hyperion (Farinella et al., 1997).

Models in which Titan is volatile-rich (ammonia and methane) evolve with time so as to maintain a very thin ice-I crust, typically 20 km or less, up to the last half billion years of Titan's history, because of the low thermal conductivity and high rigidity of methane clathrate hydrate in contrast to ice-I (Tobie et al., 2006). This, along with the onset of convection in the rocky core halfway through Titan's history and the gradual thickening of the crust via freezing of ice-I in the last half billion years, provides a potential setting for repeated outgassing of methane to the surface to replace that destroyed by atmospheric photo- and charged-particle chemistry (Lorenz and Lunine, 2005). However, the lines of evidence for the early presence of ammonia and outgassing of methane through geologic time are indirect, principally through the abundances of nonradiogenic and radiogenic argon (Niemann et al., 2005), and so the models must be regarded with caution.

10.18.7.4 Enceladus

As revealed by the *Cassini* mission, Enceladus is one of the very few planetary bodies in the solar system for which present-day activity was confirmed (Porco et al., 2006). Considering only the terrestrial planets and the satellites (not including comets, for instance), Enceladus is by far the smallest among these objects, with the others being the Earth, Io, and Triton. The huge amount of energy required to drive the cryovolcanic plumes, which are the dominant source of Saturn's E ring (Kempf et al., 2010; Spahn et al., 2006), and to cause the high temperatures and heat flow detected near Enceladus' south pole (Howett et al., 2011; Porco et al., 2006; Spencer and Nimmo, 2013; Spencer et al., 2006, 2009) still longs for an explanation. The geologically young terrain at several places on Enceladus and the recently strongly modified surface in the south-pole region further suggest that Enceladus contains internal heat sources. The plumes and the maximum temperatures correlate with the so-called tiger stripes, parallel fractures at the south pole, approximately 130 km long and separated by ~35 km (Porco et al., 2006; Spencer et al., 2006). The tiger stripes have raised margins enclosing a central trough approximately 2 km wide and 0.5 km deep (Spencer and Nimmo, 2013). From high-resolution imaging, the sources of erupting jets have been identified as the warmest regions within individual tiger stripes (Spitale and Porco, 2007). The strong correlation between the brightness of the plume and the orbital phase (Hedman et al., 2013) demonstrates the role of tidal forces in controlling the dynamics of the jets that compose the plume: at apoaxis, tidal forces create extensive stresses along the tiger stripes allowing material to be extruded more easily than at apoaxis (Hurford et al., 2007).

The nature of the heat-generating processes still remains unclear. One suggestion, already discussed in earlier works and motivated by surface images from the *Voyager* flybys, is tidal heating (Peale, 2003; Poirier et al., 1983; Ross and Schubert, 1989; Squyres et al., 1983a). Due to its proximity to Saturn and its elliptical orbit, Enceladus is subject to periodic tidal deformation, which will lead to internal friction and thus heating. Enceladus' eccentricity is forced by Dione, which is locked in a 2:1 mean motion resonance with Enceladus, thus keeping the eccentricity finite, presently at 0.0045. Depending on the internal temperature and rheological state of the satellite, tidal friction may be sufficient to power the observed activity. From *Cassini*'s composite infrared spectrometer instrument, an output of at least 5.8 ± 1.9 GW at the south-pole hot spot was derived (Spencer et al., 2006, 2009), which would be within the range of heat calculated from global tidal heating models under certain conditions. More recent estimates (Howett et al., 2011) suggest a heat output of 15.8 ± 3.1 GW. However, due to the complexity of the measurement, the true uncertainty might be larger (Spencer and Nimmo, 2013). A liquid layer decoupling the ice shell from the rock core would additionally enhance the tidal heating rate (as compared to a completely solid body) by approximately an order of magnitude. Global tidal heating models, however, cannot explain the asymmetry between the

north pole and the south pole of Enceladus by itself. Furthermore, Roberts and Nimmo (2008) had shown that under present orbital conditions, the heat flow would exceed the heat production rate due to tides and radiogenic heating, leading to freezing of the entire ocean. To prevent the ocean from freezing, specific assumptions on the rheology of the ice, on the orbital evolution, and/or on the composition have to be made.

Pockets of liquid water and local tidal heating restricted to the south-pole region is another option (Behounkova et al., 2012; Collins and Goodman, 2007; Tobie et al., 2008). In all these models, an additional process triggering vigorous tidal heating is required. A runaway process, similar to the one suggested for the rocky mantle of Io by Peale et al. (1979), is problematic because it would be expected rather for the innermost satellite Mimas, than for the more distant Enceladus. Under similar rheological conditions, tidal heating rates are at least ten times greater on Mimas, due to its proximity to Saturn and its greater orbital eccentricity (Squyres et al., 1983a). The striking differences between the two satellites, with Mimas being heavily cratered and geologically inactive for billions of years and Enceladus showing an enormous internal activity, are thus even more puzzling. Schubert et al. (2007) suggest that the higher rock content of about 60%, which was derived from the determination of the mean density by *Cassini* (Porco et al., 2006) compared to 20% in Mimas and the resulting higher radiogenic heating rates in Enceladus, can lead to the obviously different evolutionary paths.

Meyer and Wisdom (2007a) computed the tidal heating rate based on the assumption that the Enceladus–Dione resonance is currently in equilibrium. This would imply that the rate of decrease in orbital eccentricity due to dissipation in Enceladus is compensated by the rate of increase in eccentricity due to tidal torques by Saturn and the resulting increased eccentricity forcing by the resonance with Dione. Independent from a specific rheological model of Enceladus, the equilibrium heating rate would not be sufficient to explain the present-day heat flow of Enceladus (Meyer and Wisdom, 2007a). It should be noted that the calculated heating rate does depend on the assumed quality factor Q_S of Saturn. $1/Q_S$ is a measure for the energy dissipated in Saturn during one orbital cycle. It thus determines the total amount of energy available for the Enceladus–Dione system. The greater Q_S, the lesser dissipative is Saturn. However, for reasonable values of Q_S, the models do not match the measured heat flow values (e.g., $Q_S = 18\,000$ suggested as a lower bound by Meyer and Wisdom (2007a) would imply a maximum equilibrium heating rate in Enceladus of 1.1 GW).

There is evidence from the relaxation of craters (Bland et al., 2012) and the analysis of flexural uplift along a rift zone (Giese et al., 2008b) that Enceladus has passed through several periods of enhanced heating in its past. It should be noted that these high-heat-flow regions are not confined to southern latitudes only. Analogous to Io in the Jupiter system, episodic heating including periodic changes in eccentricity and heat production (Ojakangas and Stevenson, 1986) might be a possibility. However, according to Meyer and Wisdom (2008), the application of this model does not lead to oscillations about the tidal equilibrium in the case of Enceladus. A detailed analysis of the coupled thermal–orbital evolution including temperature-dependent rheological parameters and structures of Enceladus within the resonance with Dione would be required to understand Enceladus' history.

Possible modifications of the tidal scenario include a non-smooth evolution into the 2:1 Enceladus–Dione mean motion resonance involving large eccentricities, a past resonance locking with other satellites including the small satellite Janus enhancing the forced eccentricity of Enceladus (Lissauer et al., 1984), or possible spin–orbit secondary resonances before Enceladus reached its synchronous rotational state (Wisdom, 2004). The first alternative is problematic because the evolution into resonance could also be achieved smoothly, without involving chaotic behavior and large eccentricities (Peale, 2003). Meyer and Wisdom (2007b) have investigated Enceladus' evolution into the current resonance with Dione including several resonance passages. These simulations suggest that the Enceladus–Dione 2:1 resonance is entered close to tidal equilibrium, implying heating rates around 1.1 GW, only. However, a detailed dynamic evolution of Enceladus into the resonance including tidal heating and thermal–orbital coupling, that is, time-dependent rheological parameters, has not yet been undertaken. The third alternative would enhance the tidal heating rate by two or even three orders of magnitude if Enceladus was locked in a 3:1 secondary spin–orbit resonance (Wisdom, 2004) and could thus easily account for the difference between Enceladus and Mimas for which such a coupling cannot be expected. However, for the *Cassini*-derived shape parameters, these spin–orbit couplings are unlikely to be obtained by Enceladus.

If the physical librations of Enceladus' ice shell are large enough, they might cause significant tidal heating in the ice shell (Hurford et al., 2009). However, large libration amplitudes could not yet be confirmed by *Cassini*. The libration amplitude would be significantly enhanced if the ice shell is decoupled from the deep interior by a global ocean (as, e.g., suggested by Patthoff and Kattenhorn, 2011). Therefore, detecting the diurnal libration and measuring its amplitude is a crucial experiment to distinguish between global and local ocean models.

All the models involving global tidal heating cannot explain the strong asymmetry between the two poles of Enceladus, and to concentrate the heat sources within one relatively small region still is an open issue. Suggested mechanisms to enhance tidal heating locally include one-degree convection (Grott et al., 2007) and a locally mechanically weak lithosphere (Barr, 2008; Han et al., 2012; O'Neill and Nimmo, 2010; Roberts and Nimmo, 2008). Other processes, for example, shear heating (Nimmo et al., 2007), may be triggered by such hemispheric or local asymmetries. Reorientation would later drive the active region toward the south pole (Nimmo and Pappalardo, 2006).

As mentioned earlier, a liquid layer would enhance tidal heating significantly. However, radiogenic heating due to long-lived isotopes will be insufficient to maintain a liquid water shell up to the present time. Enceladus' mean density of 1609 kg m^{-3} (Thomas, 2010) suggests a rock-to-ice ratio of about 60–40 wt%. Although it is very likely, with regard to the energetic processes in its interior, that Enceladus is differentiated into a rock core of about 150–170 km thickness and an H_2O layer, there is no such evidence from independent measurements. Gravity flybys to determine J_2 and C_{22} are

still being analyzed (as of August 2013), and also the shape data showing several regional depressions (Schenk and McKinnon, 2009) are not easy to interpret. The differences of the satellite's main axes can be used to verify whether it has assumed a hydrostatically equilibrated shape of a rotating triaxial ellipsoid. In case of Enceladus, there is some ambiguity inherent in the data, and it cannot easily be distinguished between a homogeneous shape and, for instance, a 'frozen in' differentiated structure corresponding to a greater rotation rate in the past, when Enceladus was rotating synchronously closer to Saturn (Porco et al., 2006). Shape data are more consistent with a homogeneous structure (Thomas et al., 2007), which is on the other hand unexpected because of the activity and thermal state of the satellite. Differentiated structures would probably imply large, low-density cores. In addition, the layers might have lateral inhomogeneities in density. As noted by Thomas et al. (2007), fully relaxed, radially differentiated, laterally homogeneous models do not explain Enceladus' shape. A homogeneous structure would rule out a global ocean on Enceladus, which certainly would have implied complete differentiation. McKinnon (2013) suggested an irregular core, in terms of either density or topography, that would act to enhance the global geoid. Relaxation to the geoid could explain Enceladus' nonhydrostatic shape. Close flybys are required to further constrain Enceladus' internal structure. It should be noted that local processes, for example, a reorientation of an upwelling plume toward the south pole (Nimmo and Pappalardo, 2006), may contribute to the J_2 value. Thus, further flybys, equatorial and over the poles, would be required to reliably infer the structure of Enceladus.

The plumes observed by *Cassini* consist of a gas phase including mainly H_2O plus 5% CO_2, 1% CH_4, 1% NH_3, and small quantities of heavier hydrocarbons and organic molecules (Hansen et al., 2011; Waite et al., 2009) and a dust phase including water ice plus 1% salt, mainly NaCl (Postberg et al., 2011). The high water content can be interpreted as evidence for liquid water located close to the surface (Porco et al., 2006; Postberg et al., 2011; Schmidt et al., 2008). The required heat source to melt the ice and to power the activity, however, still remains enigmatic (see, e.g., Spencer and Nimmo (2013) and references therein).

10.18.7.5 Rhea

With a radius of 764.3 km, Rhea is the second largest satellite in the Saturn system. The density has been determined to be 1233 kg m^{-3} (Thomas et al., 2007), implying only a small amount (about 30%) of rock and a large fraction of water ice. Rhea's surface is heavily cratered. Prior to the *Cassini* flyby in November 2005, it was unclear if Rhea is differentiated, and hence, various internal structures had to be taken into account (Castillo-Rogez, 2006). The analysis of the Doppler data suggests an almost homogeneous structure (Anderson and Schubert, 2007, 2010) or a weakly differentiated satellite interior (Iess et al., 2007). Although there still remains a discrepancy in the value of C_{22} derived by Anderson and Schubert (2010) and Iess et al. (2007), a differentiated structure can be ruled out. In the latter analysis, the C_{22}/J_2 ratio is consistent with hydrostatic equilibrium within the given error bounds (Iess et al., 2007). A small degree of differentiation may be due to a concentration of rocks toward the center. Based on limb profiles, Nimmo et al. (2010) had estimated the long-wavelength topography of Rhea. Uncompensated degree-3 topography may contaminate the degree-2 gravity field data, a question that could be resolved by additional gravity flybys. Shape measurements of Rhea are consistent with the satellite being in a hydrostatic state (Thomas, 2010).

The possibility of Rhea being fully differentiated can be ruled out on the basis of the obtained data. This would most likely also rule out the existence of a deep subsurface ocean that would have been conceivable if the satellite were differentiated and contained at least small amounts of ammonia (Hussmann et al., 2006). In the models based on the *Cassini* Doppler data, the ice-I/ice-II phase transition occurs in the central region of the satellite. The formation of an ice-II core would be associated with a global contraction of the satellite that would have left its marks at the satellite's surface. However, being dominated by craters, the surface of Rhea is lacking such evidence. Whether the formation of an ice-II core occurred early in the satellite's evolution or whether temperatures were too low for the formation of ice-II remains unclear. According to Barr and Canup (2008), Rhea's partially differentiated state would imply slow accretion scenarios (~2 My) or a delayed accretion (by ~2–7 My) to avoid melting of the ices. It was also suggested that a high abundance of ammonia ice in Rhea's interior may have prevented the formation of the ice-II phase in the central regions (Prentice, 2006). Relaxation of impact crater topography suggests that Rhea has experienced heat flows of a few tens of m Wm^{-2} early in its history (White et al., 2013). Compared to Iapetus that is similar with respect to surface gravity, Rhea must have had a different thermal evolution with at least short phases of enhanced heating. The latter is probably related to rapid despinning and tidal interaction with Saturn (White et al., 2013).

10.18.7.6 Iapetus

With respect to size and density, Iapetus is comparable to Rhea. However, both satellites differ significantly in their surface characteristics as a consequence of their individual thermal and geologic evolution. Iapetus has a radius of 735.6 km and, based on its mean density of only 1088 kg m^{-3}, its rock content is even smaller than that of Rhea. Iapetus' interior is thus dominated by ice and the formation of ice-II in its central region is likely (Schubert et al., 1986). Long-lived radioactive isotopes in its small rock component are insufficient to completely differentiate the satellite (Ellsworth and Schubert, 1983; Multhaup and Spohn, 2007).

Iapetus' shape is inconsistent with its present synchronous rotation rate of almost 80 days and is best represented by an oblate spheroid (Thomas, 2010; Thomas et al., 2007). The difference between the equatorial and the polar radius corresponds to an equilibrium shape with a 16 h period. This suggests that Iapetus has preserved this shape as its rotation rate was decreasing to reach the stable state of synchronous rotation. In such scenarios, Iapetus formed at a high spin rate and achieved isostatic equilibrium by strong interior heating caused by short-lived radioactive isotopes shortly after formation (Castillo-Rogez et al., 2009, 2011; Robuchon et al., 2010). According to an alternative scenario (Sandwell and Schubert,

2010), Iapetus' shape could be a consequence of substantial porosity within the outer ice layer and subsequent compaction due to heating of long-lived radioactive isotopes. This scenario would also provide an explanation for Iapetus' equatorial ridge, a surface feature on Iapetus that is unique in the solar system. It stretches around almost the entire satellite with height up to 13–20 km (Giese et al., 2008a; Porco et al., 2005). The ridge is heavily cratered implying that it was formed early in the satellite's evolution. In the scenario by Sandwell and Schubert (2010), the ridge is a consequence of strain concentration along the equator during the process of compaction. However, formation scenarios for the equatorial ridge are still under discussion. Whereas a tectonic or volcanic origin seems to be unlikely (e.g., Singer and McKinnon, 2011), exogenic formation scenarios are promising. Ip (2006) suggested collisional accretion of an equatorial ring system shortly after satellite formation. However, in this scenario, the early time of formation is problematic because the satellite needs to be cold and rigid enough to sustain the massive load of the ridge. To overcome this, Levison et al. (2011) and Dombard et al. (2012) have suggested a giant impact and the formation of a small subsatellite and debris around Iapetus. Whereas in the scenario of Levison et al. (2011) the subsatellite eventually escapes from Iapetus, it is tidally disrupted in the scenario of Dombard et al. (2012). In both cases, the debris would form the ridge during a phase when Iapetus was already cold enough to sustain the ridge.

In the scenario of Levison et al. (2011), Iapetus is faster despun by the additional interaction with the subsatellite. Whether there is any close connection between despinning and the formation of the equatorial ridge is unclear. The formation and the preservation of this ridge are still enigmatic. The observations suggest that the interior was dissipative enough to allow for despinning and that the lithosphere was thick enough to support the mountain chain on a geologic timescale.

10.18.7.7 Triton

From the *Voyager* 2 flyby in 1989, Triton's radius, mass, and density were determined to be 1353.4 km (Thomas, 2000), 214×10^{20} kg, and 2054 kg m^{-3}, respectively (Tyler et al., 1989). However, on the basis of gravity measurements and from the shape solution derived from the analysis of limb profiles, the moment of inertia cannot be inferred (Thomas, 2000; Tyler et al., 1989), thus constraints on internal structure are sparse. The high density suggests a large rock-mass fraction of about 72%, implying substantial radiogenic heat sources in the deep interior. After Europa with a rock-mass fraction exceeding 90%, Triton has the highest density of all the icy satellites.

Because of its retrograde orbit around Neptune, it was suggested by McCord (1966) and later by McKinnon (1984) and McKinnon and Leith (1995) that Triton was captured by Neptune. As proposed by Agnor and Hamilton (2006), Triton was captured as a binary object, with the companion being lost during the capture process. Such models are motivated by Triton's high inclination of about 157° and its retrograde orbit, which are unique features among the large satellites in the solar system. With an eccentricity of 0.0004, Triton's orbit is almost an exact circle. Correia (2009) has shown how the orbit evolves from a highly eccentric one to the current circular one while Triton is captured into the synchronous rotation state. Whatever the capture mechanism was like, it involves high eccentricities shortly after capture (Ćuk and Gladman, 2005). Tidal dissipation in the satellite or gas drag within the Neptunian subnebula (McKinnon and Leith, 1995) may have efficiently damped the satellite's eccentricity, suggesting that at least Triton's early history was characterized by intense heating. However, the young surface age of about 0.1–0.35 Ga and 6–50 My regionally estimated from crater counts (Schenk and Zahnle, 2007; Stern and McKinnon, 2000; Zahnle et al., 2003) suggests that Triton was geologically active, even in its recent past. This is consistent with the diversity of geologic surface units imaged by *Voyager* 2 (Smith et al., 1989). The detection of geyser-like plumes at the surface (Smith et al., 1989; Soderblom et al., 1990) further revealed that Triton is one of only three satellites in the solar system showing present-day eruptive activity, the other two being Io and Enceladus. However, in case of Triton, the observed activity is believed to be driven by solar insolation during seasons of permanent sunlight. However, geothermal heat may additionally contribute to the required energy budget (Brown et al., 1990).

The process of being captured by Neptune would lead to strong internal heating as the orbit evolved, most probably implying differentiation of the satellite. This would result in a structure consisting of a rock core and an H_2O layer. The physical state of the latter remains unclear due to the poorly constrained abundance of volatiles and temperature profile in the shell. A subsurface ocean would be conceivable if small amounts of ammonia are present in the system (McKinnon and Leith, 1995). Based on thermal equilibrium models, and considering a pure ice-I layer above a water–ammonia ocean, the ice layer would be about 140–200 km thick covering an ammonia–water ocean of about 150 km thickness (Hussmann et al., 2006). Using estimates of the heat flow, required for explaining tectonic features on Triton, Ruiz (2003) estimated an ice-I layer thickness of only 20 km. Due to the lack of data on gravity and composition, it is also unclear if the ocean, if it exists, would be enclosed between ice-I and high-pressure ice. Thus, a 'Europa-like' structure consisting of a large silicate core, a water–ammonia ocean, and an ice-I shell cannot be ruled out. Such a structure would be intriguing because of its possible astrobiological consequences. Gaeman et al. (2012) have investigated the stability of an ocean during the phase of orbital eccentricity damping. Depending on the initial values of eccentricity, an ocean may be sustained over 4.5 Gy. If circularization of Triton's orbit is slow enough, a thin NH_3-rich water ocean might exist even today.

Whatever the past thermal history, it has permitted outgassing of enough nitrogen and methane to produce surface ice deposits that are moved seasonally from one pole to the other and maintain a thin microbar atmosphere of mostly nitrogen (Lunine and Nolan, 1992).

10.18.8 Future Prospects for Determining Satellite Internal Structure

At the time of writing of this chapter, the *Cassini* orbiter has completed 9 years of operation in Saturn orbit, more than twice the duration of its prime mission. A 2-year extended 'equinox' mission studied Titan, the other moons, rings, and

Saturn atmosphere under conditions of equinox solar illumination. A 6-year 'solstice' mission began in 2011 with the intention of operating the spacecraft until fuel exhaustion demands a destructive entry into Saturn's atmosphere in 2017. The solstice mission is allowing gravity mapping of Enceladus and more thorough gravity mapping of Titan.

Juno, a polar orbiting spacecraft launched to Jupiter in August 2011, will provide detailed information on the internal structure and perhaps the dissipation factor Q_l of Jupiter, which will help in understanding tidal interactions between the large moons, mainly Io, and Jupiter. *New Horizons* will fly by Pluto and its moon Charon in 2015, providing, however, limited information on internal structure.

ESA is preparing JUICE, the JUpiter ICy moons Explorer (Grasset et al., 2013), to orbit Ganymede and investigate Europa and Callisto by flybys. The mission will provide details on Ganymede's interior structure including higher moments of the gravity field and tidal variations that would be indicative for ocean detection and its characterization. The mission will also carry a subsurface radar instrument to investigate the upper layers (~9 km) of the ice shells of Ganymede, Europa, and Callisto. Further plans to measure in detail Europa's internal structure and thickness of its ice crust (Wahr et al., 2006) remain in limbo. JUICE will not arrive at Jupiter any earlier than 2030. Further progress on the internal structure of icy moons can be made in laboratory studies of the relevant materials, especially with respect to the physical properties of water ice mixed with other ices. High-pressure ices and clathrates could be investigated for various compositions. Thermophysical properties of interest for the evolution of icy satellites include the density, thermal expansivity, heat capacity, and thermal conductivity as a function of temperature, pressure, and composition. For tidal deformation processes and convective heat transport, the rheological properties should be investigated on different frequencies. Main parameters, crucial for the evolution of icy satellites, include rigidity, viscosity, and transient creep parameters as a function of temperature and frequency of the forcing.

Acknowledgments

The authors would like to thank Michael Bland and an anonymous reviewer for the very detailed and constructive comments on the manuscript. JIL acknowledges support from the *Cassini* Project in preparing the manuscript. Part of this work was supported by NASA's Astrobiology Institute node 'Icy Worlds' and was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

10.19.1 Introduction

Approach-phase operations began in January 2015 for the *New Horizons* spacecraft, in advance of its planned fly-through of the Pluto–Charon system on 14 July 2015 (Stern, 2008; Weaver et al., 2008; Young et al., 2008b). As the second edition of the *Treatise on Geophysics* was being prepared before the encounter, these anticipated results could not be incorporated. Nonetheless, in the past several years a substantial amount of new information has been gleaned by ground-based and space-based study of Pluto and its moons and especially of the Kuiper Belt (more broadly, the entire trans-Neptunian region). Theoretical developments in the case of the Kuiper Belt as a whole have also been notable and have driven an entirely new understanding of the evolution of our solar system.

With the agreement of the editors and original authors, what follows is a brief introduction to Pluto and the Kuiper Belt as of early 2014, updating some key aspects of the original article (which follows) and offering a prospectus for what may be learned from *New Horizons*. In outline, I will present (1) an updated view of the Pluto–Charon system, (2) a summary of salient aspects of Pluto's fellow dwarf planets and related trans-Neptunian objects (TNOs), and (3) a very brief overview of the structure of the Kuiper Belt and its implications. While limited in scope and necessarily selective, it is hoped that this brief review will serve as a springboard to dive into the primary literature of this fast-moving field.

10.19.2 The Pluto–Charon System

The most obvious change since the first edition of the *Treatise* is that two additional satellites have been discovered, now named Styx and Kerberos (**Table 1**). These are rather small moons in comparison with either Pluto or Charon and required the limiting magnitude capabilities of the *Hubble Space Telescope* (*HST*) to be detected at all (Showalter et al., 2011, 2012). It is doubtful that our knowledge of the architecture of the Pluto–Charon system is complete, and it is anticipated that *New Horizons* will discover additional moons on approach (in addition to their intrinsic scientific interest, there is the practical matter of identifying any potential dust or debris hazards to the flyby associated with such moons or moonlets).

It is notable that the entire Pluto–Charon system is coplanar and that the orbital eccentricities and inclinations are very low (or zero!) (Buie et al., 2012b). This implies that the system is highly dynamically relaxed and that the small satellites (at least) formed from a dissipative, presumably particulate, disk. That Pluto and Charon represent a binary pair that has achieved mutual spin–orbit synchronism has been appreciated for some time, and Charon is thought to have tidally evolved outward from an orbit much closer to Pluto, following that moon's formation in a massive collision ('giant impact') (e.g., Dobrovolskis et al., 1997). Similarly, the accretion of Pluto's small moons from an extended particle disk, by standard, gravitational coagulation processes, has been shown to be physically plausible (Bromley and Kenyon, 2014). The trick, however, is to make such an extended disk in the first place. Disk formation presumably also occurred during the giant impact that formed Charon, but a sufficiently *extended* disk has not been an outcome in numerical, Charon-forming impact models to date (Canup, 2005, 2011).

Alternatively, Pluto's small moons formed much closer in, and Charon tidally captured them as it evolved away from Pluto, subsequently driving them all, in lockstep, outward (e.g., Stern et al., 2006). While appealing at first, **Chapter 10.17** makes clear that this explanation suffers (what appear to be) insurmountable physical difficulties. First, the small satellites as a whole are not obviously in resonance today (although the orbital periods of Styx, Nix, Kerberos, and

Table 1 Properties of the Pluto–Charon system (Brozović et al., 2014)

Pluto		6.3872			1169–1193	1.89 ± 0.06	49–66
Charon	19 596	6.3872	0.00005	0.0	603.6 ± 1.4	1.72 ± 0.02	36–39
Styx	42 413	20.1617	0.00001	0.0	4–14	$0.0^{+5.0}_{-0.0}$	4–35
Nix	48 690	24.8548	0.00000	0.0	23–70	$0.1^{+0.2}_{-0.1}$	4–35
Kerberos	57 750	32.1679	0.00000	0.4	7–22	$1.3^{+2.2}_{-1.3}$	4–35
Hydra	64 721	38.2021	0.00554	0.3	29–86	$0.1^{+0.1}_{-0.1}$	4–35

[a]Mean orbital elements for Charon are plutocentric, whereas those for the small satellites are barycentric.
[b]Formal uncertainties are 1σ.
[c]Geometric albedos for Pluto and Charon vary with location, and especially strongly so for Pluto (Buie et al., 2010b); the ranges quoted are hemispheric averages (Buie et al., 1997). The albedo range for the small satellites is assumed and determines the radius ranges shown.

Hydra are, respectively, close to the 3:1. 4:1, 5:1, and 6:1 mean-motion resonances with Charon). Second, all resonant evolution scenarios lead to strong growth in one or more small satellite eccentricities, eccentricities that are not hinted at today (**Table 1**). The reader is directed to **Chapter 10.17** in this volume for a full discussion of this matter. Further clues to the formation and evolution of the Pluto–Charon system will no doubt be uncovered during the *New Horizons* encounter.

A by-product of the discovery of the small satellites and the detailed study of their orbits has been a relatively precise determination of the system barycenter and thus the Pluto/Charon mass ratio. Coupled with precise determinations of Charon's size by multiple stellar occultations (Person et al., 2006; Sicardy et al., 2006, 2012), Charon's mean density is now relatively well determined, both in an absolute sense and with respect to Pluto. Pluto's precise size remains uncertain due to the effects of its atmosphere on stellar occultation interpretations (**Section 10.19.2.2**) and limb darkening effects on mutual-event modeling (referring to the 1985–1990 occultations and transits of Pluto and Charon as seen from the Earth (Binzel and Hubbard, 1997; Tholen and Buie, 1997)). Both Pluto and Charon are relatively rock-rich, but Charon is somewhat icier, which is consistent with impact origin scenarios in which one or both precursor bodies were at least partially differentiated (rock separated from ice under the action of gravity) (Canup, 2005; see McKinnon et al., 2008).

Ice-rich ejecta is also the preferred route for forming a particle disk outside of Charon's initial post-giant impact orbit (Canup, 2011). In this regard, the limits on the densities of the small satellites in **Table 1** are intriguing. Although the lower limits are consistent with zero (no mass detected), the upper limits on the densities of the brightest and presumably largest of the small satellites (Nix and Hydra) are – even at the 3σ error level – consistent with very icy and porous bodies. Icy rubble-pile bodies are in fact predicted by the initial conditions of the giant impact as presently understood (conditions necessary to give an icier Charon). The small satellites will thus offer an interesting cosmogonic test during the *New Horizons* encounter, as good constraints will be placed on satellite volumes from imaging and improved satellite masses will result from optical navigation and orbital integrations (noting *New Horizons* will not pass close enough to any of the small satellites to measure their gravitational accelerations directly).

10.19.2.1 Surface Compositions of Pluto and Charon

Understanding of the basic composition of Pluto's surface has not fundamentally changed in the last few years, but there have been important refinements. Pluto's visible and near-infrared spectra are dominated by methane (CH_4) absorptions, but much of the optical surface is physically dominated by nitrogen (N_2) ice in which the methane (along with some CO) is dissolved as a minor component in solid solution (Cruikshank et al., 1997). (As is well known, methane absorbs strongly in the near-infrared and tends to dominate the spectra of bodies on which CH_4 is present, even in minor amounts.) Methane-rich surface units also exist (Douté et al., 1999; Olkin et al., 2007), which likely couple directly to the atmosphere, and earlier detections of solid ethane (C_2H_6) have been essentially confirmed, at the few percent level as a pure solid (DeMeo et al., 2010; Merlin et al., 2010).

HST images have also been used to create the best maps of the surface albedo and color distribution to date (Buie et al., 2010b). Data were taken at two visible wavelengths and show widespread albedo and color variegation on the surface of Pluto (**Figure 1**). As can be seen from the figure, the mid- to high-latitude region on Pluto's sunlit pole is, on average, more neutral in color and of generally higher albedo than the rest of the surface. Presumably, the polar surface, which has emerged from its seasonal winter over the last few decades, is rich in nitrogen ice (and its dissolved constituents). The equatorial bright spot near 180° longitude is also dominated by nitrogen ice and is relatively CO ice-rich (Grundy and Buie, 2001; Grundy et al., 2013).

The darker regions on Pluto show considerable color diversity, arguing that there must be a range of compositional units in the dark regions. The methane-ice-rich surface units mentioned earlier (which are, paradoxically, indicated by intrinsically weak CH_4 bands) are not correlated with the brighter and more spectrally neutral surface units in **Figure 1**, but neither do maximum CH_4 absorptions (of any intrinsic strength) correlate with the darkest region (and light-curve minimum) near 80–120° longitude (Grundy et al., 2013). The lowest geometric albedos on Pluto (a few %) occur in this expanse, and low albedos on Pluto generally are thought to be due to long-term photolytic and radiolytic processing of methane ice into dark, reddish, carbonaceous heteropolymers (or *tholins*) and

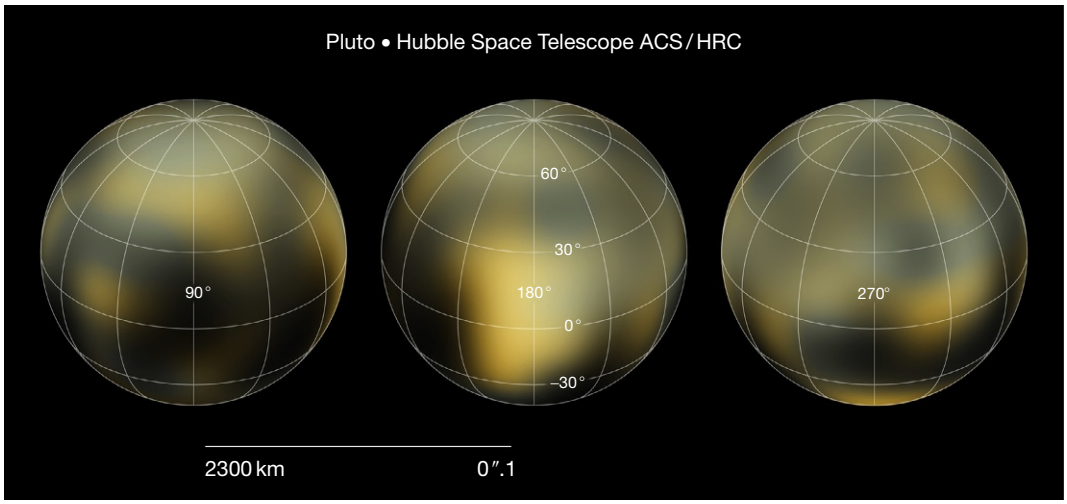

Figure 1 Albedo and color maps of Pluto created from *HST* Advanced Camera for Surveys/High Resolution Camera (ACS/HRC) images taken at 0.435 and 0.555 μm (based on Buie et al., 2010b); 0″.1 refers to angular size as seen from the Earth. Pluto's presently illuminated, south (in a celestial sense) pole is up, but as Pluto is a retrograde rotator, longitude increases to the 'east' as defined by the planet's spin. These maps will be superseded in resolution in mid 2015, by *New Horizons* imaging as the spacecraft approaches Pluto. NASA/ESA/M. Buie (SwRI).

ultimately into dark, spectrally neutral carbon (Cruikshank et al., 1997; de Bergh et al., 2008; Hudson et al., 2008; Olkin et al., 2007).

It is notable that *no* solid CO_2 has been detected so far on the surface of Pluto (Grundy et al., 2013), whereas near-infrared absorptions for CO_2 ice are quite pronounced on Triton. Triton is Neptune's large, retrograde moon and likely a captured Kuiper Belt object (KBO) and cousin to Pluto (McKinnon et al., 1995); the CO_2 absorptions on Triton imply substantial exposures of this relatively involatile 'bedrock' on this satellite (Grundy et al., 2010; Quirico et al., 1999). The spectral signature of water ice is also seen on Triton and not seen on Pluto, and H_2O ice is either unnecessary or contraindicated when modeling Pluto's spectra (cf. DeMeo et al., 2010; Grundy et al., 2013; Merlin et al., 2010; Olkin et al., 2007). It may be that the pronounced surface–atmosphere interactions on Pluto have buried, coated, or otherwise obscured exposures of CO_2 or H_2O ice on Pluto, or such exposures may be very limited; it may also be that the more volatile ices (N_2 and CH_4) form a geologically substantial

crustal layer on Pluto. Imaging spectroscopy from *New Horizons* should prove telling, especially if the volatile ices are thin enough that deeper materials are exposed by impacts or other geologically disruptive phenomena (Moore et al., 2014).

Charon's near-infrared spectrum, in contrast, is *dominated* by the signature of crystalline water ice (H_2O), with no hint of N_2, CH_4, CO, or CO_2 (e.g., Merlin et al., 2010). Remarkably, however, it is the spectral signature of ammonia hydrate ice ($NH_3{\cdot}nH_2O$, in some form or forms) that is seen on Charon, near 2.2 μm (Brown and Calvin, 1999; Cook et al., 2007; Dumas et al., 2001; Merlin et al., 2010; **Figure 2**). Ammonia, due to its spectacular effect on lowering the minimum melting point (or eutectic) of ammonia hydrate (e.g., Kargel, 1992), is long thought to have been involved in 'cryovolcanic' activity in the outer solar system, but had not been confirmed on a solid solar system body until the detections on Charon. Ammonia is thought to be the ultimate source for much or all of the N_2 in the atmosphere of Titan (Atreya et al., 2009) and perhaps on large KBOs such as Pluto as well (McKinnon et al., 1997). Ammonia is, of course, known as a component of cometary ices (Mumma and Charnley, 2011) and is seen in the vapor component of the Enceladus plume (Waite et al., 2009), in both cases at the percent level or less compared with H_2O.

Ammonia, whether hydrated or not, is notoriously unstable under UV and charged particle irradiation (Lanzerotti et al., 1984; Strazzulla and Palumbo, 1998), so it is important to consider what makes Charon special in this regard. Is it simply its distance from the Sun, or does Pluto's escaping atmosphere have something to do with it, perhaps by protecting Charon from direct solar wind bombardment? Cook et al. (2007) proposed that we see ammonia hydrate on Charon because of recent cryovolcanic activity, while Dumas et al. (2001) speculated that the ammonia hydrate is a product of implantation of N_2/N^+ from Pluto's atmosphere into Charon's water ice surface, followed by radiolytic processing. Perhaps something as prosaic as impact exhumation of subsurface ammonia hydrate is involved. Whatever the situation, *New Horizons* imaging and spectral capabilities should provide important new constraints on the origin of ammonia on Charon and perhaps other large KBOs (see **Section 10.19.3.1**).

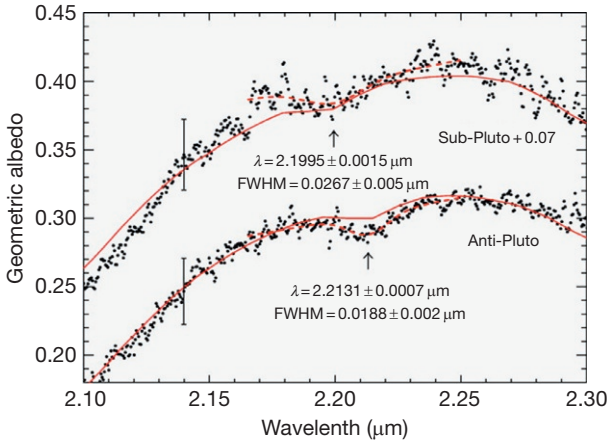

Figure 2 Ammonia hydrate feature in the spectrum of Charon. Solid red lines indicate a model fit (water ice, continuum absorber, plus ammonia hydrate); dashed lines are a Gaussian fit to the absorption feature. The absorption feature is seen at all aspects: on the sub- and anti-Pluto hemispheres (as shown) and on the leading and trailing hemispheres of motion (Verbiscer et al., 2007). Reproduced from Cook JC, Desch SJ, Roush TL, Trujillo CA, and Geballe TR (2007) Near infrared spectroscopy of Charon: Possible evidence for cryovolcanism on Kuiper belt objects. *Astrophysical Journal* 663: 1406–1419.

10.19.2.2 Pluto's Atmosphere

Pluto's atmosphere is supported by the vapor pressure of nitrogen frost. Stellar occultations offer a sensitive probe of that atmosphere and thus of the temperature of Pluto's surface nitrogen ice and the seasonal evolution of the surface–atmosphere couple. The last few years have a boon to occultation studies as Pluto (as seen from the Earth) traversed the galactic plane, leading to observed occultations in 2006 (Elliot et al., 2007; Young et al., 2008a), 2007 (McCarthy et al., 2008; Person et al., 2008), 2008 (Sicardy et al., 2011), 2010 (Person et al., 2010), 2011 (Person et al., 2013), 2012 (Bosh et al., 2013), and 2013 (Olkin et al., 2014). A typical, derived temperature profile is shown in **Figure 3(a)**, along with various relevant model aspects or benchmarks. The retrieved thermal profile displays a warm (~100 K) upper atmosphere and a sharp, stratospheric temperature inversion (temperature increasing with height), as have atmospheric thermal profiles since Pluto's atmosphere was first discovered, during a stellar occultation (Elliot et al., 1989). A photochemical or condensation haze layer may also be present and was one explanation for the pronounced, symmetrical 'kink' or 'knee' in the original occultation light curve from 1988. The knee was greatly diminished or absent in light curves from later years but has apparently returned or strengthened in 2011–2013 (Olkin et al., 2014; Person et al., 2013). This is likely a testament to the variability of Pluto's atmosphere on decadal timescales, even if the physical explanation is unclear.

Pluto's atmosphere expanded and increased in mass (and thus surface pressure) by a factor of 2 between the 1988 and 2002 occultations (Elliot et al., 2003, 2007). During this time, the planet passed through perihelion (peak insolation) *and* equinox, which turns out to be important for understanding this behavior (Young, 2013). The inference of increased atmospheric mass is now backed up by general circulation models (Zalucha and Gulbis, 2012). Later occultations (2006 through 2013) show that this 'bulked up' atmosphere has been maintained since 2002 (e.g., Young et al., 2008a) and the atmosphere may even be increasing in mass at present (Olkin et al., 2014). Pluto's atmosphere will thus be fully available for study by *New Horizons* and, in the favored model of Olkin et al., does not completely collapse at all during the Pluto year, because of the quantity of nitrogen ice available at both poles and the high thermal inertia of the ice assumed in the favored model. Pluto's atmospheric variations are presumably tied to the surface albedo, color, and spectral variations observed on the same time frame (Buie et al., 2010a,b; Grundy et al., 2014).

The decrease in atmospheric temperature with height in Pluto's upper atmosphere in **Figure 3(a)** is real. It is a product of both radiative cooling by CO and the expansion of Pluto's atmosphere (via enhanced Jeans escape) out into space (Zhu et al., 2014). The temperature maximum is due to heating due to infrared absorption by CH_4 (Yelle and Lunine, 1989). Both

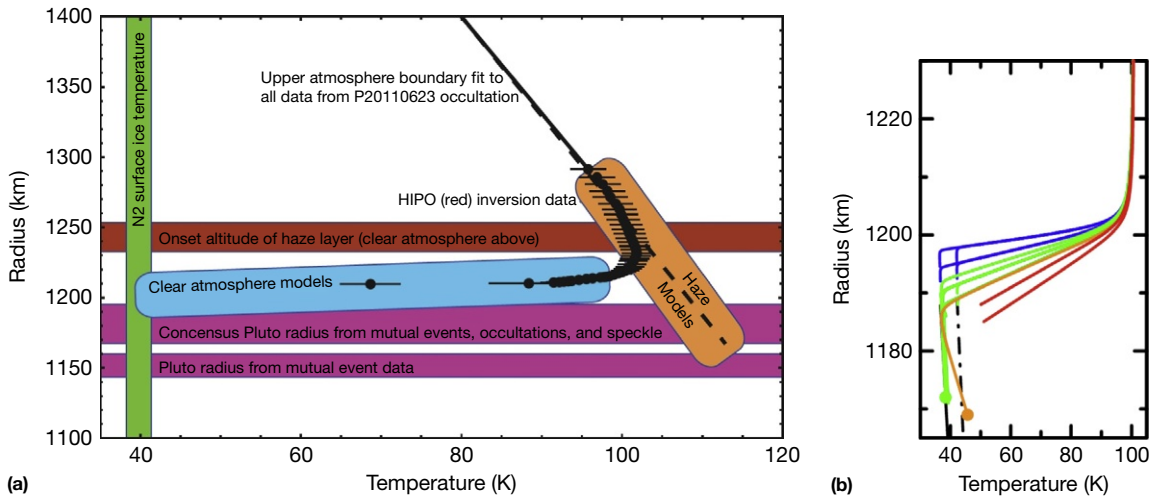

Figure 3 (a) Derived temperature profile from the 23 June 2011 stellar occultation of Pluto's atmosphere, along with model elements and constraints. Reproduced from Person MJ, Dunham EW, Bosh AS, et al. (2013) The 23 June 2011 stellar occultation by Pluto: airborne and ground observations. *Astronomical Journal* 146:83 (15 pp.). HIPO refers to the High Speed Imaging Photometer for Occultations aboard *SOFIA*. Models with haze extend warm 'thermospheric' temperatures downward, but the profile must eventually turn back toward the cold surface. (b) Family of possible temperature profiles for Pluto's atmosphere. Modified from Lellouch E, Sicardy B, de Bergh C, Käufl H-U, Kassi S, and Campargue A (2009) Pluto's lower atmosphere structure and methane abundance from high-resolution spectroscopy and stellar occultations. *Astronomy & Astrophysics* 495: L17–L21. All of the models in b assume a clear atmosphere (no haze) with different stratospheric thermal gradients. Most assume little or no cool, basal troposphere. Solid black vertical line is the N_2 saturation curve; dot-dashed line is saturation curve for a 0.5% CH_4 mixing ratio. Tropospheric temperature gradients are shown following either the wet (green) or dry (orange) N_2 adiabat, with maximum tropospheric depths indicated by dots. Reproduced with permission from *Astronomy & Astrophysics*, © ESO.

gaseous CH_4 and CO have now been directly detected in Pluto's atmosphere (Lellouch et al., 2009, 2011) (in addition to being known components of Pluto's surface ices), which supports theoretical models of the atmosphere (Yelle and Elliot, 1997). The expansion and escape of Pluto's atmosphere are driven by far- and extreme-ultraviolet heating, and the exobase is predicted to be out near 8 Pluto radii at present (Zhu et al., 2014). The *New Horizons* trajectory may thus take the spacecraft directly through the planet's extended atmosphere (depending, of course, on the atmosphere's interaction with the solar wind at encounter time).

Due to differential atmospheric refraction, Pluto's solid surface cannot be seen in stellar occultations in the present epoch, from the Earth. Light curves probe down to the ≈1190–1200 km radius level at best (Lellouch et al., 2014; Young et al., 2008a). **Figure 3(b)** illustrates possible Pluto temperature profiles for a range of stratospheric temperature gradients that are constrained by occultation light curves *and* the relatively warm temperature of the methane gas detected by Lellouch et al. (2009). This limits the possible depths of cold tropospheres as shown. Lellouch et al. (2009, 2014) argued that any troposphere on Pluto may be limited to a scale height (20 km) or less, which is consistent with the view of emerging general circulation models (Zalucha et al., 2011). As **Figure 3(a)** alludes to, there has been a long-standing mismatch between estimates of Pluto's size from mutual-event data and stellar occultations.

Matters pertaining to Pluto's atmosphere will be vastly clarified by the *New Horizons* encounter in 2015. Pluto's solid-body radius will be determined once and for all by imaging, and the distribution of surface ices and their compositions will be mapped by the infrared spectrometer. Surface temperatures will be measured by radio science (antenna and receiver) operating in a passive mode. UV solar and stellar occultations will determine the atmosphere's composition and thermal structure in its upper reaches, while radio science will sound the pressure and temperature of the lower atmosphere. All these data should provide an exquisite picture of Pluto's surface and atmosphere at a single epoch, one that can be used as a tie point to interpret both older measurements and new data to come as Pluto sails off to aphelion.

10.19.2.3 Interior and Geologic Activity

Among the most anticipated aspects of the *New Horizons* flyby are detailed images and spectra of the surfaces of Pluto and Charon (resolutions exceeding 100 m px^{-1} for Pluto, for the nominal trajectory). These new data will quantify the level of geologic activity on these bodies, now and in the past, and in Pluto's case should provide an important comparison with Triton, which was visited by Voyager 2 in 1989 (Moore et al., 2014).

The fly-through of the Pluto–Charon system by *New Horizons* also offers the first opportunity to determine both the total system mass and the individual masses of Pluto and Charon by direct Doppler tracking. Simulations of the encounter by the Radio Science Experiment (REX) indicate the potential accuracies of the combined and individual mass determinations of Pluto and Charon are on the order of 0.1% (Paetzold et al., 2013; Tyler et al., 2008), a substantial improvement in precision (especially for Charon). This will put to rest a long-standing limitation on modeling and understanding Pluto and Charon's internal structure and evolution (McKinnon et al., 1997).

Based on the values in **Table 1**, Pluto's rock/ice ratio is 0.65–0.70 by mass, calculated on an anhydrous basis and neglecting the planet's bulk carbonaceous component. Pluto's

differentiation state was debated in McKinnon et al. (1997), but the case for Pluto being differentiated (having a rocky core) has strengthened considerably since then. First, solid-state convection is now seen as a less efficient mechanism of interior heat transport in the so-called stagnant lid regime, in which a cold, conductive, and essentially immobile lid overlies a much warmer, convecting interior. This regime, which should apply to Pluto and Charon, has been shown to imply greater internal temperatures than had been estimated by earlier theory (see, e.g., McKinnon, 2006; Solomatov and Moresi, 2000; **Chapter 10.08** in this volume, and the comprehensive overview of Schubert et al., 2001). This implies greater internal temperatures, all other things being equal, and if internal temperatures are higher, the likelihood of ice melting and thus the inward settling of denser rock under the action of gravity (differentiation) are greater. Second, Charon's somewhat lower density than Pluto implies at least partial differentiation of one of the precursor bodies, prior to the Charon-forming collision (as noted in **Section 10.19.2.1**). Third, at least one other major KBO, Haumea, is clearly differentiated (Brown, 2008) (see **Section 10.19.3.1**). If differentiated, Pluto should have a relatively large rocky core, approaching 900 km radius, depending on core rock hydration state and the extent of any refractory carbonaceous component.

It is also possible, from the densities in **Table 1**, that Pluto and Charon have the same or similar densities, considering the stated uncertainties at the 3σ level and the effects of porosity (which should be greater for Charon). If Pluto and Charon were close in density after all, it could change our view as to how the binary formed. The precursor bodies, or at least the impactor, would then have to have been undifferentiated (Canup, 2005). Similar densities would also allow consideration of formation of the Pluto–Charon binary by direct gravitational instability (Nesvorný et al., 2010), a formation mechanism presently disallowed because it does not predict manifestly different densities or compositions for individual binary members. On the other hand, mutual-event solutions permit a substantially denser Pluto than those given in **Table 1** (Tholen and Buie, 1997). Determining the precise Pluto/Charon *density* ratio is clearly an important objective for *New Horizons*.

Exploration of the outer solar system has also revealed that many large icy satellites possess or probably possess interior oceans, among them Europa, Ganymede, Callisto, and Titan, and even midsize satellites (i.e., Enceladus) may possess oceans or seas if they are tidally heated (see Sohl et al. (2010) and **Chapter 10.18** in this volume for detailed reviews). The efficiency of solid-state convection in removing heat from a planetary interior, or lack thereof, plays a critical role. In Pluto's case, an ocean may exist between its surface ice shell and its rock (+metal + refractory organics) core (McKinnon et al., 2008). Specifically, if the deep ice is convecting, and the ocean contains *no* 'antifreezes' such as ammonia or methanol, then an ocean may or may not exist (i.e., be thermodynamically stable). If the deep ice is not convecting, but instead transports heat by conduction only, then an ocean must exist because the temperature gradient will be much larger than in the convecting case and intersect the ice melting curve for present-day heat flows (see McKinnon, 2006). Furthermore, if there is dissolved ammonia and/or methanol in Pluto's ocean, then it is extremely difficult (if not impossible) to freeze the ocean completely. In this case, and depending on the concentration of these species, Pluto's conductive ice shell could be ~200–300 km thick, overlying an ocean perhaps 100 km thick, albeit one cold and chemically noxious (Hussmann et al., 2006).

Charon in contrast is a modest-sized body and one that is not being tidally heated, so nominally, its interior should be rather cold today. Even if differentiated, it should not sustain an internal ocean (McKinnon et al., 2008; Schubert et al., 2010). The discovery of ammonia–water ice in Charon's spectrum (**Section 10.19.2.1**) has, however, prompted theoretical models that provide for survival of ammonia–water melt deep inside Charon up until the present day, for a narrow range of parameters (Cook et al., 2007; Desch et al., 2009).

Determining Pluto's (or Charon's) state of differentiation, much less the existence of oceans, will not be easy. *New Horizons* will not pass close enough to measure the degree-2 gravity field for either body (nor was such an original measurement requirement or mission objective), but shape determination from imaging offers the possibility of determining differentiation state. For this to be successful, however, Pluto or Charon must be in hydrostatic equilibrium. For all hydrostatic models of these two bodies, the differences between the lengths of the principal axes of their figures are predicted to be less than 1 km, and the differences between differentiated and undifferentiated models smaller still (McKinnon, 2013). Thus, discriminating between the two cases will be an observational challenge. Furthermore, either Pluto or Charon may choose not to cooperate, if they retain fossil tidal figures from earlier in their mutual tidal evolution, in the manner of Iapetus (e.g., Singer and McKinnon, 2011). These fossil figures would be larger (more biaxial in the case of Pluto and more triaxial for Charon), and thus much easier to measure, but would nevertheless provide important clues to the thermal and structural evolution of both bodies and Pluto in particular (Robouchon and Nimmo, 2011).

The comparisons with Triton that *New Horizons* should provide will be important not only in their own right but also for what they will imply about the geologic evolution of large KBOs generally. Triton's active geology and young crater retention age (Schenk and Zahnle, 2007; Stern and McKinnon, 2000) are often linked to the extreme tidal heating Triton almost certainly suffered after its capture by Neptune, but that capture event likely occurred billions of years ago (Nogueira et al., 2011; and see discussion in Schubert et al., 2010). From this perspective, then, Triton's recent activity would have to be powered instead by long-lived radiogenic heat (U, Th, or ^{40}K), acting in concert with a surface rich in very volatile (and hence geologically mobile) materials. And if so, Pluto should behave similarly today.

The specter of Triton's activity being driven by tidal heating has been recently resurrected, however. Although Triton's orbital eccentricity is essentially zero, because its orbit is highly inclined (157°) and retrograde, it has a small obliquity of order 0.5° (meaning its spin vector is slightly offset from its orbit normal). Jankowski et al. (1989) estimated that any heating due to solid-body tides raised by Neptune within Triton should be unimportant compared with radiogenic heating. Nimmo and Spencer (2014) proposed in contrast that tidal heating in a putative *ocean* within Triton supplies a substantial amount of heat. This is not a heat source available to Pluto or other large KBOs, so if this is the case, Pluto's level of geologic vigor will not match that of Triton today.

10.19.3 The Largest Trans-Neptunian Dwarf Planets and Dwarf Planet Candidates

There are at least a baker's dozen of large TNOs in the Pluto and Charon size class, including four presently recognized by the IAU as 'dwarf planets' (Eris, Makemake, Haumea, and Pluto of course) (Brown, 2008; Grundy et al., 2009; Sheppard et al., 2011). **Table 2** lists a 'top ten' KBOs in terms of size, as determined by a variety of methods, of which the stellar occultation method is deemed the most definitive. Other than Pluto, none of these bodies are either close enough to the Sun at present to raise, or are they large enough to sustain, a substantial atmosphere that could compromise measurement of a stellar occultation chord from the Earth. These relatively large bodies are all likely to have achieved hydrostatic equilibrium at low spherical harmonic degree, at least at some point in their histories, based on comparisons with icy satellites of similar size; thus, they are all probably dwarf planets (except for Charon, which is excused on a technicality). Ceres is included for comparison and to emphasize that the largest asteroid is an order of magnitude less massive than the largest KBOs.

Large KBOs are found in all of the dynamical groups or (sub)classes in the Kuiper Belt (Sheppard et al., 2011), although the great majority are found in the dynamically excited (or 'hot') resonant, scattered, and detached classes (Brown, 2008) (see **Section 10.19.4** for further discussion of these classes). In terms of the bodies in **Table 2**, Pluto–Charon and Orcus are both trapped in the 3:2 mean-motion resonance with Neptune (which makes Orcus a *plutino*).

Makemake, Haumea, and 2002 MS_4 are all part of the dynamically hot (high-inclination) component of the main, or classical, Kuiper Belt. Quaoar, at $i = 9°$, is often counted with this high-inclination group, but might be better thought of as an outlier of the dynamically 'cold' or low-inclination classical group, given its low eccentricity (0.04) and very red visible colors (a hallmark of the cold classical population) (Sheppard et al., 2011).

Eris, the most massive KBO known, is quite distant, but its orbit takes it close enough to Neptune at perihelion that it is generally viewed as a scattered disk object (i.e., Sheppard et al., 2011), although in the present epoch, it is no longer *scattering* and is formally classified as dynamically detached (Gladman et al., 2008); 2007 OR_{10}, with similar orbital elements, actually comes closer to the Sun than Eris but is protected from approaching Neptune by being in a mean-motion resonance with Neptune, albeit a weak, higher-order one (the 10:3).

Sedna is the most dynamically unusual TNO in **Table 2**, as its semimajor axis attests. It is dynamically *isolated*. With a perihelion of $\approx$75 AU, Sedna does not interact with Neptune or the other giant planets, yet its orbit is still too close to the Sun to be appreciably affected by passing stars or galactic tides (Brown, 2008; Gladman et al., 2008; and see Sheppard et al., 2011). The moniker 'detached' is an understatement.

10.19.3.1 Surface Compositions

The largest KBOs are also the brightest, generally, and thus can be spectroscopically interrogated. They are also generally higher-albedo bodies compared with the Kuiper Belt as a whole (Brown, 2008; Sheppard et al., 2011), a plausible consequence of geologic activity bringing ices and volatiles to their surfaces at some point (see McKinnon et al., 2008). Identified ices on a given body tend to be dominated spectrally by either H_2O or CH_4, whereas fainter KBOs tend to be spectrally featureless (e.g., Barucci et al., 2008a; Trujillo et al., 2011). Small band shifts of methane lines (a few to a few 10s of Å) are interpreted as a dilute solid-state solution of CH_4 in N_2 ice (as on Pluto and Triton), or vice versa (N_2 contamination of CH_4 ice), even if the 2.15 μm N_2 overtone feature cannot itself be detected (e.g., Tegler et al., 2008). Ethane (C_2H_6) ice is an expected photolytic and radiolytic alteration product of methane, and its detection is taken as corroboration that methane is indeed present on a given body.

The overall pattern of volatile identification can be understood, to first order, by considering both a KBO's size, and hence its ability to retain volatiles against escape, and its orbit, which determines surface temperature and surface temperature variation (Schaller and Brown, 2007b). Temperature determines which ices are likely to sublimate and raise a sensible atmosphere in vapor-pressure equilibrium, and insolation variation drives surface–atmosphere interactions that can cycle and refresh surfaces on seasonal timescales (e.g., Young, 2013). **Figure 4** illustrates how these factors interact. Methane ice is very easily seen spectroscopically and is detected on all the large, labeled KBOs in the figure to the right of the CH_4 stability line, with the

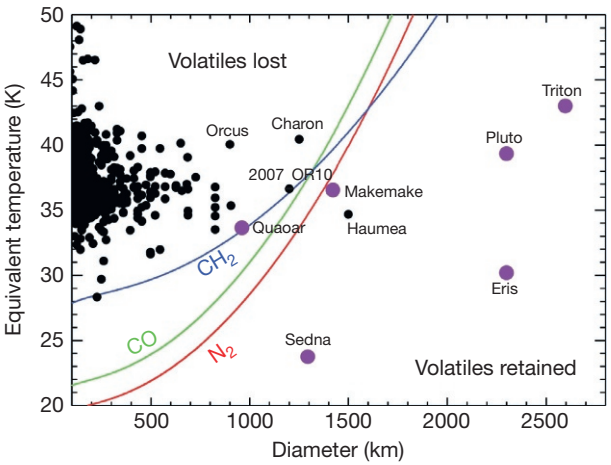

Figure 4 Volatile retention and loss in the Kuiper Belt. Objects to the left of the CH_4, CO, and N_2 lines are too small and too hot to retain any of those surface volatiles against Jeans escape over the age of the solar system, while objects to the right can retain those volatiles. All objects shown in purple have had CH_4 measured on their surfaces, although the detection of CH_4 on Sedna is less than conclusive (Barucci et al., 2010). In addition, Pluto, Triton, Eris, and Makemake have had N_2 or CO detected or inferred. No objects to the left of the lines have had any of these volatiles definitively detected. Methane is strongly suspected on 2007 OR_{10} (Brown et al., 2011). Note that diameters shown are not necessarily the same as (the more recent values) in **Table 2**, and equivalent temperature is that which provides the same escape flux as integration over an orbital period. Modified from Schaller EL and Brown ME (2007b) Volatile loss and retention on Kuiper Belt objects. *Astrophysical Journal Letters* 659: L61–L64; Brown ME, Burgasser AJ, and Fraser WC (2011) The surface composition of large Kuiper Belt object 2007 OR10. *Astrophysical Journal Letters* 738: L26 (4 pp.).

exception of Haumea (discussed in the succeeding text). Methane is a well-determined component of cometary ices (Mumma and Charnley, 2011), so its presence on the surfaces of KBOs that are more than large enough to have been internally active at some time (McKinnon et al., 2008) is not a surprise.

Nitrogen ice is perhaps more interesting. N_2 and CO are both 'supervolatile,' and whereas CO is a known component of cometary ices, molecular N_2 is not (Bockelée-Morvan et al., 2004) (N_2 is also notoriously difficult to detect; e.g., Cochran, 2002). Thus, the source of N_2 may be something else (and is commonly thought to be NH_3). If so, the presence of N_2 on Pluto and Triton (**Section 10.19.2.2**) and its inferred presence on Makemake and Eris (Tegler et al., 2008, 2010) may also be hallmark of large KBO thermochemistry. Sedna is large enough and cold enough for N_2 (or CO) to persist on its surface (cf. Barucci et al., 2005, 2010), but as Brown (2012) pointed out, Sedna is so cold that any nitrogen ice should be in the α phase and almost impossible to detect because of the extreme narrowness of its 2.15 μm absorption compared with that of β nitrogen. At its distance from the Sun, Sedna is a difficult target for spectroscopy (low signal/noise), and even the absorption features attributed to CH_4 are only marginally detected (Barucci et al., 2010).

Regarding the transitional bodies in **Figure 4** – Quaoar, 2007 OR_{10}, and Makemake – these bodies should have retained methane ice, but lost much of their allotment N_2 or CO. This is consistent with spectral information, especially considering that 2007 OR_{10} and Quaoar are likely somewhat larger than plotted in the figure (Braga-Ribas et al., 2013; Santos-Sanz et al., 2012). All three bodies are spectrally very red (a plausible signature of methane irradiation), and Quaoar and Makemake have methane *and* ethane on their surfaces (Brown et al., 2007a; Dalle Ore et al., 2009; Schaller and Brown, 2007a). Quaoar and 2007 OR_{10} also exhibit the signature of H_2O ice (Brown et al., 2011; Jewitt and Luu, 2004), which indicates that these two bodies have reached an advanced stage of methane loss. Makemake, in contrast, has a very methane-rich surface (Brown et al., 2007a; Licandro et al., 2006) and still retains a modest amount of N_2 (or CO), based on very small band shifts in its methane absorptions (Tegler et al., 2008). These small shifts imply either frost patches of N_2-rich ice or, perhaps more likely, small amounts of N_2 dissolved in CH_4-ice crystals as a contaminant. This is consistent with Makemake's position on the figure.

Charon and Haumea sit on opposite sides of the stability lines in **Figure 4**. Both are spectrally dominated by water ice absorptions (Barucci et al., 2008a; Brown, 2008). Haumea could, conceivably, stably host N_2 or CO ices on its surface. This remarkable KBO is orbited by two known satellites and itself orbits adjacent to a dynamical family of fragments, all of which bear clear, deep spectral signatures of crystalline water ice (Brown et al., 2007b). Haumea is also rather dense and rotating so rapidly (with a 3.9 h period) that it has apparently distorted into a Jacobi-figure-like triaxial body. This state of affairs is most elegantly explained by a massive collision in which a differentiated proto-Haumea lost much of its icy mantle (Brown et al., 2007b) or in which both impactor and target lost substantial ice (Leinhardt et al., 2010) (see also Schlichting and Sari, 2009; Ortiz et al., 2012; Ćuk et al., 2013). Presumably, any volatile-ice-rich crust was lost along with ejected mantle, leaving mostly water ice behind.

Charon, of course, is also likely the product of a massive collision, so its water ice surface may be similarly explained. But Charon is a smaller and warmer body than Haumea, and CH_4, N_2, and CO would not be stable on its surface over the age of the solar system regardless, according to the simple model shown. On the other hand, Charon is spectrally neutral in the visible (Buie et al., 2010b); this may imply that Charon's surface ices have always lacked CH_4 or other light hydrocarbons such as methanol. Otherwise, UV and radiation processing would surely have reddened some of the hydrocarbons, permanently reddening Charon's surface.

Finally, Orcus, in the upper left of **Figure 4**, shares with Charon a flat, spectrally neutral visible spectrum and well-defined water ice absorptions at 1.6 and 2.0 μm (Brown, 2008). There is also a smaller absorption at 2.2 μm that is reminiscent of Charon's spectrum at that wavelength, but the signal-to-noise ratio is such that a clear identification (e.g., of ammonia) cannot yet be made (Barucci et al., 2008b; Carry et al., 2011; Delsanti et al., 2010). Overall, the utility of **Figure 4** for understanding volatile-ice compositional patterns is remarkable and suggests common cosmochemical processes are at work.

As an aside, one of these cosmochemical processes must be the preservation of crystalline water ice against radiation-induced amorphotization. The 1.65 μm absorption feature specific to *crystalline* water ice is ubiquitous among KBOs and icy satellites where H_2O ice is seen. A number of authors, when first detecting this band, have implicated recent icy or cryovolcanism, regardless of the size or context of the body in question. That midsize and larger KBOs possess crystalline water ice should not be surprising: these bodies are all of the size that impact and/or long-term radiogenic heating would have caused any amorphous water ice originally accreted (and which is, after all, metastable) to crystallize (e.g., McKinnon, 2002; McKinnon et al., 2008). Water ice exposed at the surface to the space environment and thus to ionizing radiation may, however, be expected to reamorphotize (Cook et al., 2007), yet this is not seen. Of course, ionizing UV radiation does not penetrate deeply, and cosmic rays may penetrate too deeply to compete with impact-driven regolith gardening. Clearly, our understanding is incomplete.

10.19.3.2 Densities and Interiors

As important as surface compositions are, bulk densities are at as least as important for constraining formation, origin, and composition. Taken together, they provide deeper insight into solar nebula chemistry and planetary formation processes (see, e.g., **Chapter 10.02** in this volume). Although it has been historically difficult to determine bulk densities accurately, recent years have seen the discovery of satellites for a number of large and midsize KBOs (some of the latter are sometimes listed as Centaurs, but here, we follow the definition of Gladman et al. (2008) that Centaur semimajor axes must be less than that of Neptune). With the discovery of satellites, or binarity, Kepler's 3rd law gives the system mass and, with size estimates from occultations or radiometry, densities.

Figure 5 illustrates densities of TNOs for which constraining mass and radius estimates are available. Typhon, Ceto, Sila, and 1998 SM_{165} are all binaries, while 1999 TC_{36} is a triple system, which complicates radiometric interpretations of diameter.

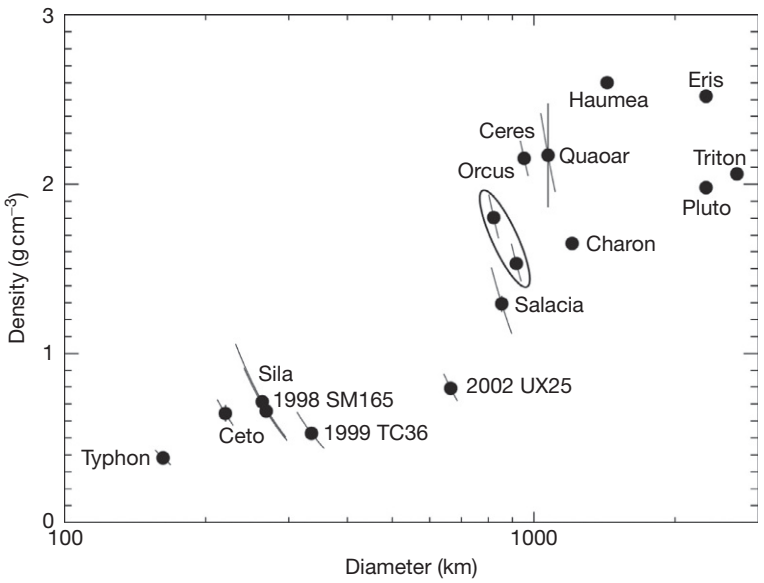

Figure 5 Densities of large and midsize Kuiper Belt objects (KBOs) and Ceres. Uncertainties in diameter generally dominate uncertainties in mass. Diameters from radiometry (midsize KBOs) are judged less reliable than those from stellar occultations (most of the large KBOs and Ceres). The correlation of density with diameter cannot simply be a function of decreasing porosity with increasing body size, but implies a trend of decreasing iciness as size increases (see text). Note that, as with **Figure 4**, diameters shown are not necessarily the same as in **Table 2**. Modified from Brown ME (2013) The density of mid-sized Kuiper belt object 2002 UX25 and the formation of the dwarf planets. *The Astrophysical Journal Letters* 778: L34 (5 pp.).

The apparent correlation of KBO size with density has been noted by a number of authors. As discussed by McKinnon et al. (2008), one simple explanation that has been offered is that all KBOs have a solid or grain density near 2 g cm^{-3} – a value independently supported by cosmochemical arguments (e.g., Wong et al., 2008) – but that smaller KBOs are substantially porous. There are, however, limits to the maximum porosity that can be reasonably, frictionally supported in any midsize 'rubble-pile' KBO, probably about 40% and decreasing with increasing pressure (Durham et al., 2005). The inference, then, is that all the low-density bodies in **Figure 5** are substantially icier than, for example, Pluto, Triton, or Eris.

What alternative process could then lead to the size–density correlation in **Figure 5**? One clue is offered by Haumea. It appears to be the densest known KBO at present and, as discussed previously, is thought to have lost up to half its icy mantle in a massive impact (Brown et al., 2007b). Haumea's satellites and family members presumably could be water ice-rich (consistent with their spectra), porous, and of low density. If this phenomenon can be generalized, then large KBOs, if differentiated, would tend to evolve to be more rock-rich, while any ejected icy fragments would tend to make the smaller and midsize KBO population more ice-rich as a whole. Brown (2012) outlined a simple, heuristic model of this process, but concluded that the ice/rock fractionation process was too inefficient to explain the observations.

The size–density correlation in **Figure 5**, if real, is clearly an important one and offers an important clue as to how the Kuiper Belt formed. For example, if large KBOs formed by the traditional hierarchy of two-body, accretionary collisions (coagulation) (Kenyon and Bromley, 2012), and KBO-forming planetesimals all started suitably rock-rich, then as Brown (2012) determined, it may be difficult to create enough ice-rich, smaller KBOs to much affect the composition of the small and midsize population as a whole. If, however, KBOs are all 'born big,' that is, formed from the gravitational collapse of large aggregates of very small 'pebbles' concentrated by streaming instabilities in the solar nebula (Johansen et al., 2012; cf. Morbidelli et al., 2009), then most smaller KBOs should be fragments created by impacts of and on these larger KBOs. This second generation of smaller KBOs could then be quite icy by their very nature, but only if the original, large KBOs had differentiated early on.

The issue of the compositions of small and midsize KBOs is connected to the issue of the compositions of comets (A'Hearn, 2011). It is certainly not obvious that comets are collisional fragments as opposed to being primordial planetesimals (Mumma and Charnley, 2011), although estimates of cometary densities are certainly compatible with the low densities in **Figure 5**. (And it should be noted that the internal stresses in 1–10 km diameter comet nuclei are so low that almost any porosity can be maintained by internal strength.) Nor is the robustness of the correlation in **Figure 5** established. Densities based on direct imaging or radiometric modeling have tended to be replaced over time by more accurate stellar occultation values. For example, Quaoar is no longer viewed as rocky as estimated initially (Fraser and Brown, 2010). Also, Phoebe, the 210 km diameter irregular satellite of Saturn, is widely thought to have been captured from the Kuiper Belt, and its mean density is well known at 1.64 g cm^{-3} (see Wong et al., 2008). More accurate measurements of midsize KBO densities are needed.

10.19.4 The Kuiper Belt

The small body populations of the solar system are the archaeological or 'fossilized' remnants of what were once vast

and innumerable planetesimal swarms. The extant trans-Neptunian population, viewed broadly, stretches from the Jupiter-family comets, through the Centaurs, across the 'classical' KBOs outside Neptune's orbit, to scattering and detached deep space objects well beyond (Gladman et al., 2008; **Figure 6**). As of this writing, over 1650 TNOs are known, but the actual population is much larger, perhaps 200 000 bodies of 100 km diameter or more and with a combined mass of 0.05–0.10 Earth masses (Fuentes and Holman, 2008; Gladman et al., 2012; Kaib et al., 2011; Petit et al., 2011). The dynamical complexity of the entire Kuiper Belt is evident in **Figure 6**, and understanding its details has opened a window to understanding the origin and evolution of the early solar system that never existed before.

As alluded to earlier, the Kuiper Belt population can be divided into two broad populations, dynamically excited (in terms of eccentricity e or inclination i), or 'hot,' and much less dynamically excited (low e and i), or 'cold.' Further distinctions are physically meaningful (**Figure 6**). Following Petit et al. (2011), resonant objects are those currently in a mean-motion resonance with Neptune, and scattering objects are those which over 10 My integrations experience encounters with Neptune resulting in a semimajor axis a deviation of more than 1.5 AU. Classical bodies can be further subdivided into the inner classical objects (a interior to the 3:2 mean-motion resonance), main classical objects (a between the 3:2 and 2:1 mean-motion resonances), and outer classical objects (a exterior to the 2:1 mean-motion resonance). Classical objects can also be categorized as dynamically hot or cold, but all the cold classicals ($i < 5°$ or so) are in the main group.

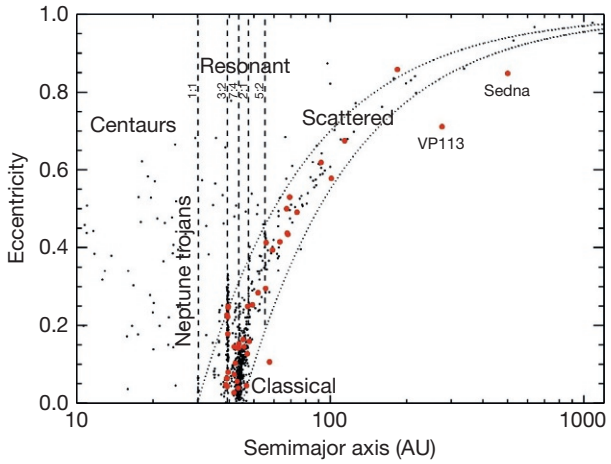

Figure 6 Semimajor axis versus eccentricity of multiopposition trans-Neptunian objects (updated from Sheppard et al., 2011; S. Sheppard, personal communication). Large circles represent TNOs with absolute magnitude $H \leq 4.5$ magnitude (including those in **Table 2**). Several distinct dynamical KBO populations are shown. Vertical dashed lines indicate the main mean-motion resonances with Neptune as well as the Neptune Trojans in the 1:1 resonance. In this figure, 'scattered disk' objects have perihelia between 30 and 45 AU as shown between the dashed lines, but this does not have the same meaning as scattering objects, as described in the text. 'Classical' objects are in the lower center portion of the figure and include the high- and low-inclination populations. An edge near 48 AU can clearly be seen for low-eccentricity objects. Centaurs are on unstable orbits between the giant planets. Sedna and 2012 VP_{113} stand out as being significantly below the perihelion line shown at 45 AU and are dynamically decoupled from Neptune, as discussed in **Section 10.19.2**. Some authors (e.g., Trujillo and Sheppard, 2014) regard these two bodies as inliers of a much more massive, inner Oort cloud population.

Detached objects, such as Sedna and 2012 VP_{113} (Trujillo and Sheppard, 2014), have a beyond the 2:1 mean-motion resonance as well as high eccentricities, though the distinction between detached objects and outer classicals is somewhat arbitrary (an eccentricity cut) (Petit et al., 2011). Finally, those 'KBOs' on dynamically unstable orbits between the giant planets (and with $a < a_{\text{Neptune}}$) are classified as Centaurs. Of the 1650 known TNOs in the preceding text, about 385 are Centaurs or scattered disk objects, and 9 are Neptune Trojans (www.minorplanetcenter.net). And it is worth remembering that, with the exception of the detached objects, KBO orbits generally *overlap* in physical space but not in orbital parameter space (**Figure 6**).

10.19.4.1 Nice Models

The family of dynamical models known as 'Nice' (after the city of their birth) has taken a broad variety of ideas in planetary formation and attempted to create a comprehensive working model of what actually might have happened during the solar system's earliest epochs (e.g., Morbidelli et al., 2008). It takes as a point of departure that the solar system was once much more compact, in the sense that the giant planets were all located between ~5 and 15 AU, and there was a remnant planetesimal disk that stretched out to ~30–35 AU (Tsiganis et al., 2005). Slow evolution (migration) of the giant planets' orbits (see Hahn and Malhotra, 1999; Malhotra, 1995) eventually leads to resonance crossing by Jupiter and Saturn, which creates systemic orbital instability. This instability expels the ice giants into the planetesimal disk, and after which, all four giant planet orbits settle down by means of dynamical friction (exchange of orbital energy) with the planetesimals (**Figure 7**).

In the original quantitative 'proof-of-concept' calculations, the secular architecture (a, e, and i) of the giant planets was correctly reproduced (Tsiganis et al., 2005). The model had the additional attribute of providing a mechanism for creating a 'Late Heavy Bombardment' in the inner solar system at ~3.9 Ga, provided the instability could be delayed (and the planetesimal disk survive) for some 600 My (Gomes et al., 2005). This does not mean that matters proceeded precisely as outlined in **Figure 7** (see, e.g., Batygin and Brown, 2010), but the Nice model and its extensions (e.g., Brasser et al., 2009; Levison et al., 2011; Walsh et al., 2011) have proved remarkably adept at explaining various features of solar system architecture. Most relevant to the present discussion is the structure of the Kuiper Belt.

Figure 8 shows the outcome of a numerical simulation in which the Kuiper Belt is filled by chaotically scattered planetesimals in the original formulation of the Nice model ('Nice I') (Levison et al., 2008). The Kuiper Belt region in this model is initially *empty*. The correspondence between the observed and simulated KBOs in **Figure 8** is qualitatively and even quantitatively rather good, once observational biases are taken into account (i.e., distant, as well as high-e or high-i, objects are less likely to be detected in a given survey). Specifically, the

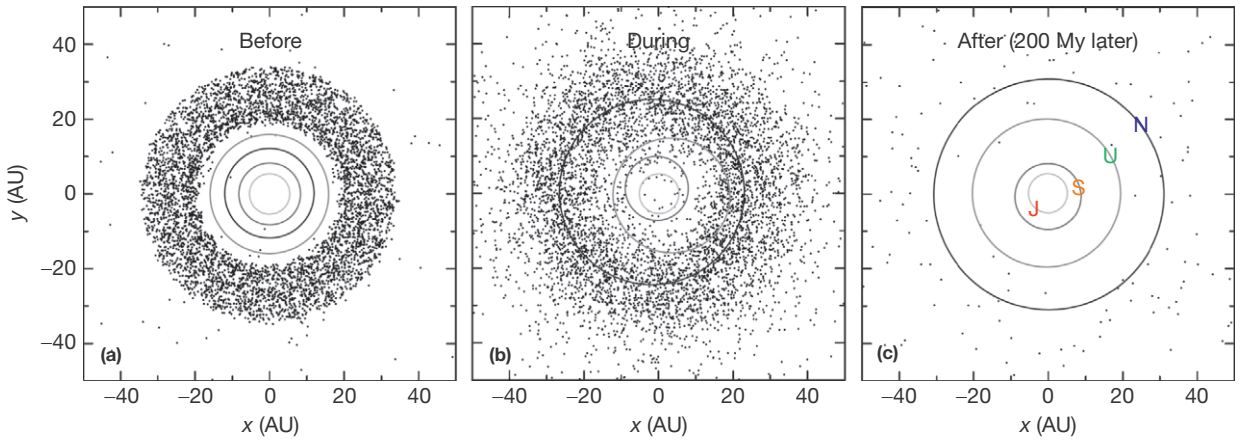

Figure 7 Evolution of a compact, primordial giant planet architecture and surrounding planetesimal disk, in the original demonstration of orbital migration and cataclysmic instability now known as the 'Nice model.' The mass (~30 M_{Earth}) and outer truncation of the planetesimal disk near 35 AU are critical elements in getting the correct, final giant planet orbits. The scattered planetesimals represent the 'Kuiper belt.' Modified from Gomes R, Levison HF, Tsiganis K, and Morbidelli A (2005) Origin of the cataclysmic Late Heavy Bombardment period of the terrestrial planets. *Nature* 435: 466–469.

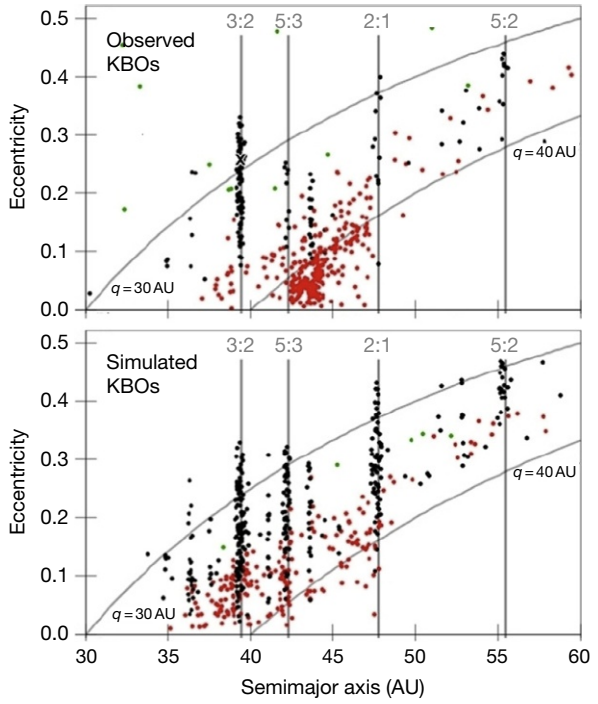

Figure 8 Eccentricity versus semimajor axis distributions for multiopposition KBOs (top) and the results of a Nice model installment simulation (bottom) (modified from Levison HF, Morbidelli A, VanLaerhoven C, Gomes R, and Tsiganis K (2008) Origin of the structure of the Kuiper belt during a dynamical instability in the orbits of Uranus and Neptune. *Icarus* 196: 258–273). Black dots represent resonant objects (with mean-motion resonances indicated), green dots are scattering objects, and red dots are stable, nonresonant objects; X marks Pluto. The simulation is a reasonable facsimile of the observed distribution, once observational biases are taken into account. The simulation displays a deficit of nearly circular objects in the classical Kuiper Belt, however, but does somewhat better with reproducing the spread in cold classical inclinations (not shown). Note the change in semimajor axis scale with respect to **Figure 6**.

mean-motion resonances are populated as well as the 'scattered disk' and hot classical regions. The overall structure in **Figure 8** is mostly due to Neptune, as it completes its outward migration and its eccentricity damps from larger values.

An important aspect of the Kuiper Belt that the simulation in **Figure 8** obviously does not reproduce, as Levison et al. (2008) discussed, is the cold classical population, especially the low-*e* populated region between the 5:3 resonance and 44 AU (**Figure 8**, top). One explanation is that this region contains survivors of a primordial planetesimal disk at this location. This is in some ways an attractive explanation, as the cold classicals are known to be physically smaller (lack large bodies, see next section) and to be spectrally redder than the hot populations (e.g., Doressoundiram et al., 2008). A much larger fraction of the cold classicals are wide binaries (10s of percent), compared with the hot classicals (Noll et al., 2008a,b). In other words, the cold classicals appear to be a physically *and* dynamically distinct population.

Analytic and numerical models have shown that Nice-like instabilities can be compatible with a preserved and only modestly dynamically excited cold classical population, provided Neptune's dynamical behavior conforms to certain strictures (Batygin et al., 2011; Dawson and Murray-Clay, 2012). On the other hand, too much mass in an extended planetesimal disk (out to ~48 AU) would mean that Neptune's outward migration would not halt near 30 AU, so other explanations for the cold classical 'kernel' may yet emerge (Morbidelli et al., 2014; Petit et al., 2011).

The prospect that the cold classical population may represent a primordial, *in situ* population is nonetheless exciting, for two reasons. First, as Batygin et al. (2011) pointed out, the cold classical population would be a "unique laboratory for the study of [disk] surface processes as well as the chemistry of the primordial solar nebula." Second, the *New Horizons* mission, in its extended post-Pluto phase, could fly by a cold classical KBO in the 25–50 km size range. As of this writing, a suitable KBO target has not been found, despite several years of

ground-based searches (Buie et al., 2012a; Parker et al., 2013). Suitable in this case means a KBO that can be reached using the thruster fuel still on board the spacecraft. This search will be renewed in the summer of 2014.

10.19.4.2 Kuiper Belt Population Characteristics

The size distribution of the Kuiper Belt and its various populations are fundamental properties that reflect the accretional and collisional processes that created and shaped these bodies. A great deal of effort over the years has gone into estimating their size-frequency distributions (SFDs), as summarized in Petit et al. (2008). The difficulty lies in converting measurements of apparent luminosities, of distant objects subject to numerous observational biases and incompletenesses, into robust estimates of size. Recent efforts, however, appear to be converging in several important regards. The Canada-France Ecliptic Plane Survey (CFEPS) reports KBO detections from an exceptionally well-characterized survey from a single telescope (Petit et al., 2011). They find that the dynamically hot classicals follow a cumulative magnitude slope $\alpha_{\rm hot} \approx 0.8$, whereas the cold classicals are steeper with an $\alpha_{\rm cold} \approx 1.2$. These slopes can be converted into a differential power-law index of the form $dN/dR \propto R^{-q^*}$, where $q^* = 5\alpha + 1$, N is number of objects, and R is object radius (assuming uniform albedos). Both of these differential size distributions are steep when compared to the collisional slope of Dohnanyi (1969), $q^* = -3.5$ (for size-independent strength). Similar slopes for the cold and hot populations are reported by Fraser et al. (2014) from their multisurvey derivation of KBO absolute magnitudes.

In both Petit et al. (2011) and Fraser et al. (2014), the slopes earlier refer to the bright or large size end of the KBO populations in question. The steep slopes are considered to be a fossilized signature of the accretion of larger bodies from smaller ones (Kenyon and Bromley, 2012; Kenyon et al., 2008). Fraser et al. (2014) further reported that the magnitude distribution of fainter KBOs follows a rather shallow $\alpha_{\rm faint} \sim 0.2$–$0.4$ ($q^* \sim 2$–3), with a break diameter of ~110–140 km. The differences between the hot and cold populations and the inference for a break or knee in the SFD go back to the deep HST survey results of Bernstein et al. (2004), but there now appears to be agreement on this aspect of the population structure.

Analysis of deep *Subaru* imaging (Fraser and Kavelaars, 2009; Fuentes and Holman, 2008; Fuentes et al., 2009) also supports a knee or double power law for the TNO SFD. Shankman et al. (2013) further allowed (based on CFEPS data for the scattering population) that, rather than a simple knee in the SFD, there may be deficit or 'divot' of bodies below a break diameter of ~100 km and, at still smaller sizes, a steepening of the distribution (to perhaps $\alpha_{\rm faint} \sim 0.5$). At the very faint end (<10 km diameter), there are very few direct observational constraints, and some rather complex SFDs have been proposed (Schlichting et al., 2013).

An important aspect of all this work is that similarly steep population indices appear to characterize all the hot populations, classical, scattered, and resonant, at the bright ends of their distributions (Fraser et al., 2014; Gladman et al., 2012; Petit et al., 2011; Schwamb et al., 2014). Moreover, Fraser et al. (2014) found that the known, broken power-law SFD of the Jovian Trojan asteroids is a statistical match with their hot population model (i.e., the hypothesis that the hot population and the Trojans were drawn from the same parent population cannot be rejected). Capture of Trojan populations is a prediction of the Nice model (Morbidelli et al., 2005; Nesvorný et al., 2013), so these populations should be similar (barring strong, separate collisional evolution). A further implication is that the cold classicals are truly a different, and possibly *in situ*, population, as discussed earlier.

It remains to be seen, however, how the different color (spectral slope) characteristics of the resonant KBO populations can be explained (Sheppard, 2012). Naively, they should all share the same 'hot population' color characteristics, but for example, objects in the 5:3 and 7:4 resonances are mostly of the 'ultrared' variety, which is characteristic of the low-inclination, cold classicals. These two resonances are, however, anchored (in terms of semimajor axis) in the core of the cold classical population (**Figure 8**, top). Indeed, they may actually have been populated from the cold classicals, as Neptune completed its migration (Batygin et al., 2011; B. Gladman, personal communication), as opposed to being populated by bodies transported from closer to the Sun, as in Levison et al. (2008).

There is clearly much to learn about how the resonant populations of Kuiper Belt were created and what that implies for the global evolution of the solar system. For example, based on CFEPS detections, Gladman et al. (2012) estimated that resonances beyond the 2:1 are more populated than Nice model simulations have shown to date. Deeper surveys will be necessary to put our understanding of these more distant, resonant populations on a firmer footing.

10.19.5 Final Remarks

The revelation of the Kuiper Belt is arguably the most important advance in solar system science in the last 30 years. Its only rival would be the discovery and characterization of planets around other stars. Yet, taken together, these represent a paradigm shift in terms of the stability and nominally uniformitarian evolution of our solar system. Most researchers now recognize that the solar system was likely much different (compact) and far more dynamic (violent) in its first 600 million years. The Kuiper Belt contains the richest record of this bygone era. Dwarf planets such as Pluto likely accreted well inside their present orbital positions and have much to teach us about the chemical and physical conditions in the earlier trans-Neptunian disk. Our understanding of the Pluto–Charon system should improve dramatically in 2015, and in 2016, because the data downlink from the July 2015 *New Horizons* encounter will take over a year. Beyond that, the coming generation of ground-based and space-based telescopes should probe trans-Neptunian space ever deeper and more completely. The full story of Pluto and Kuiper Belt is yet unwritten.

Acknowledgments

Support for this introduction and review was provided by NASA and the *New Horizons* project. I thank Brett Gladman, Will Grundy, Scott Sheppard, and Tilman Spohn for their comments. Deep searches by *HST* in summer 2014 have located one, and possibly two, post-Pluto KBO tragets for *New Horizons*.

10.20.1 Overviews

It is now widely recognized that Pluto's discovery was a harbinger of the discovery of the Kuiper Belt (KB), the third major architectural zone of our solar system, after the terrestrial planet and giant planet zones. It is less widely recognized, but nonetheless the case, that Pluto has over time also been a harbinger of dwarf planets, of slow rotation periods, of bodies containing exotic surface volatiles, of bodies trapped in mean motion resonance (MMR) with Neptune, and of satellites that are now seen to be common among Kuiper Belt objects (KBOs). Someday, Pluto may be seen as a harbinger of KBO atmospheres.

In this section, we provide an overview of what is known about the Pluto system, the KB, and KBOs. In subsequent sections, more detail is provided.

10.20.1.1 The Pluto System

The discovery of Pluto by Tombaugh in 1930 opened a chapter in planetary science that is still unfolding. Almost immediately after this discovery was announced, it was recognized that this new planet was highly unusual, owing to its small size and its highly elliptical, highly inclined orbit. As a result, struggles to place Pluto in the context of the architecture of our solar system continued for many decades. The range of conjecture concerning Pluto spanned the space from it being an ejected asteroid, to an escaped satellite, to a member of a distant debris belt related to planet formation (e.g., see Stern et al., 1997).

However, owing to limitations in observing and computing technology, little progress was made in understanding Pluto's context before the 1980s, when serious discussion of the KB (Duncan et al., 1988; Fernandez and Ip, 1984; Stern, 1991) and the population content of 1000 km-sized bodies in the deep outer solar system was seriously examined from a quantitative standpoint.

Similarly, owing to its faintness and small angular size on the sky, which put its study well beyond the capabilities of mid-twentieth-century technology, little progress regarding Pluto's nature was made before the 1950s. However, from 1955 to the present, the increasing pace of technological advances in astronomical telescopes and instrumentation, combined with advances in perspective drawn from the initial reconnaissance of the terrestrial and giant planets, and the discovery of the KB, led to an increasingly full picture of Pluto and its context. Major advances achieved in this era included the following:

- Discovery of Pluto's 6.4-day rotation period (Walker and Hardie, 1955).

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00179-2

- Discovery of Pluto's 3:2 mean motion heliocentric resonance with Neptune (Cohen and Hubbard, 1965).
- First crude spectrum, revealing a reddish surface color (Fix et al., 1970).
- CH_4 ice detected (Cruikshank et al., 1976).
- Charon was discovered, yielding a system mass (Christy and Harrington, 1978).
- Stellar occultation revealed that Charon's radius is close to 600 km (Walker, 1980).
- Onset of a rich series of mutual occultation events between Pluto and Charon (Binzel et al., 1985).
- Determination of reliable radii for Pluto and Charon (Tholen et al., 1986), in turn yielding a 2 g cm^{-3} average system density.
- Water ice was discovered on Charon (Marcialis et al., 1987).
- Pluto's atmosphere was revealed by stellar occultation (Elliot et al., 1989).
- Mutual events produced evidence for polar caps (Binzel, 1989).
- Arguments that ice dwarf planets like Pluto were common in the early solar system (Stern, 1991).
- Discovery of the KB (Jewitt and Luu, 1992).
- Discovery of N_2 and CO ices on Pluto (Owen et al., 1993).
- Hubble Space Telescope (HST) imaging revealed Pluto's highly variegated surface (Stern et al., 1997).
- Detection of CH_4 in Pluto's atmosphere (Young et al., 1997).
- Discovery of Pluto's small satellites Nix and Hydra (Stern et al., 2006; Weaver et al., 2006).

With many of these facts in hand, by the late 1980s, it was clear that Pluto was a very different kind of world from either the terrestrial planets or the giant planets, replete with multiple surface volatiles; a complex, escaping, seasonally variable atmosphere; and a highly variegated surface. Moreover, Pluto was seen to be a binary planet, that is, an object with a satellite so large, and so close, that the system barycenter lies outside the primary in free space between the planet and the moon. By the early 1990s, it had also been argued that Pluto was not a misfit among the planets, but the first of a large population of 1000 km-sized KB and more distant bodies in a population that likely include objects of sizes extending up to Earth mass or somewhat larger (Stern, 1991).

10.20.1.2 Kuiper Belt

The existence of the KB was first predicted by mid-twentieth-century astronomers such as Kenneth Edgeworth (1943, 1949) and Gerard Kuiper (1951). These and other astronomers of the 1930s, 1940s, and 1950s postulated that a debris belt of material left over from planetary formation might orbit the Sun beyond Neptune. However, the faint object detection technology of the mid-twentieth century was too primitive to give astronomers real hope of finding bodies out there – they were simply too faint to be found.

By the late 1980s, however, dynamicists found strong evidence in the inclination distribution of the Jupiter family comets that they are coming from a disklike reservoir just beyond Neptune's orbit (Duncan et al., 1988). This dynamic evidence was bolstered by the discovery of 2060 Chiron, orbiting in a short-lived, dynamically chaotic orbit, between Saturn and Uranus (Kowal et al., 1977). Unfortunately, although Kowal's survey data set did detect several large KBOs, his manual detection technique failed to identify them as trans-Neptunian bodies, so they remained undiscovered for another 20+ years.

As a result of the discovery of Chiron and computer modeling that argued strongly for a disklike reservoir of comets beyond the giant planets (e.g., Duncan et al., 1987), a number of searches were begun in the late 1980s for the belt of material that Kuiper predicted. The first KBO was subsequently discovered (Jewitt and Luu, 1992). This object, designated 1992 QB_1, is more than 1000 times fainter than Pluto and probably some 10–20 times smaller in radius.

Over 1200 other KBOs and centaurs had been discovered by late 2006, with estimated diameters ranging from 30 to perhaps 2700 km (e.g., Bernstein et al., 2004; Bertoldi et al., 2006). Based on the large fraction of sky left to be searched and the sky density of faint, distant objects being found in deep charge-coupled device (CCD) images, it is estimated that over 100 000 KBOs with diameters more than 50 km may orbit in the KB. From the orbital distribution of KBOs, the KB has been revealed to be a disklike or belt-like structure that stretches from 30 to at least 55 astronomical units (AU) from the Sun. It is now recognized that the KB is a far greater collection of objects, particularly large objects, than the asteroid belt between Mars and Jupiter.

Collisional processes are known to play a key role in the KB (e.g., Davis and Farinella, 1997; Durda and Stern, 2000; Stern, 1995, 1996). A significant result of collisional modeling is that KBOs smaller than ~50 km in diameter cannot have survived the collisional bombardment of the current-day KB over time and therefore must be much younger than the age of the solar system. This implies that the Jupiter family comets, which have their source region in the KB, are recently produced from chipped-off larger, ancient KBOs.

Based on the sizes and orbits of KBOs, it appears that the birthplace of the KBOs was well on its way to growing one or more large planets, perhaps even something the size of the Earth, or even Neptune, when the growth process was interrupted (e.g., Farinella et al., 2000; Stern and Colwell, 1997a,b). Perhaps, the formation or transport of Neptune near 30 AU interrupted this growth.

Numerous excellent reviews of the structure and dynamics of the KB have been written (e.g., Morbidelli, 2006). Here, we give only a brief recapitulation of the primary structure and orbital populations of the KB, in order to set the context for our discussions concerning KBOs themselves.

The KB consists of two broad dynamic populations, the classical KB (CKB) and the scattered KB (SKB). Both populations involve bodies on orbits that lie beyond Neptune. Former KBOs, which currently penetrate deeply into the giant planets' region owing to dynamic loss from the CKB and SKB, are referred to as centaurs. Centaur bodies have short (e.g., $10^{6.5}$–$10^{7.5}$ years) orbital lifetimes that typically end with a strong scattering event that ejects them back outside the giant planet region.

The classical belt contains objects that orbit beyond Neptune but generally within ~60 AU. Both Neptune-resonant and Neptune-nonresonant classical KBOs (CKBOs) are recognized. Those on resonant orbits are often referred to as

plutinos, in honor of Pluto, the first object discovered on such an orbit type. Although Pluto orbits in the 3:2 Neptune MMR, plutinos have also been found in the 2:1, 5:3, and 7:4 Neptune MMRs as well.

The MMR orbits of the plutinos provide strong evidence for the migration of Neptune, probably by many astronomical units, early in the history of the solar system (e.g., Malhotra, 1993; Morbidelli et al., 2005). Further, the broad distribution of CKBO orbital inclinations and the presence of the scattered KBOs (SKBOs) indicate a violent dynamic history there. This might involve a passing star, large migrating planetary embryos, or sweeping secular resonances during the time that the KBOs were forming (see, e.g., Morbidelli (2006)).

Estimates of the mass of the current-day KB fall in the range of $10^{-2}\,M_{\rm Earth}$ to $10^{-1}\,M_{\rm Earth}$, with crudely equal proportions in the CKB and SKB (Morbidelli, 2006). Less than 0.1% of this mass is at any time orbiting closer as centaurs (Morbidelli, 2006).

The fact that large bodies hundreds and thousands of kilometers across orbit in the KB provides inescapable evidence that these bodies formed in an environment with approximately 10^2–10^3 times higher surface mass density than is present today (e.g., Farinella et al., 2000; Kenyon and Bromley, 2001; Stern, 1995, 1996). This in turn suggests either that the KB region was formerly far more massive and was subsequently dynamically and/or collisionally eroded (e.g., Stern and Colwell, 1997a,b) or that the large bodies in the KB were dynamically transported outward to their current orbits after formation closer to the Sun (Morbidelli, 2006).

A key dynamic characteristic of the KB is that many of the orbits there are dynamically 'hot,' that is, they have substantial eccentricities and inclinations as high as 40°. These orbits provide strong forensic evidence of one or more dynamic excitation mechanisms that operated in the past. Suggested excitation mechanisms include but are not limited to scattering by the giant planets, migration of the giant planets, perturbations from formerly present planets in the KB, and external perturbations from passing stars. Hot orbits are also common to the SKB. Most discovered SKBOs were very likely excited to their current orbits by scattering off Neptune.

The CKB also contains a population of bodies on cold (low-eccentricity and low-inclination) nonresonant orbits (Brown, 2001; Levison and Stern, 2001) that imply formation in situ, that is, without the strong dynamic transport of the hot population. This population includes large KBOs, providing strong evidence that there was indeed sufficient mass in the primordial disk extension beyond Neptune for such objects to form.

A cold SKB population has also been proposed (Stern, 1996; Stern and Colwell, 1997a) in order to explain the surface mass density deficit of the KB and the possible in situ growth of Sedna (Stern, 2005). Because no such bodies have yet been detected, it is not yet possible to determine definitively whether the primordial protoplanetary disk was compact (i.e., ~20–30 AU in radius), a less compact structure (perhaps 50 AU in radius), or a broad disk (which might reach out to 500 AU or more, as observed in many extrasolar debris disks).

10.20.1.3 Kuiper Belt Objects

The properties of KBOs are discussed in greater detail in the succeeding text, but a few relevant facts are as follows. The surfaces of KBOs are relatively unreflective, typically scattering only 3% to perhaps 15% of the light that falls on them, though Eris and Pluto have very high surface albedos (e.g., Grundy et al., 2005a,b). KBOs have a wide range of surface colors (Barucci et al., 1999a,b; Davies, 2001; Jewitt and Luu, 1998; Luu and Jewitt, 1996; Tegler and Romanishin, 1998), varying from almost gray to very red, but it is not clear whether this is due to genetic differences among KBOs or evolutionary effects (e.g., space weathering and collisional resurfacing). It is thought that KBOs consist primarily of mixtures of water ice and rock, with some amount of organic and other complex compounds as well. Most KBOs rotate on their axes in a few hours, but some take days to rotate. Some have sufficiently low enough densities ($<1\ {\rm g\ cm^{-3}}$) to clearly indicate internal macroporosity (e.g., McKinnon, 2002; Mckinnon and Barr, 2006). There is already evidence for water and more exotic ices like N_2 and CH_4 on KBOs (e.g., Delsanti and Jewitt, 2006; Licandro et al., 2006). But it is not known if KBOs fall into clear compositional groups as the asteroids do or whether they instead simply form a broad continuum of surface colors and compositions. Other than Pluto, no KBO is known to have an atmosphere, but at last, there are good reasons to expect that some large KBOs exhibit atmospheres, at least transiently (Stern and Trafton, in press).

In mid-2005, it was also discovered that Pluto has two smaller moons (Weaver et al., 2006), making the system a quadruple. Pluto's smaller satellites orbit in nearly circular orbits and in the same plane as Charon; they lie near or at the location of MMRs with Charon. These attributes strongly imply a common origin for all of Pluto's satellites in the giant collision that created Charon (Stern et al., 2006).

In 2001, the first satellite orbiting a KBO, 1998 WW31, was discovered (Veillet et al., 2002). Since that time, numerous other KBOs have been discovered to have satellites. Based on detection statistics and taking into account selection effects that bias detection frequency, it has recently been estimated that at least 10% of all KBOs have satellites (Margot et al., 2004; Noll et al., 2002; Stephens and Noll, 2005); owing to some strong detection biases, the actual fraction of KBOs with satellites may be considerably higher. By late 2006, within 5 years after the discovery of the first KBO binary, there were over two dozen KBOs and centaurs with known satellites. No KBOs except Pluto (with three known satellites) and 2003 EL61 (with two known satellites) are as yet known to have more than one satellite.

Knowledge about KBO satellite albedos is nonexistent; so are colors, except for Pluto's three satellites (Stern et al., 2006). As to satellite spectra, the only published information we are aware of as of mid-2006 is that the brightest satellite of 2003 EL61 exhibits strong water ice features at 1.5 and 2.0 μm that are much deeper than typically found on KBOs (Barkume et al., 2006). We hope that much more information will soon be obtained on KBO satellites, since interesting questions revolve around whether KBOs and their satellites are similar in color, composition, and albedo, or not. Whether the highly dichotomous colors, surface compositions, and albedos of Pluto and Charon are typical, or not, is an open question.

10.20.1.4 On KBO Nomenclature

We, like many others, refer to all bodies orbiting in the KB as KBOs. Therefore, in effect, the KBO designator is merely an

indication of the location of bodies orbiting there, rather than an indication of the kinds of bodies orbiting there. The term 'trans-Neptunian object' (TNO) also is used in the literature, and we occasionally use it in what follows, also as an indication of location without any information content about the kind of body that object in this region is.

It is also useful to classify KBOs into size categories as follows:

- *Debris*. KBOs with diameters $D < 50$ m
- *Comets*. KBOs with 50 m $< D <$ 500 km
- *Dwarf planets*. KBOs with 500 km $< D <$ 5000 km
- *Satellites*. Secondary bodies orbiting any KBO

If KB bodies with diameters >5000 km are later discovered (the SKB region is the most likely region in this regard), we would refer to these objects as planets.

In what follows, we will also use the term 'binary' from time to time. When we do so, we are referring to two objects that orbit a common center of mass and that have a barycenter in free space between the two orbiting bodies. An example of a KBO binary is thus the binary planet Pluto–Charon.

10.20.2 Environment

The salient environmental characteristics of the KB region are its low population and surface mass density, its cold thermal conditions, and its location within the solar heliosphere. We now discuss the various environmental factors that influence KBOs; these include insolation, collisions, ISM grain erosion effects, and radiation fluence. We describe each in turn. These various influences affect the surfaces of KBOs and therefore shed light on the interpretation of KBO physical measurements, which are discussed later in this chapter.

10.20.2.1 Insolation

The thermal environment of the KB is dominated by the Sun. Although the extant insolation is diluted relative to conditions at 1 AU by factors of order 10^3–10^4, it is still capable of heating surfaces to characteristic temperatures of ~20 to ~70 K, depending on heliocentric distance, polar obliquity, surface albedo, and surface emissivity.

Because many KB bodies range over great swaths of heliocentric distance (as Pluto does) and have substantial polar obliquities (as Pluto also does), significant annual and seasonal variations in surface temperature are expected on individual KBOs.

At the cold temperatures characteristic of the KB, virtually all cosmogonically abundant molecules have negligible vapor pressures; this includes the common outer solar system ices H_2O and CO_2. The only thermophysically active molecules of cosmogonic importance in the KB temperature regime are, in order of decreasing volatility with temperature, O_2, N_2, CO, and CH_4. In addition to these four molecular species, the noble gases He, Ne, Ar, and Kr are also volatile in the KB thermal regime. For those KBOs with surface-lying or near-surface-lying volatiles, one expects insolation to drive sublimation, followed by the formation of either global or patchy atmospheres (Stern and Trafton, in press).

10.20.2.2 Collisions

As discussed previously, collisional processes are important in the KB; this has been known for some time (e.g., Stern, 1992, 1995; see Farinella et al. (2000) for a thorough review). Although, owing to the more dilute population density and lower orbital speeds, intrinsic collision rates (the number of collisions per unit surface area per unit time) are lower by a factor of about 1000 in the KB compared to the main asteroid belt, the population of objects there is roughly 1000 times as great. As a result, the overall level of collisional processing of individual objects is of similar scale in the KB as in the main asteroid belt.

Durda and Stern (2000) showed that in the current KB, surface modification by small impactors is expected to be extensive. In particular, they estimated that the cumulative fraction of the surface area of KBOs ranges from a few to a few tens of percent over 3.5 Gy. Such collisions structurally modify surfaces and excavate buried materials, potentially including volatiles, from depths up to several times the impactor diameter.

At typical KB collision speeds, typically 0.5–1.5 km s^{-1}, little surface vaporization of H_2O and CO_2 is expected. What about vaporization of more volatile surface ices? Unfortunately, no studies of the vaporization fraction of more volatiles ices like N_2, CO, and CH_4 are available, so it is not known whether significant mobilization or even loss of these volatiles occurs (E. Pierrazzo, personal communication). However, by excavating fresh material, collisions may be responsible for creating both high-albedo ejecta rays that influence KBO albedos, and the competition between the excavation of fresh material and its subsequent reddening by radiation may also create surface color variability with time (e.g., Jewitt, 2002; Stern, 2003).

KB collisions happen at sufficiently high speeds that they are erosional for bodies with diameters of a few hundred kilometers and smaller, causing KBO comets and smaller debris to lose surface material over time. In fact, the time-averaged rate of erosion in the KB is so high that virtually all KBOs with diameters of 5 km and smaller are thought to be fragments from 'chipped-off' larger KBOs in the last 10–20% of the age of the solar system (e.g., Davis and Farinella, 1997; Durda and Stern, 2000; Stern, 1996). Hence, most KB comets are expected to exhibit low surface exposure ages and are therefore not expected to exhibit many impact craters.

10.20.2.3 Erosional Interactions with the Interstellar Medium

The Sun carries the KB through the interstellar medium (ISM) at a high velocity of approximately 30 km s^{-1}. The resulting impacts of KBOs with ISM grain are important in several ways. They are a contributor of darkening agents to KBO surfaces. They can also erode KBO surfaces, particularly on bodies too small (i.e., with <500 km diameter) for the resulting ejecta to remain bound to the target. This process may in total have caused KBOs with sizes of 10 to perhaps 200 km to have lost from about 1 m to perhaps 20 m of surface material since their formation (Stern, 2003).

10.20.2.4 Radiation Processes

The radiation environment of the KB naturally divides into two subcategories: energetic photon bombardment and charged particle bombardment. Interstellar and solar ultraviolet (UV; i.e., $h\nu > 3$ eV) photons have copious fluxes in the KB, providing the energy necessary to break bonds and initiate substantial chemical change in Oort cloud comet surfaces. Because of their much closer proximity to the Sun, KBOs experience a much (i.e., $\sim 10^5$ times) higher UV and solar cosmic ray (SCR) surface doses, dramatically increasing the total deposited charged particle energy incident on the surfaces of these bodies, relative to Oort cloud comets. However, the galactic cosmic ray (GCR) dose on KBOs inside roughly 100 AU is expected to be far reduced, relative to Oort cloud comets, because of the shielding effects of the heliosphere.

UV photosputtering is capable of eroding away the uppermost few micrometers of icy surfaces of atmosphereless bodies (Throop, 2000). But more importantly, in a classic series of laboratory experiments and theoretical studies, UV photons would produce significant alteration of the composition, color, and volatility of the upper several to few tens of micrometers of cometary surfaces (e.g., Greenberg, 1982). Thompson et al. (1987) and Hudson and Moore (2001) confirmed and extended these results, showing that UV photons promote surface darkening (to albedos of only a few percent) and a devolatilization that becomes progressively more severe with dosage and therefore age.

Like UV photons, charged particle radiation is capable of both sputtering surfaces and breaking bonds, thereby inducing chemical reactions and consequently reordering the surface ice matrix (e.g., Gerakines et al., 2001). The irreversible radiation-driven conversion of the original, water-dominated ice matrix to a more complex 'crust' inevitably leads to the darkening of surfaces, via the formation of longer-chain molecular species, notably hydrocarbons and nitriles. The cosmic ray damage layer on KBOs may reach several meters in depth, depending on the near-surface density and porosity (e.g., Strazzulla and Johnson, 1991).

The red color of Pluto's surface is widely believed to be the result of radiolysis on its CH_4—N_2—CO surface. The red colors of many KBOs (see succeeding text) may also be the result of radiolysis, though there may also be intrinsically red materials on these bodies as well.

10.20.3 Physical Properties

In this section, we summarize the current state of knowledge about the physical properties of KBOs. We begin with their albedos, light curves, and colors. We then discuss KBO surface compositions and atmospheres. We then discuss KBO densities and internal structure. In each area discussed, we compare what is known about the Pluto system to other KBOs.

10.20.3.1 Albedos

Owing to their small sizes on the sky and photometric faintness, few KBOs have measured albedos. The 'albedo' of an object is a measure of its reflectivity (the ratio of reflected to incident light). Since the albedo can be a function of wavelength, it is common to refer to the wavelength band or magnitude region of the measurement (e.g., the 'V-magnitude albedo' refers to the reflectivity of the object in the wavelength region covered by the commonly used astronomical V (green–red) filter).

Not surprisingly, Pluto and Charon's albedos are best known. As discussed by Tholen and Buie (1997), Pluto itself has a V-magnitude albedo of 0.55; Charon's V-albedo is near 0.37.

Initially, many workers assumed that KBOs would have comet-like albedos of 0.04. And indeed, when the first measurements of KBO sizes and albedos were obtained, for two relatively large KBOs (1993 SC and 1996 TL66), using infrared (IR) measurements from the ESA Infrared Space Observatory (ISO), results gave radii of 164 km, corresponding to albedos of 0.02–0.03 (Thomas et al., 2000). Soon, however, other KBOs and centaurs were observed and were found with much higher albedos; the centaurs Chiron and Asbolus were found to exhibit albedos of 0.17 ± 0.02 and 0.12 ± 0.03, respectively (Fernández et al., 2002).

Circumstantial evidence for higher albedos also came from KBO satellite formation studies (Stern, 2003), which indicated the need for typical albedos of 0.15 or higher in order to make collisions sufficiently common to explain the growing population of KBO binaries. Then, KBO 2002 AW197 was found to have an albedo of 0.17 ± 0.03 (Cruikshank et al., 2005), and Lykawka and Mukai (2005) and Grundy et al. (2005a,b) demonstrated a tendency for increasingly larger objects to have increasingly higher albedos (**Figure 1**).

Table 1 reveals that few measured KBO albedos are <5%, and few are higher than 20%; instead, most measured albedos lie in the range 15 ± 7%. The few KBOs with very high albedos, like Pluto and Eris, may – like Pluto – exhibit atmospheric recycling mechanisms that refresh the surface albedo (e.g., Stern et al., 1988).

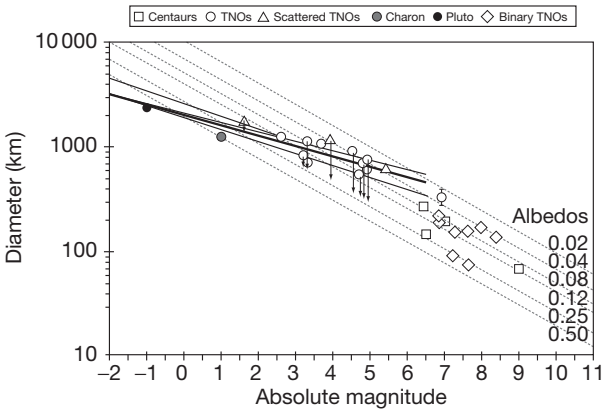

Figure 1 Some KBO (aka TNO) and centaur albedos determined from measured sizes and absolute magnitudes. The dashed line shows various albedo values that can be assumed when size measurements are not available. Reproduced from Lykawka PS and Mukai T (2005) Higher albedos and size distribution of large trans-Neptunian objects. *Planetary and Space Science* 53: 1319–1330.

It will be interesting to see how increasingly larger albedo data sets affect these conclusions and whether distinctions appear with dynamic class.

10.20.3.2 Rotational Properties and Light Curves

Rotation rates and light curves of KBOs hold clues to their shapes and surface variegation, as well as to their rotational dynamics. The definitive detection of Pluto's rotation rate came from photoelectrically observing its 6.4-day rotational light curve over 50 years ago (Walker and Hardie, 1955). Recently, it has been possible to use HST to separate the individual light from Pluto and Charon (Buie et al., 1997; see **Figure 2**), showing rotation rates and orbital period of the pair are synchronous, which is consistent with expectations from tidal evolution theory (e.g., Dobrovolskis et al., 1997). Of more direct importance to our interests here, Charon's low-amplitude (~8% peak-to-peak) light curve was shown to exhibit little variation, quite unlike Pluto's high-amplitude (~30% peak-to-peak) light curve.

Over 65 KBOs and centaurs now have measured light curves or light curve upper limits (Trilling and Bernstein, 2006), as shown in **Figure 3**. Approximately half of these have established light curve periods and amplitudes. All measurements of KB light curve periods except Pluto's lie between 3.5 and 27 h. Only three exceed 16 h. Hence, to first order, KBO light curve periods appear to be similar to asteroid light curve periods. Most measured KBO light curve amplitudes are <25%. It is not known what relative roles shape effects and albedo effects play in the observed population of measured light curve amplitudes.

10.20.3.3 Colors

The faintness of KBOs makes it difficult to measure accurate photometry and colors. This is problematic in several respects, including the biasing of available measurements to brighter, and therefore typically larger, KBOs.

As with rotation albedos and periods, the first color information obtained on objects in the KB was from measurements of Pluto. Pluto's surface was determined to be red as early as the 1950s. Later, color variations were observed with rotational phase, and color maps were made from HST (Stern et al., 1997) and mutual event data (e.g., Binzel, 1988; Young et al., 2001). In contrast to Pluto, Charon's surface appears to be spectrally neutral, with no significant rotational variation.

The first collections of KBO color data were published in the late 1990s (see Barucci et al., 1999a,b; Davies, 2001; Jewitt and Luu, 1998; Luu and Jewitt, 1996; Tegler and Romanishin, 1998). However, whereas Luu and Jewitt (1996) found a continuous range among the colors of their 13 objects (four centaurs and nine KBOs), Tegler and Romanishin (1998) found that KBO colors fell into two distinct populations separated by a color gap: one population had colors slightly redder than the Sun, and the other had colors significantly redder, containing the reddest objects in the solar system.

This disagreement spurred observations by several groups, none of whom found evidence for a bimodal color distribution (e.g., Barucci et al., 2000a,b; Boehnhardt et al., 2001; Delsanti et al., 2001). A statistical, principal component analysis of 22 KBOs (Barucci et al., 2001) also found that the colors of KBOs and centaurs were consistent with a continuous (rather than a bimodal) distribution, and when Jewitt and Luu (2001) analyzed a larger data set than in their 1996 and 1998 papers,

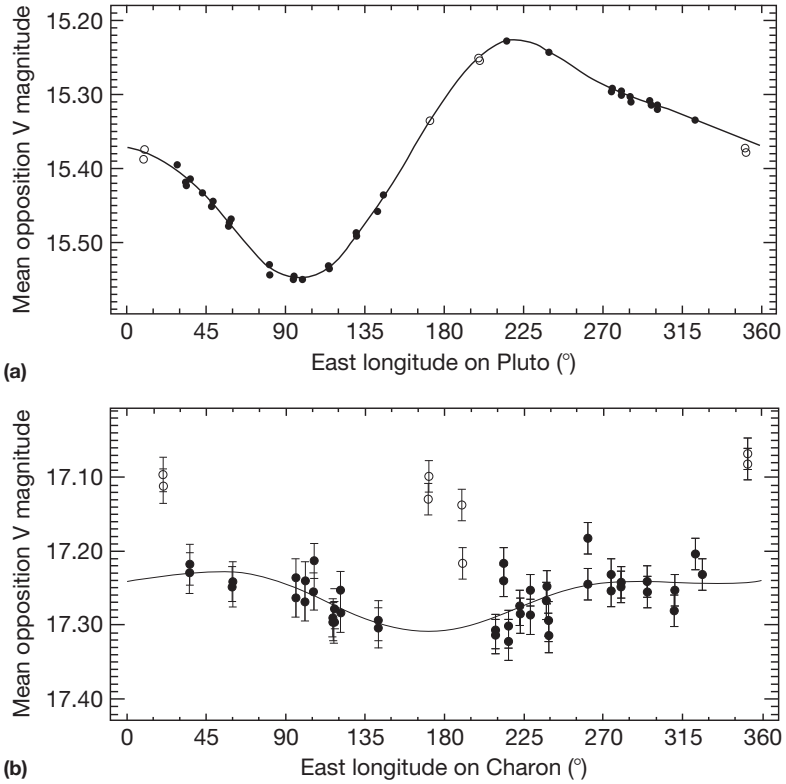

Figure 2 Rotational light curves of Pluto (a) and Charon (b). The mean opposition V magnitude is plotted against sub-Earth longitude in degrees. For Pluto, the error bars are smaller than the symbols and are therefore not shown. The open circles were not included in the fit and correspond to points in the orbit when Pluto and Charon are at a minimum separation. The solid curves represent best-fit light curves. Reproduced from Buie MW, Tholen DJ, and Wasserman LH (1997) Separate light curves of Pluto and Charon. *Icarus* 125: 233–244.

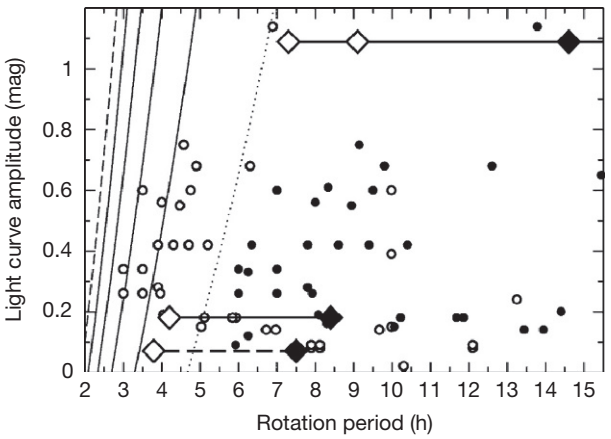

Figure 3 Measured light curve amplitudes of KBOs and centaurs (Trilling and Bernstein, 2006 – TB06). Diamonds represent TB06's own data; circles represent data from other sources. Open symbols indicate photometric periods, and filled symbols indicate rotation periods that are twice the observed photometric period. Objects known to have double-peaked light curves are plotted only as filled symbols. The curves represent solutions for critical rotation periods for various densities in grams per cubic centimeter: 0.5 (dotted line), 1, 1.5, 2, 2.5, and 3 (dashed line). Regions above and to the left of a given curve are dynamically unstable for a given density.

they again found a continuous distribution. However, when Tegler and Romanishin (2003) performed a statistical analysis of 107 KBOs (50 objects from their own observations and 57 objects observed by other groups), they again found a bimodal distribution, which they argued is not detectable in the measurements of other groups due to larger average photometric uncertainties. Peixinho et al. (2003) countered that the bimodal distribution exists within the centaurs, but not KBOs themselves (**Figure 4**).

Currently, there is a broad consensus that KBOs and centaurs display a wide range of colors; but it is not clear whether the color distribution is continuous or separated into distinct groups, though the majority of papers claim the former.

What is the reason for the wide range of KBO colors? Is it related to their origin (e.g., composition) or their evolution (e.g., owing to impacts, transient atmospheres, and varying radiation environments)? Alterations by impacts can compete with irradiation by cosmic rays, so the color of objects in different regions could vary with the local rate of impacts (Gil-Hutton, 2002).

To attempt to constrain the origin versus evolution scenarios further, a variety of workers have searched for color correlations with various orbital and physical parameters in order to address the source of the KBO color diversity. Tegler and Romanishin (1998) did not find any correlation of their

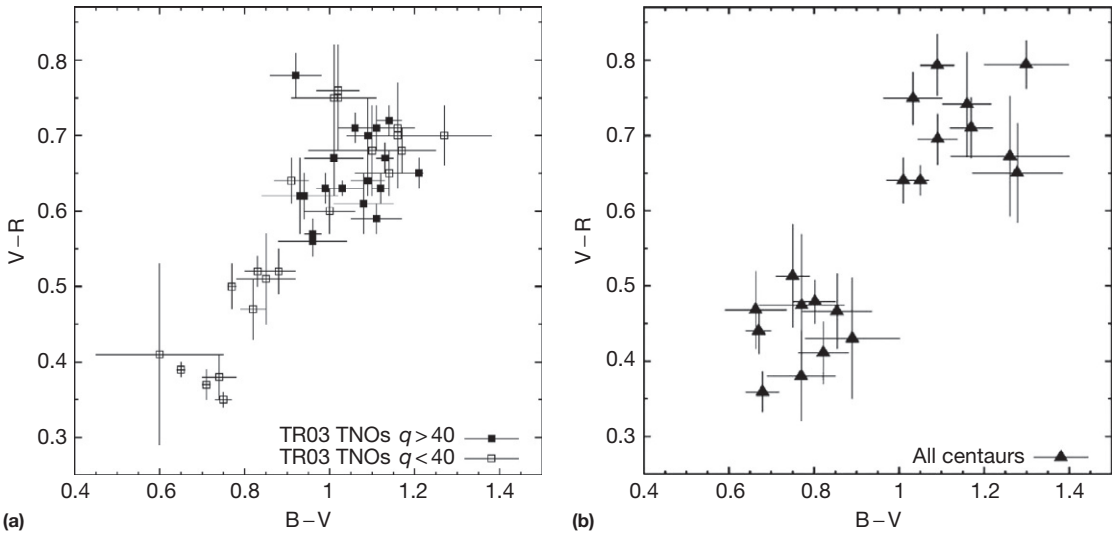

Figure 4 V–R and B–V magnitude color–color plot for KBOs (a) and centaurs (b). B–V is the brightness difference (hence color) seen through the commonly used 'blue' and 'visible' standard astronomical filters, and V–R is the color between the 'visible' and 'red' filters. Reproduced from Peixinho N, Doressoundiram A, Delsanti A, Boehnhardt H, Barucci MA, and Belskaya I (2003) Reopening the TNOs color controversy: Centaurs bimodality and TNOs unimodality. *Astronomy and Astrophysics* 410: L29–L32.

color populations with orbital parameters of the objects, speculating that other factors in the objects' history must come into play, such as solar UV photons, solar-wind and solar-flare particles, and cosmic rays. Barucci et al. (1999a,b) not only discussed the compositional surface variety among centaurs but also found no relationship with orbital parameters, for example, perihelion distance. Tegler and Romanishin (2000) however reported that all nine KBOs in their survey with nearly circular orbits with perihelion distances greater than 40 AU have very red surfaces. This work was later extended to show that the color variations with different dynamic classes point toward a primordial origin, with gray objects forming closer to the Sun than red objects. Hainaut and Delsanti (2002) found that cold classical belt objects apparently have significantly redder colors, whereas the plutinos have the opposite trend. However, Trujillo and Brown (2002) found a correlation between the BVR colors and the orbital inclination of classical KBOs. McBride et al. (2003) found a weak correlation between inclination and color in the classical KB, which they more specifically characterize as a lack of blue objects with low inclinations. Stern (2002) found a correlation between colors of KBOs and the mean random impact speed the objects would experience as a function of their orbital eccentricities and inclinations. This is consistent with KBO colors being driven by a competition between collisional excavation of neutral material and subsequent radiation reddening. Thébault and Doressoundiram (2003) and Doressoundiram et al. (2005) also found a correlation of color with mean impact velocity.

At present, the root cause or causes of the color variation among KBOs remain ambiguous. There is clearly no shortage of ideas; instead, however, there is a shortage of data from which to make strong conclusions. It may require several hundred or several thousand KBOs with well-established colors for definitive progress to be made. Progress will also derive from studies of color variegation on KBOs as they rotate and with the eventual, hoped-for return of color imagery of KBOs by *New Horizons*.

10.20.3.4 Surface Composition

As with other types of physical studies, the spectra of objects in the KB were taken on Pluto. Methane frost was identified on Pluto's surface by Cruikshank et al. (1976). Owen et al. (1993) later added the identification of N_2 and CO to the inventory of Pluto surface frosts. Owen et al. (1993) also recognized that methane must be mixed at the molecular level with nitrogen because of the shift in the methane band centers. Later, Douté et al. (1999) identified more bands of CO and CH_4 on Pluto's surface, in an analysis of IR spectra from 1.4 to 2.5 μm (**Figure 5**). Recently, Cruikshank et al. (2006) reported the detection of C_2H_6 (ethane) on Pluto's surface.

Studies by Douté et al. (1999), Grundy and Fink (1996), and Grundy and Buie (2001) provided important information of the compositional heterogeneity of Pluto's surface (**Figure 6**). They found that CO frost is more abundant in the peak in the sub-Charon hemisphere and that two distinct units containing CH_4 frost exist: one described by the strong methane bands that correlates with the visible light curve and another described by the weak methane bands that does not correlate with the visible light curve.

Pluto's surface variegation in albedo, color, and composition is likely due to a combination of internal activity, volatile transport, and atmosphere–surface interactions; impacts may also play a role. At present, the available data sets do not have sufficient resolution to distinguish uniquely between the various possibilities in order to determine which aspects of the variegation at which locations are due to specific processes.

Owing to Charon's close angular proximity to Pluto, spectroscopy of Charon itself was first possible only as a result of mutual event observations. Such spectra were obtained in the visible by Fink and DiSanti (1988) and in the near-IR by Marcialis et al. (1987) and Buie et al. (1987). This technique involved subtracting the Pluto-only spectrum (when Charon was behind Pluto) from the combined spectrum taken just

adjacent to the eclipse event. The resulting visible-wavelength spectra showed Charon to be neutral in color, but the near-IR spectra of Charon obtained this way detected water ice on Charon's surface.

HST IR observations using the NICMOS IR imaging spectrometer (Buie and Grundy, 2000) were later obtained at four different longitudes in 1998. These spectra revealed that the near-IR spectrum of Charon varies only weakly with longitude and is consistent with crystalline water ice with grain sizes in the tens of micrometers (Brown and Calvin, 1999; Buie and Grundy, 2000), plus an unknown spectrally indistinct absorber. Ground-based IR spectra obtained in very good seeing conditions using the Keck 10-meter telescope (Brown and Calvin, 1999) also revealed evidence for crystalline H_2O ice and the possible presence of ammonia hydrates, suggesting the possibility of geologic activity. Cook et al. (2006) later confirmed these findings.

Spectroscopy of KBOs is considerably more difficult than Pluto and Charon because they are so much fainter. Most KBOs that have been studied show featureless reflectance spectra. However, strong 1.5 and 2.0 μm water ice features were

detected on the centaur (10199) Chariklo by Brown and Koresko (1998), on Pholus by Cruikshank et al. (1998), and on Chiron by Foster et al. (1999) and later Luu et al. (2000). Water ice features were first detected on a KBO by Brown et al. (1999) in a spectrum of 1996 TO66. Interestingly, these data indicated possible variations with rotational phase, perhaps indicating a patchy surface. Licandro et al. (2001) found deep water ice absorption in 2000 WR106. IR observations of the KBO (50000) Quaoar detected both crystalline water ice and ammonia hydrate (Jewitt and Luu, 2004). These data were interpreted to indicate that Quaoar has recently been resurfaced from either impacts or cryovolcanic activity. Crystalline water ice was also clearly detected in spectra of 2003 EL61 (Trujillo et al., 2006), again implying a resurfacing process taking place.

As to constituents other than water ice, the available data set is meager. Perhaps, the most interesting results are IR spectra of the large KBO 2005 FY9, which appears to be very similar to Pluto, but with even stronger prominent absorption bands of CH_4 (Licandro et al., 2006; see **Figure 7**). The tentative detection of N_2 on Sedna and Eris and CH_4 on Sedna has also been reported (Licandro et al., 2006).

10.20.3.5 Atmospheres

The only known KBO with an atmosphere is Pluto, which possesses an atmosphere with a base pressure of order 10 μb and a composition that is largely N_2, with traces of CO and CH_4. For excellent reviews, see Trafton et al. (1997) and Yelle and Elliot (1997).

Perhaps, the most important aspect of Pluto's atmosphere for the purpose of this review is that it seasonally collapses to the surface as Pluto draws away from the Sun and cools (e.g., Stern and Trafton, 1984; Trafton and Stern, 1983). This results in the seasonal/orbital transport and deposition of a high-albedo frost of thickness some millimeters to centimeters that persists for most of Pluto's orbit, when the atmosphere cannot be supported by thermally driven ice sublimation (Stern et al., 1988).

In order to support a significant atmosphere, a KBO must either exhibit internal outgassing or possess volatile ices that are warmed sufficiently to generate a nonnegligible vapor pressure equilibrium or both. Indeed, with the discovery of CH_4 frost on Pluto's surface (Cruikshank et al., 1976), the possibility of an atmosphere supported by vapor pressure equilibrium was already inferred.

This same process will occur on KBOs that generate seasonally or orbitally forced atmospheres, if the KBO is large enough to retain its atmosphere against immediate hydrodynamic (i.e., comet-like) escape. The estimated diameter for a KBO to retain its bound atmosphere is about 700 km (Lykawka and Mukai, 2005). For KBOs in excess of this size that possess atmospheres, one would expect a cyclic 'atmospheric laundry' to renew the surface albedo, as at Pluto (Stern et al., 1988).

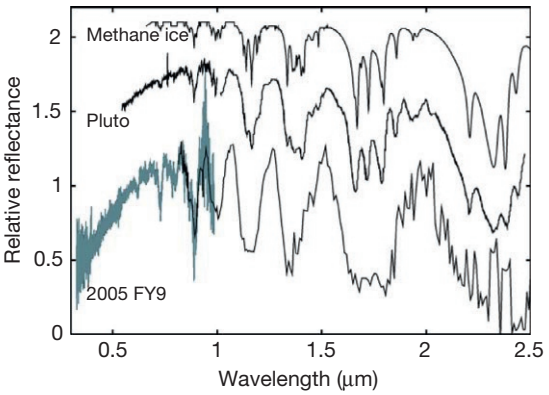

Figure 7 The spectrum of 2005 FY9 compared to Pluto and pure methane ice (Licandro et al., 2006); the latter two spectra were shifted vertically for clarity.

10.20.3.5.1 Pluto's atmosphere

Since vapor pressures have an exponential dependence in temperature, frost temperature is a critical parameter for understanding the density and pressure of Pluto's atmosphere. Temperature observations of Pluto's surface first measured the flux at the IR and millimeter wavelengths. Altenhoff et al. (1988), Stern et al. (1993), and Jewitt (1994) found brightness temperatures of ~30–40 K from millimeter measurements at 800–1200 mm. A similar result was obtained using the temperature-diagnostic 2.148 mm feature of N_2 as a thermometer (Tryka et al., 1994). However, Infrared Astronomical Satellite (IRAS) measurements by Sykes et al. (1987) found the brightness temperature to be warmer (55 K) at 60 mm, near the peak of Pluto's blackbody emission. The discrepancy between the *IRAS* and larger wave temperature measurements was and still is attributed to the presence of both hot (inert) and cold (sublimating) regions on Pluto's surface. Stern et al. (1993) predicted that if the latter was in fact the case, Pluto's visible and thermal light curves should be inversely correlated. Subsequently, observations using the ISO spacecraft detected a thermal light curve for the Pluto–Charon system at 60 mm, indicating that Pluto's surface is not isothermal (Lellouch et al., 2000), with maximum dayside temperatures of 54–63 K.

Combining information from surface temperature measurements and surface spectroscopy, one infers that either N_2 or CO must dominate Pluto's atmosphere and that CH_4 must be present only in trace amounts. N_2 is expected to dominate CO based on Raoult's law, that is, because it is dominant on the surface and the two have similar volatilities.

It was not until 1988 that Pluto's atmosphere was definitively detected using the technique of stellar occultation (Elliot et al., 1989; Hubbard et al., 1988). All of the 1988 stellar occultation light curves exhibit a sharp change of slope, or 'knee' during immersion and emersion (see **Figure 8**).

The structure of Pluto's atmosphere as probed by the 1988 occultation was well modeled by an isothermal upper atmosphere (above a radius of 1215 km) with a temperature of 104 ± 2 K for composition of nitrogen. This temperature is significantly greater than any surface temperature measurements for Pluto. The 'knee' in the occultation light curve can be explained by either a temperature gradient of 10–30 K km^{-1} (Eshelman, 1989; Hubbard et al., 1990; Stansberry et al., 1994) or a haze layer (Elliot et al., 1989). These mechanisms are not mutually exclusive and both may be or have then been at work.

Yelle and Lunine (1989) realized that CH_4 can act as a thermostat in Pluto's upper atmosphere by absorbing energy at the ν_3 band at 3.3 mm, cooling via the ν_4 band at 7.6 μm, and conducting heat to the surface. This mechanism may explain the high temperatures at the microbar pressure level in light of the colder surface temperatures. Strobel et al. (1996) expanded on this model and developed a radiative–conductive atmospheric model, including the effects of heating and cooling by methane at 3.3, 2.3, and 7.6 μm, cooling by CO rotational line emission (originally considered by Lellouch et al. (2000)), and heat conduction. Doing so, they found that the 2.3 μm band was more important for heating the atmosphere than the 3.3 μm band. Their preferred model can reproduce the temperature gradient of the occultation light curve but has an upper atmosphere temperature that is too warm (134 K).

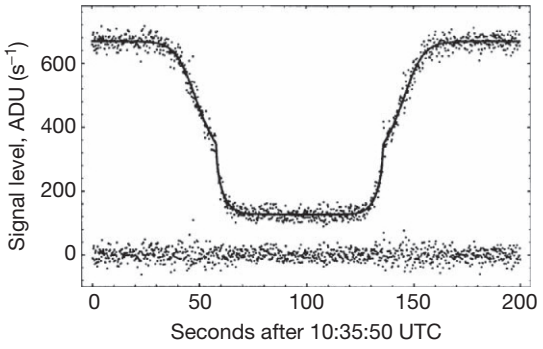

Figure 8 Data (points; Elliot et al., 1989) and model (line; Elliot and Young, 1992) of the 1988 stellar occultation light curve of Pluto observed with NASA's Kuiper Airborne Observatory. The points near the zero level along the bottom are the residuals from the fit of the model to the data.

Of course, all of the 'CH_4-thermostat' models for Pluto's atmospheric thermal structure rely on sufficient quantities of CH_4 in the atmosphere. And while CH4 had been inferred indirectly from the combination of its known presence in solid state on the surface and surface thermal measurements, its actual atmospheric abundance was highly uncertain because it was not known if the CH_4 source regions were in Pluto's cold or hot regions.

Spectroscopic detection of gaseous CH_4 was first obtained in 1994 (Young et al., 1997) with a subsequent confirmation in 2006 (Roe, 2006). This work confirmed that the gaseous CH_4 in Pluto's atmosphere is only a trace constituent. The partial pressure of methane is overabundant for methane in solid solution with nitrogen but consistent with methane in vapor pressure equilibrium with pure CH_4 at 41–45 K, as shown in **Figure 9**.

From the well-observed stellar occultation of August 2002, it was discovered that Pluto's atmospheric pressure had doubled since 1988 (Elliot et al., 2003; Sicardy et al., 2003; **Figure 10**). The increase in atmospheric pressure is consistent with a change in nitrogen frost temperature by 1.3 K (Elliot et al., 2003), which may be due to a thermal phase lag following the 1989 perihelion maximum in insolation (e.g., Stern et al., 1988; Trafton, 1990; see also the review by Spencer et al. (1997)).

In addition to the increase in atmospheric pressure, an increase of turbulence in Pluto's atmosphere was evidenced by more refractive spikes in the occultation light curves of 2002, compared with 1988. These spikes indicate the presence of waves or turbulence and were practically nonexistent in the 1988 observations. These spikes were also seen in the lower atmosphere in the 2002 observations (Pasachoff et al., 2005).

Another important change seen from 1988 to 2002 is the declining strength of the kink in the occultation light curves,

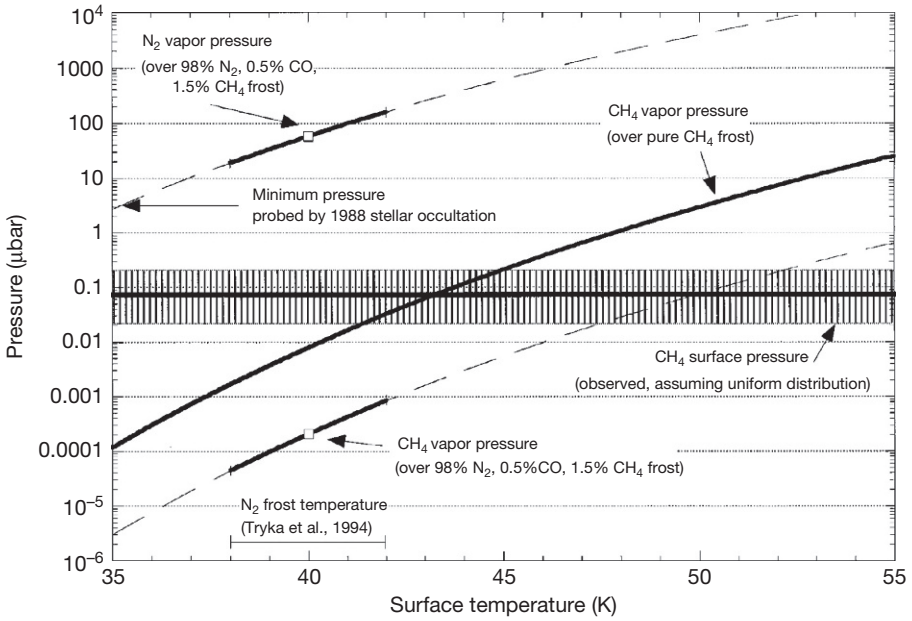

Figure 9 Surface vapor pressures on Pluto as a function of temperature of the sublimating material. The solid parts of the various curves show the vapor pressures for a frost temperature of 40 ± 2 K. Reproduced from Young LA, Elliot JL, Tokunaga A, de Bergh C, and Owen T (1997) Detection of gaseous methane on Pluto. *Icarus* 127: 258–270.

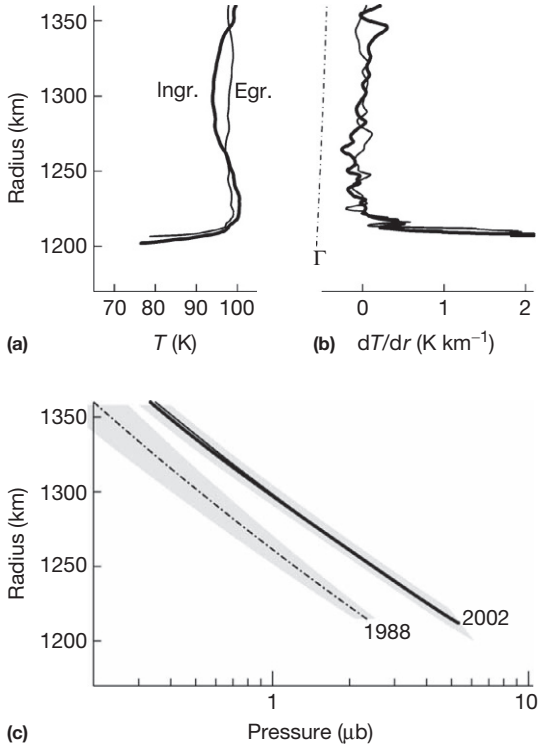

Figure 10 Temperature and pressure profiles of Pluto's atmosphere derived by Sicardy et al. (2003) from the inversion of the occultation light curve, assuming a spherically symmetrical and transparent pure nitrogen atmosphere. (a) Pluto's atmospheric temperature profiles $T(r)$ at ingress (thick curve) and egress (thin curve). The radius is the distance to the planet center. (b) The corresponding temperature gradient profiles dT/dr. The dash-dotted line provides the adiabatic lapse rate profile $\Gamma = -g/c_p$, to the left of which the atmosphere would become convectively unstable, where $c_p = 103\ \mathrm{J\ K^{-1}\ kg^{-3}}$ is the specific heat at constant pressure for N_2. (c) The corresponding pressure profiles. The dash-dotted line is the pressure profile derived from the Kuiper Airborne Observatory light curve of 9 June 1988, with the associated error domain as the shaded region. The ingress and egress profiles derived from the Canada–France–Hawaii Telescope (CFHT) light curve of 2002 are the nearly coincident thick and thin solid lines, respectively.

relative to what was seen in 1988. This indicates that a change in the atmosphere's vertical structure has also taken place. Elliot et al. (2003) reported on observations of the August 2002 occultation at effective wavelengths from 0.75 to 2.2 μm. The minimum flux of the light curve varies with wavelength, indicating that there is extinction in Pluto's lower atmosphere, that is, a haze layer. A purely refracting atmosphere would produce a light curve with the same minimum flux regardless of the wavelength.

All of the effects seen in the 2002 occultations were seen again in 2006, but the number of turbulence-driven refractory spikes appears to have further increased (e.g., Elliot et al., 2006; Sicardy et al., 2006; Young et al., 2006). Clearly, Pluto's atmosphere is changing, most likely due to postperihelion changes in insolation and subsolar latitude. When will atmospheric collapse take place? We do not know, but models (e.g., Trafton, 1990; Trafton et al., 1997) indicate it will occur before 2020.

10.20.3.5.2 Other KBOs

Regarding centaurs, 2060 Chiron has long been known to exhibit both photometric variability (Hartmann et al., 1989) and a cometary coma (Meech and Belton, 1989). Somewhat surprisingly, Chiron has exhibited activity at all points of its orbit with no clear correlation between the level of cometary activity and heliocentric distance. In fact, Chiron was more active at its aphelion in 1970 than it was in following decades when it was closer to the Sun. The level of activity can vary by more than a factor of 2 and last anywhere from weeks to months. Bus et al. (1991) detected CN in Chiron's coma, and Womack and Stern (1999) reported a detection of CO, which may be the sublimation agent responsible for Chiron's cometary activity. This suggestion is consistent with the models indicating that Chiron's activity can be explained by a composition of CO near the surface as an ice or as a gas trapped in the amorphous ice that is released by delayed thermal pulses (Capria et al., 2000; Prialnik et al., 1995). The variability of Chiron's outbursts, the apparent lack of a correlation between activity and distance from the Sun, and the observations of discrete jetlike features observed during an occultation (Elliot et al., 1995) imply that Chiron's surface may be unevenly covered with volatile material and may exhibit geysers like those seen on Triton (e.g., Smith et al., 1989).

In contrast to the known atmosphere around Pluto, only upper limits have been placed on possible atmospheres around other KB bodies.

Although no atmospheres have as yet (November 2006) been detected around KBOs other than Pluto, Hainaut et al. (2000) found a change in the light curve of KBO 1996 TO66 from a double peak to a single peak over the course of a year, which they suggested may have resulted from an episode of cometary activity. Further, the discoveries of N_2, CO, CH_4, and C_2H_6 (ethane) on the KBO 2005 FY9 (Brown et al., 2006; Licandro et al., 2006), and the tentative detection of N_2 on Sedna and Eris and CH_4 on Sedna (Licandro et al., 2006), indicate that KBO atmospheres may be discovered in the future. However, given the exponentially sensitive dependence of vapor pressures to temperature and therefore to heliocentric distance and seasonal (obliquity-driven) effects, it is natural to predict that such atmospheres should in many cases be transient with seasonally or orbitally driven cycles, as Pluto's is.

Finally, it is worth noting that the captured dwarf planet Triton, now a satellite of Neptune, is known to possess an N_2-dominated atmosphere with some CH_4 and a base pressure not unlike Pluto's. Since Triton is also roughly Pluto's size and density and is widely thought to have originated in the same region of the solar system as Pluto, it serves as a possible guide to future discoveries that may be made around dwarf planets in the KB and farther out as well.

10.20.3.6 Densities

With the discovery of two new satellites in the Pluto system (Weaver et al., 2006), Buie et al. (2006) had been able to derive a better estimate of the mass ratio of Charon to Pluto, and

therefore the individual masses of each, than had previously been possible. Combining this new mass ratio with the recently improved 604 ± 3 km radius of Charon from the stellar occultation in 2005 (Sicardy et al., 2006), we now also have a much more accurate estimate for Charon's density, 1.66 ± 0.06 g cm^{-3} (Buie et al., 2006). The current best estimate of Pluto's density is 2.03 ± 0.06 g cm^{-3} (Buie et al., 2006).

Densities for KBOs are only available for a subset of the two dozen objects with satellites. In such binary systems, we can determine the mass ratio of the satellite to the primary from the KBO satellite mutual orbit, but we also need an estimate of the diameter to derive the density; the latter requires direct resolution of the KBO's size by HST, thermal IR measurements, or mutual events – all of which are difficult to obtain. As a result, only a few KBO and centaur densities are available. Spencer et al. (2006) reported a density of 0.51(+0.29, −0.11) g cm^{-3} for KBO (26308) 1998 SM165; this is comparable to the 0.5–0.8 g cm^{-3} density derived for KBO (47171) 1999 TC36 (Stansberry et al., 2006). Grundy et al. (2007) reported a density for centaur (65489) 2003 FX128 of 1.38(+0.65, −0.32) g cm^{-3}. However, Rabinowitz et al. (2006) reported a far higher, model-dependent density of 2.6–3.3 g cm^{-3} for 2003 EL61 from studies of this KBO's rotational dynamics.

Clearly, the study of KBO densities is in its infancy. Only a handful of results are available. All concern large KBOs and all but one concern binary KBOs. However, already there appears to be a wide diversity in KBO densities, ranging from ~0.5 to >2 g cm^{-3}. This in turn implies a wide range of internal porosities and water ice/rock fractions in the KBO population.

10.20.3.7 Interior Models

Several groups have begun to investigate the thermal evolution of KBOs. One motivation for such studies is the current-day presence of surface volatiles on Pluto after what appears to be 4 Gy of active atmospheric escape. As demonstrated some time ago (Stern, 1989a), this argues for the possibility of present-day internal activity to pipe new volatiles to compensate escape losses. Another motivation for such studies results from the sporadic activity of the 160 km wide centaur Chiron, which shows no correlation with heliocentric distance, solar activity, or obliquity-derived season (e.g., Bus et al., 1991; Duffard et al., 2002).

Models show that radiogenic heating and solar irradiation of an initially undifferentiated KBO can sublime and deplete most of the volatile ices near the surface. The resulting internal heating can result in a compositionally layered structure, with interlaced layers depleted and enriched in volatiles. When such bodies are injected into the inner solar system, episodic activity can occur as the volatile-rich layers reach sublimation temperatures. Thermal evolution can also be affected by the heating of collisions, which can sublimate ices, induce gas flow in porous structures, and eject gas and dust. Depths thermally affected by KBO impacts can vary by large amounts and to depths greater than 1 km (Orosei et al., 2001).

To better understand interior evolution, McKinnon (2002) and Choi et al. (2002) conducted studies of the thermal evolution of KBOs of various sizes up to almost 1000 km in diameter. These workers agree that ^{26}Al cannot be an important heat source, owing to the long accretion timescale for KBOs relative to the 0.73 My half-life of ^{26}Al. They also found that for 100 km KBOs, radiative losses to space prevent central temperatures from exceeding 80 K; for 150 km KBOs, the central temperature limit found was near 105 K. However, for a 450 km radius KBO, central temperatures can exceed 270 K; this opens the possibility of liquid H_2O in large KBOs and Pluto.

Moreover, McKinnon (2002) found that even KBOs in the 75–225 km radius range can transform H_2O ice from its amorphous to crystalline state in their interiors. Other important thermal benchmarks include 155 K, where a eutectic CH_3OH–H_2O melt can form, and 190 K, where solid-state H_2O ice creep and hence sintering/densification become important. McKinnon (2002) concluded that over a wide range of parameter choices, long-lived radioactive energy release probably powered activity in the largest KBOs for hundreds of millions of years, at least. These findings indicate Pluto and other large KBOs may well show early, and perhaps even persistent, signs of internal activity.

Most recently, McKinnon and Barr (2006) and Hussman et al. (2006) had discussed the possibility of internal liquid H_2O oceans in large KBOs, including both Pluto and Charon. For rock ratios of 0.65 (consistent with Pluto's density) and surface temperatures near 40 K, internal oceans were commonly found, though at a range of interior depths and with various thicknesses. This exciting possibility begs for tighter constraints on KBO densities and compositions, so as to better constrain the range of parameter space available to modelers.

10.20.4 Origin

Unlike early ideas in which the trans-Neptunian debris belt contains only leftover material in the form of very small bodies from the era of giant planet formation (e.g., Kuiper, 1951), the real KB actually contains very large numbers (i.e., $>10^5$) of bodies that reached sizes of 100 km and at least several dozen and more likely many times more objects (depending on the large body population of the SKB) that reached 1000–3000 km in diameter.

The standard paradigm of planet formation involves three major stages. We review this paradigm briefly here but refer the reader to excellent, succinct reviews with more detail, such as Ward (1996) and **Chapter 10.17**.

The first stage of planet formation involves the coagulation of dust grains into macroscopic objects that grow by gentle accretion when physical contact occurs but at a rate dominated purely by two-body, physical (i.e., projected surface area) collision cross sections. Stage 2, the so-called midstage of accretion, begins when collision rates are substantially affected by gravitational cross sections, which accelerates growth from an R^2 process to an R^4 process. Midstage growth terminates when bodies self-isolate by growing to a size where they have depleted the feedstock of smaller material within their gravitational reach. The third and final stage of accretion results from the mergers of the planetary 'embryos' created in stage 2. These mergers occur on longer timescales driven by dynamic effects that cause the embryos to perturb one another onto mutually

crossing orbits that inevitably cause collisions among relatively like-sized bodies.

In order for solid-body accretion to proceed, two key conditions must be simultaneously obtained on a relevant timescale. These are (1) a sufficient supply of material to promote collisions on the relevant timescale and (2) sufficiently gentle collisions to permit growth, rather than erosion and/or destruction.

Shortly after the discovery of the first KBOs, when crude estimates of the population of the KB first became available, it was recognized (Stern, 1995) that the current-day KB does not satisfy either of these two conditions for accretion. More specifically, it was pointed out that (1) the surface mass density of the current-day KB is too low by a factor of approximately 10 to allow the growth of the observed KBOs in the age of the solar system and (2) current-day collision velocities (calculated from the mean random crossing speeds of intersecting orbits) are too high by a factor of about 10^4 to initiate and sustain stage 1 growth. These facts in turn led to the conclusion (Stern, 1995, 1996) that the current KB must be highly evolved from its primordial state, in which both the mass density of material must have been far higher and the mean random orbital inclinations and eccentricities must have been much lower.

Subsequent, more detailed accretional simulations (e.g., Davis and Farinella, 1997; Kenyon and Bromley, 2001; Kenyon and Luu, 1998, 1999; Stern and Colwell, 1997a,b) reached similar conclusions and refined an accretion scenario for the formation of the KB that can be summarized as follows. The early KB region between 30 and 50 AU originally contained some 10–50 M_{Earth} of material in the form of dust and small debris. The region was dynamically cold, so that collisions promoted growth. It was likely located somewhat closer to the Sun, perhaps by as much as 5–10 AU, as testified to by Neptune's now well-established migration (e.g., Malhotra, 1993). After order 100–300 My, objects of size 30–50 km had emerged on nearly circular orbits. These objects were of sufficient size to accelerate their own growth by gravitational runaway. During this midstage accretion, objects of size 100–2000 km were rapidly grown. At this point, dynamic excitation of the region was terminated, either by the nearby growth of Neptune or by Mars-sized objects either grown or scattered into the region. This terminated growth by transforming the accretional environment to an erosional one, with characteristic collision velocities of order 1–2 km s^{-1}, as are observed in the KB today. The onset of erosion initiated a fratricide among small bodies, which resulted in the loss of much mass to grinding followed by radiation transport out of the region (Stern and Colwell, 1997b). (Bodies hundreds of kilometers in diameter and larger, by virtue of their mass and gravitational binding energy, were relatively immune to this fratricide.) It was estimated that over 4 Gy, erosional mass loss could deplete the KB down to a few tenths of an Earth mass of material. Although this is higher than the observed KB mass by a factor of a few to perhaps 30 (in the extreme), dynamically driven losses have been shown to be capable of further mass depletion by a factor of 2 to several, thereby making this scenario viable. In the in situ accretion scenario (ISAS), plutinos, which migrated to their current orbits after being trapped in Neptune MMRs during their outward migration, preferentially formed at somewhat closer distances (e.g., 20–30 AU) than nonresonant CKBOs and SKBOs.

The salient features of this ISAS are that (1) the early KB region initially contained an amount of mass consistent with a simple extrapolation of the surface mass density of the giant planet region out to the 20–50 AU zone and (2) growth proceeded until excitation by external (or perhaps internal) perturbers interceded, some time between 0.1 and 1 Gy after the formation of the protosolar disk.

An alternative to the ISAS described just earlier has recently developed (e.g., Morbidelli, 2006). This scenario, called the 'push out scenario' (POS), was motivated by dynamicists attempting to recreate various aspects of the orbital distribution of KBOs. In the POS, all of the objects in the KB were accreted in the giant planets' region (5–25 AU), rather than beyond this region as the ISAS assumes. These objects were then subsequently transported outward by a combination of gravitational clearing (i.e., scattering) by the giant planets and resonance migration driven by the outward migration of Neptune to conserve angular momentum during the clearing of the giant planets' zone.

The ISAS and POS each have strengths and weaknesses, but a detailed discussion of such is beyond the scope of this chapter. So we restrict our discussion to the point that while the POS points to a compact solar nebula, initially truncated inside ~20 AU, the ISAS points to a broader, dynamically cold disk, stretching out to distances of ~50 AU or even much farther.

Therefore, a distinguishing test between these scenarios surrounds the issue of whether there is a dynamically cold population of KBOs or smaller debris lying farther from the Sun than the ~50 AU cutoff of the cold KBO population now observed. Existing observational constraints make clear there is no such cold disk of large KBOs between ~50 and ~90 AU. However, this could be the result of a dynamic clearing of this region due to the former presence of a passing star or large planets temporarily scattered there during outer solar system clearing or due to a change in the accretional environment beyond 50 AU that stunted the growth of bodies there at much smaller sizes than the KBOs in the 30–50 AU zone reached (making such bodies less detectable). Future deep surveys will be required to resolve the question of whether any substantial cold disk lies beyond ~50 AU. Such work must constrain both the population density of small (e.g., 1–10 km) bodies on low-eccentricity, low-inclination orbits in the 50–100 AU zone and the population of large (e.g., >100 km) bodies on low-eccentricity, low-inclination orbits in the region beyond 100 AU.

10.20.5 Future Observational Goals and Prospects

Existing KBO data and models provide rich insights into this region of the solar system, but, realistically, this field of planetary research is still in its infancy. In the next couple of decades, we expect to see far faster growth in our knowledge and understanding of the KB than in the past, driven by new ground-based observatories, space-based telescopes, space missions (see **Chapter 10.23**), and computer and detector advances. In this section, we examine some of the highest priority objectives for future KB studies and then discuss the expected advances in ground-based and space-based observations that are expected in the next decade.

10.20.5.1 Goals

The broad goals for the next stage of observational study of KBOs are relatively straightforward. They are to (1) develop a broad understanding of the various populations in the KB and (2) determine the evolutionary processes that have shaped KBOs to their current state. The first of these goals requires collecting large surveys of albedo, color, composition, shape, and density information. It also requires thorough searches for KBO atmospheres and the determination of KBO satellite size–frequency–orbital types. It is also strongly desired to begin studying surface heterogeneity on KBOs other than Pluto; this includes albedo, color, and compositional heterogeneity. An additional goal should be to better define the KBO size–frequency histograms down to sizes of kilometers for each orbit type in the KB.

Of particular interest, we point out that binary and higher-order multiple systems offer great potential as tools for studying the physical properties of their components. Knowledge of the orbit of the secondary relative to the primary provides a system mass, and component masses can be determined if absolute astrometry is available to provide motions for each component. Relative sizes can be determined from photometry if one assumes equal reflectance, and absolute sizes inferred if one assumes particular values for the albedos. From sizes and masses, densities can be determined, providing information regarding interior properties and constituents. Of particular interest will be mutual events, like those observed between Pluto and Charon from 1985 to 1990. Such events occur when the line of sight from the Earth intersects the orbital plane of the satellite, so that the parent and satellite(s) occult and transit each other. Photometric and spectroscopic observations during these occultations can provide measurements of absolute sizes, probe atmospheres, and identify surface features and properties on scales far smaller than the resolution limit of the telescopes.

10.20.5.2 Future Ground-Based Observatories

Several large-scale survey telescopes with revolutionary capabilities for KB studies are currently in development, notably the Large Synoptic Survey Telescope (LSST) and the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS). These projects are designed to observe the entire sky observable from the site at a daily or weekly frequency.

The significant new aspect of both these projects compared to previous surveys is to provide regular monitoring of 'variation' of objects over the full sky. These projects will provide revolutionary new capabilities for surveying the content of the KB, obtaining large numbers of accurate orbits, and studying KBO light curves, phase curves, colors, and satellite orbits.

The LSST (e.g., Davison and Angel, 2002; Tyson, 2002) is an 8.4 m telescope that will survey the entire available sky every three nights with multiple color filters. Its 3.5-degree CCD field of view will generate 3 billion pixels per image with a plate scale that will be close to 0.2 arcsec/pixel. Some 30 terabytes of data will be produced per night, requiring massive storage and a fast data-processing pipeline. LSST's performance specifications mentioned earlier indicate it will accomplish a complete survey of KBOs brighter than 25th magnitude every three nights, which will find ~50 000 KBOs on the order of 100 km in diameter. Potential observatory sites have been narrowed to three: Cerro Pachon (in Chile), Las Campanas (in Chile), and San Pedro Mártir (in Mexico). The project goal is to begin operations in 2012.

Pan-STARRS (Hodapp et al., 2004; Jewitt, 2003; Kaiser et al., 2002) will take a different approach to a similar goal. It will consist of four 1.8 m telescopes coordinated to observe the same part of the sky simultaneously with a roughly 3 square degree field of view and a plate scale of 0.3 arcsec. Exposure times of 30–60 s are expected to reach a limiting magnitude of 24. The sky from its site in Hawaii will be observed three times during the darkest nights of each lunation. The first prototype telescope for Pan-STARRS had first light in early 2006, and the full system is planned to be in operation before 2010.

After 3–5 years of operations, it is expected that these projects will produce a complete, flux-limited sample of KBOs that should be free of observational biases. Many tens of thousands of new KBOs should be discovered. This will yield a census of the populations of all known and any major as-yet-undiscovered dynamic groups, as well as substructures therein. They will also provide a vast database of KBO light curves, phase curves, colors, and other data, as noted earlier.

Smaller-scale 'pencil beam' and wide-area surveys to even greater depth using large telescopes will continue to be necessary to probe the extremes of the size distribution of objects in the KB.

Another approach will be taken by TAOS, the Taiwan–America Occultation Survey (Alcock et al., 2003). The goal of TAOS is to sample the low end of the size distribution, by detecting occultations of stars by KBOs with sizes down to a few kilometers. TAOS is designed to compensate for the weakness of doing direct detection of KBOs by reflected light, in which the brightness of the objects decreases approximately by its distance to the fourth power owing to the compound inverse square law of reflected light sources. TAOS will employ three small (20 in.) robotic telescopes with 2-degree fields of view. They monitor a fixed set of stars throughout the year, observing the same areas of sky simultaneously, and possible events are cross compared to reject false detections. The third TAOS telescope was installed in April 2004, but the system is still in test as of late 2006. Although detections of asteroid occultations have been made, no definitive KBO occultation events have been detected.

Other ground-based advances to look forward to in the coming 10–15 years include

- occultation campaigns on known KBOs to better determine their sizes and albedos,
- photometric and spectroscopic campaigns to study mutual event seasons for KBOs with satellites, and
- spectroscopy of KBOs using a new generation of very large optical telescopes coming on line near the middle to end of the 2010–20 decade.

10.20.5.3 Future Space-Based Observations

Two new major space mission capabilities are now under development. We discuss both here. We do not describe missions in study phase or proposals for future missions.

The HST will be able to continue obtaining observations for several more years. If a space shuttle servicing mission occurs as planned in 2008, it will install new gyros, batteries, and a fine guidance sensor, with two new instruments – the Wide Field Camera 3 (WFC3) and the Cosmic Origins Spectrograph (COS). WFC3 will have greater sensitivity than WFC2, allowing for improved photometry and imaging of fainter objects. COS will restore HST's UV spectroscopy capabilities and extend them to sources a factor of about 20 times fainter than other HST spectrographs allowed.

The James Webb Space Telescope (JWST), formerly the Next Generation Space Telescope (NGST), will be a large, IR-optimized space telescope to follow HST. JWST is expected to be launched to the second Lagrange point (L2) in 2013–15 and has an expected lifetime of 5–10 years. It will have a 6.5 m diameter mirror (made of 18 hexagonal segments) and an IR camera and spectrograph, providing higher resolution and perhaps a couple or more orders of magnitude greater sensitivity than HST. Studies by the NGST working group estimate that 10 km diameter objects could be detected at distances of 50 AU. However, JWST will not be able to observe at long enough wavelengths (for the thermal peak around 75 mm) to determine definitive albedos and sizes of KBOs, as can be done with the Spitzer Space Telescope (Emery et al., 2004; Grundy et al., 2005a,b; Stansberry et al., 2004). JWST will be able to study the IR spectra of numerous KBOs and their satellites.

10.20.5.4 Space Missions to the KB and Centaurs

NASA's *New Horizons* mission (Stern and Cheng, 2002) to Pluto and the KB successfully launched on 19 January 2006. After a gravity assist flyby of Jupiter in March 2007, the spacecraft will make its closest approach flyby of the Pluto system on 14 July 2015. *New Horizons* will then go on to conduct one or possibly two KBO encounters in the succeeding 5–6 years. After that time, the spacecraft will emerge from the main region of the KB and into the depleted region beyond 50 AU. KBO targets will be chosen in 2014.

New Horizons carries a suite of seven instruments that include visible light images, IR mapping spectrometers, UV mapping spectrometers, radio science, radiometry, in situ plasma detectors, and dust detectors.

Its primary objectives at each flyby target are to map surface compositions and temperatures, characterize geology and morphology, characterize (or search for) the neutral atmospheres, and study escape rates. Secondary objectives include searches for new satellites and rings, ionospheric studies, stereo mapping, and refinement of bulk parameters such as masses, densities, and orbits.

No missions to centaur bodies are in development yet, but *New Horizons* will conduct a distant (~2.8 AU) flyby of centaur 2002 GO9 in 2009–10, allowing the first-ever measurement of a phase curve for studying the photometric and Bond albedo of such a body.

No additional missions to bodies in the KB are currently in development, but the US Decadal Survey of Planetary Science did place high priority on exploring the diversity of KBOs with space missions. Hence, it would not be surprising to see proposals for future missions.

10.21.1 Introduction

Until nearly the close of the twentieth century, the search for planets beyond the solar system was a fraught and generally less-than-fully respectable endeavor. For generations, the scientific community was subjected to spurious announcements of discovery of planets orbiting nearby stars. Famous examples include erroneous claims, starting in 1855, of a planetary mass object in the 70 Ophiuchi system (e.g., Jacob, 1855; See, 1896) and of one, or possibly two, Jupiter-like planet(s) harbored by Barnard's Star, the red dwarf that is our Sun's nearest neighbor aside from the Alpha Centauri triple-star system (van de Kamp, 1963, 1969).

If we adopt the frequently used definition that requires the planetary mass, M_p, to lie below the $13M_J$ deuterium-burning limit, where M_J denotes the mass of Jupiter, then it might be appropriate to credit the first bona fide detection of an extrasolar planet to Latham et al. (1989), who used Doppler radial velocity (RV) measurements to sense an object with a minimum mass of 11 Jupiter masses on an eccentric 83.9-day orbit around HD 114762, a relatively nearby, solar-type star. With hindsight, this object belongs to the class of giant planets that tend to be more massive than Jupiter, which often have substantial orbital eccentricities and which are found in orbit around ~5% of local solar-type dwarfs (Butler et al., 2006). At the time of HD 114762 b's discovery, however, as a consequence of the abysmal track record of extrasolar planet claims, Latham et al.'s announcement did not generate significant excitement within the wider community. Indeed, the profound difference between HD 114762 b's mass and orbit from those of our solar system's planets led Latham et al. to state, "This leads to the suggestion that the companion is probably a brown dwarf, and may even be a giant planet." Given that HD 114762 b's product of its mass and sine of the inclination angle between its orbital planes, $M_p \sin i$, is so near this physical mass boundary and $\sin i < 1$, Latham et al.'s statement can still be considered as a proper assessment of our current knowledge of this object a quarter century later!

Soon thereafter, astronomers developed a sudden and abiding interest in extrasolar planets. The catalyst was the pulse-timing detection, by Wolszczan and Frail (1992), of two terrestrial-mass planets, with $M_p \sin i = 3.4M_\oplus$ and $2.8M_\oplus$ and with Mercury-like periods of 66.5 and 98.2 days, orbiting the millisecond pulsar PSR 1257 + 12. Pulsars, which are rapidly rotating, strongly magnetized neutron stars, emit radio waves that appear as periodic pulses to an observer on Earth. The pulse period, Doppler shifted to the frame of motion of the barycenter of our solar system, can be determined very accurately. Although a pulsar emits an exquisitely periodic signal, the times at which the pulses reach the receiver are not equally spaced if the distance between the pulsar and the telescope varies in a nonlinear fashion, and if periodic variations are present in data that have been properly reduced, they may indicate the presence of companions orbiting the pulsar. In the case of PSR 1257 + 12, measurements are so accurate that deviations from Keplerian orbits of the two planets mentioned in the preceding text caused by their mutual interactions have been measured and used to calculate their actual masses, $M_p = 4.3 \pm 0.2 M_\oplus$ and $3.9 \pm 0.2 M_\oplus$, implying that the system is inclined by ~50° from the line of sight (Konacki and Wolszczan, 2003). A handful of other pulsar planets have been found, including a lunar-mass third planet orbiting PSR 1257 + 12 and a long-period Jupiter-mass planet in a circumbinary orbit about a pulsar-white dwarf binary system (Sigurdsson et al., 2003).

The pulsar planets were followed in 1995 by Michel Mayor and Didier Queloz's discovery of 51 Pegasi b, a gas giant planet with a minimum mass roughly half that of Jupiter and a startlingly short 4.23077-day orbital period about a metal-rich but otherwise ordinary G-type main-sequence star. ('Official' exoplanetary names are a compound of the name of the parent star and a lower-case letter. The first planet detected in orbit around a given star is denoted *b*, the second, *c*, etc.). Thereafter, the pace of discovery ballooned, along with our understanding both of the planetary census and of the physical characteristics of alien worlds. The study of exoplanet

characteristics has largely been made possible by the detection of transiting planets, which partially eclipse the light of their star once per orbit. The first transiting planet was discovered in 1999 in the orbit around HD 209458 (Charbonneau et al., 2000; Henry et al., 2000).

It is no exaggeration to say that a fully independent branch of astronomy has been created from scratch. The rapid pace of progress is reflected in Figure 1, which charts $\log_{10} M_p \sin i$ as a function of the year of discovery. The lower envelope of the discovery masses in this semilog plot is well described by a constant slope, indicative of a Moore's law behavior with a $\tau \sim 2$-year halving time of the lowest-known extrasolar planetary mass.

10.21.2 Planetary Detection Methods

Given the inherent difficulties associated with the detection of extrasolar planets, it is genuinely remarkable that a very broad range of observational methods for characterization and detection either have been successfully employed or are being seriously prepared for future use. As a corollary to the vast interstellar distances, all extrasolar planets are extremely faint; to a distant optical observer, Jupiter's brightness, $L_J \approx 10^{-7}$, is the solar value.

Most detection methods, therefore, are *indirect*, in that the planets are sensed through their influence on the host star or on the path of light emitted by a distant star. A range of distinct observation methods are sensitive to different classes of planets, and importantly, they provide us with complementary information about the planets they do find. Without question, a full quiver of techniques is required in order to provide an optimal characterization of the diversity of planets and of planetary systems.

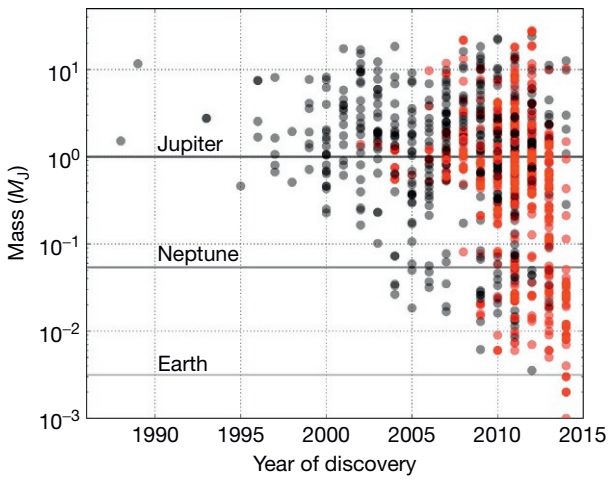

Figure 1 Discovery of extrasolar planets with discovery date versus estimated mass for extrasolar planets orbiting normal stars (not pulsars) over time, with a logarithmic *y*-axis showing mass (or for the cases of Doppler detections, $M \sin i$), and time (in the form of the discovery date) running linearly along the *x*-axis. The lower envelope of this semi-log plot shows a clear Moore's law-like progression and demonstrates that the field has collectively arrived (in the past 1–2 years) at the discovery of planets with $\sim 1 M_\oplus$. Transiting planets are shown in red, whereas planets detected only via Doppler radial velocity are shown in gray. Data are taken from www.exoplanets.org database table, accessed 2/2/2014.

To date, two methods – photometric transit detection and Doppler RV measurement – have generated the vast majority of the successful detections. The Doppler RV technique hinges on the ability to monitor tiny time-dependent wavelength displacements among the profusion of atomic lines in a star's spectrum. By measuring the net overall shift, $z = \delta\lambda/\lambda$, using a large number of individual spectral lines, the velocity at which the star is moving toward or away from an observer can be precisely determined. Astronomers then subtract the motion of the telescope relative to the barycenter of the solar system and other known motions, revealing the radial motion of the target star that results from the tug of its own planets. Transit photometry identifies planet candidates by the periodic drops in observed stellar brightness that are caused by the planet obscuring a portion of the stellar disk once per orbit. Note that transit photometry can only detect planets whose orbits are viewed nearly edge on.

Exoplanet detection using either the RV method or the transit photometry method requires very precise measurements of light from the planet-hosting star. The techniques used to achieve such high precision are based on differential measurements of observations taken at different times. Absolute accuracies, therefore, need not be particularly high, so the mean velocity (relative to the solar system) of a star hosting RV-detected planets is generally not known to an accuracy approaching 1 ms^{-1}, nor is the spectrophotometric brightness of a star hosting a planet observed via transit photometry known to the, for example, part per thousand level needed in relative brightness to detect Neptune-sized planets.

As with pulsar timing, RV measurements yield the product of the planet's mass (divided by that of the star, whose mass can usually be estimated fairly accurately from its spectral characteristics) and the sine of the inclination angle between the orbital plane and the plane of the sky, $M_p \sin i$. The total half-amplitude, *K*, of the stellar reflex velocity induced by an orbiting planet is the measured quantity and is related to $M_p \sin i$ through

$$K = \left(\frac{2\pi G}{P}\right)^{1/3} \frac{M_p \sin i}{(M_\star + M_p)^{2/3}} \frac{1}{\sqrt{1-e^2}} \qquad [1]$$

indicating that the RV technique is most sensitive to massive planets and to planets in short-period orbits. The RV technique allows estimation of the period, *P*; orbital eccentricity, *e*; the mean anomaly, $M = 2\pi(T - T_{\mathrm{periastron}})/P$; and orientation, generally expressed as the longitude of periapse, ω, of the stellar orbit relative to the system center of mass. Multiparameter estimation techniques have reached a high degree of refinement for the problem of determining best-fit orbital elements and uncertainty estimates. For reviews that cover the process of RV modeling, see Ford (2006), Meschiari et al. (2009), Dawson and Fabrycky (2010), and Dumusque et al. (2011). (We recommend the *Systemic Console* software package, available at www.oklo.org, as an intuitive framework for exploring RV and transit-timing data.)

Leading research groups are now routinely achieving instrumentally based velocity errors of $a\ \sigma \sim 50\,\mathrm{cm\,s}^{-1}$ (representing a Doppler shift of two parts in 10^9) on stable, bright,

chromospherically inactive stars. For context, Jupiter causes the Sun's velocity to vary with a half-amplitude $K_J = 12.5\ \mathrm{ms}^{-1}$ and a period $P_J = 11.86$ years; Saturn's effect is the next largest, with an amplitude of $2.7\ \mathrm{ms}^{-1}$ and a period, P_S, of almost 30 years, but the Earth induces a mere $K_\oplus = 6\,\mathrm{cm\,s}^{-1}$ fluctuation. To date, the planet with the lowest RV amplitude signal yet announced is Alpha Centauri Bb, with $K = 51\,\mathrm{cm\,s}^{-1}$, $P = 3.2357$ days, and $M \sin i = 1.1 M_\oplus$ (Dumusque et al., 2012). Earth-like planets orbiting Sun-like stars at astrobiologically interesting distances (where liquid water could be stable on their surfaces) remain somewhat beyond the capabilities currently achieved.

Precise RV measurements require the good statistics that come from aggregating individual measurements of a large number of spectral lines. High-precision measurements thus cannot be achieved for hotter stars with temperatures $T\mathrm{eff} > \sim 6200$ K (corresponding to spectral types O, B, A, and early F), as these stars have far fewer spectral features than do stars of solar type or cooler. Stellar rotation and intrinsic variability (including star spots) also represent major sources of noise that confound RV measurements. The RV surveys, such as the Geneva Extrasolar Planet Search (Mayor et al., 2009), the California Planet Search (Howard et al., 2011), and the Lick–Carnegie Exoplanet Survey (Vogt et al., 2010), are therefore increasingly focusing on very nearby, old, photometrically quiet late G-, K-, and M-type main-sequence dwarfs. The 451 stars that constitute the HARPS Guaranteed Time Observations high-precision sample (Sousa et al., 2008) encompass most of the Sun-like stars at declination $\delta < 20°$ N that are currently receiving intense surveillance.

Planets can also be detected via the wobble that they induce in their parent star's motion projected onto the plane of the sky. This so-called *astrometric* technique is most sensitive to massive planets orbiting stars that are relatively close to Earth. Because the star's motion is detectable in two dimensions, the planet's actual mass, rather than just the combination $M \sin i$, can potentially be measured. Planets on more distant orbits are ultimately easier to detect using astrometry because the amplitude of the star's motion is larger, but finding these planets requires a longer timeline of observations due to their greater orbital periods. To date, despite decades of optimistic expectations (see, e.g., Black and Scargle, 1982), the astrometric method has yet to unambiguously detect an exoplanet. This situation is likely to change soon, however. Simulations by Casertano et al. (2008) indicate that ESA's *Gaia* mission, launched on 19 December 2013 and designed to achieve 7μ as precision on $V = 10$ stars, should be capable of detecting several thousand giant planets out to 3–4 AU from stars lying within 200 pc of the Sun.

The Doppler and astrometric techniques measure a planet's gravitational pull on its star and are thus sensitive to the planet's mass. By contrast, transit photometry detects the amount of starlight that a planet can obscure and thus yields an estimate of the planet's size. If the line of sight from the parent star to the Earth lies in or near the orbital plane of an extrasolar planet, that planet passes in front of the disk of its star once each orbit as viewed from Earth and periodically blocks a small fraction of the star's light. Sufficiently precise photometric time-series measurements of the star's brightness are used to reveal transits, which can be distinguished from rotationally modulated star spots and intrinsic stellar variability by their periodicity, their effectively square-well shapes, and their relative spectral neutrality. Although geometric considerations limit the fraction of planets detectable by this technique (planetary orbital angular momentum vectors are aligned apparently randomly with respect to the galactic plane; the angular momentum of the solar system ultimately derives from the level of turbulent motions that existed within the Sun's parent giant molecular cloud and is not a direct consequence of the differential rotation of the galactic disk), thousands of stars can be surveyed within the field of view of one telescope, so transit photometry is potentially quite efficient. Indeed, transit photometry now generates a clear majority of new planetary candidates. Ground-based surveys, for example, the HATNet Exoplanet Survey (Bakos et al., 2012) and SuperWASP (Smith et al., 2013) survey, are generating dozens of confirmed planets per year.

The preliminary version of the *Kepler* Q12 planet candidate catalog, consisting of signals identified using the first 3 years of *Kepler* data, contains 3538 candidate planets, at least ~90% of which are expected to represent true exoplanets (Casertano et al., 2008; Lissauer et al., 2014a; Morton and Johnson, 2011; Santerne et al., 2013). Almost half of these objects are associated with target stars having two or more planet candidates, implying that configurations of tightly spaced, highly coplanar planets are ubiquitous (Lissauer et al., 2011b). More than 90% of these candidates have estimated radii $R_p < 6R_\oplus$, and almost half have radii $R_p < 2R_\oplus$ despite observational biases against detecting smaller planets. (For an up-to-date list of *Kepler* candidates, see http://exoplanetarchive.ipac.caltech.edu/cgi-bin/ExoTables.) In many of *Kepler's* multiple-transiting planet systems, the transit events exhibit deviations from strict periodicity. These so-called transit-timing variations (as well as transit duration variations that are, much more rarely, also observed) can be attributed to planet–planet interactions within the systems and have, in many cases, established to high confidence that a particular candidate system is the genuine item rather than a false positive. Scores of *Kepler* candidates, furthermore, have been confirmed with Doppler follow-up measurements, for example, Cochran et al. (2011) and Marcy et al. (2014), and hundreds of candidates have been validated to be planets at very high confidence through statistical arguments (e.g., Rowe et al., 2014; Torres et al., 2011).

Reaching further into the box of astrophysical tricks, one finds the microlensing method, which has been successfully employed to investigate the distribution of faint stellar and substellar mass bodies within our galaxy (Alcock et al., 1997) and which has now produced published detections of 18 extrasolar planets (Kains et al., 2013). The microlensing phenomenon stems from the general relativistic bending of the light from a distant star (the source) by a massive object (the lens) passing between the source and the observer. Such lensing can cause the source to appear to gradually brighten by a factor of a few or, for special configurations leading to high-magnification events, factors exceeding 100, over a timescale of weeks to months. If the lensing star has planetary companions, then these far less massive bodies can produce brief enhancements in the brightness – generally of a few hours in duration – provided that the line of sight passes close to the planet. Under favorable circumstances, planets as small as the Earth can be detected. The properties of individual planets, however, and usually even of the stars that they orbit can only be estimated in a statistical sense because of the many parameters

that influence a microlensing light curve (see, e.g., Gaudi, 2012; Peale, 1997). The microlensing technique is comparatively well suited to the detection of planets with long periods and can readily probe Jovian or even super-Earth mass planets in orbits similar to that of Jupiter itself. Due to the prevalence of M-type main-sequence stars in the stellar mass function, the microlensing technique has found a number of examples of giant planets and Neptune-mass planets beyond the locations of the so-called nebular snow lines for these stars (Bennett et al., 2010). Sumi et al. (2011) extensively analyzed several years of microlensing survey data from the galactic bulge and reported the discovery of a population of 'isolated' planetary mass objects with $M \sim M_J$, which appear to occur with somewhat higher frequency than main-sequence stars. Either these planetary mass objects lie in very distant orbits ($d > 100\,\mathrm{AU}$) from undetected parent stars, or they are gravitationally unbound and thus floating freely through the galaxy. The potential presence of hundreds of billions of drifting planetary mass objects, should these worlds withstand statistical scrutiny, would have important consequences for the theory of planet formation and would serve as a definitive endorsement of the microlensing technique.

All of the foregoing are indirect methods to locate extrasolar planets, but what about imaging planets directly? While observational efforts to directly detect extrasolar planets can be traced back to Christiaan Huygens in the 1600s, only very recently have the extreme planet–star brightness contrasts and angular separations been successfully challenged. The reflected starlight from planets with orbits and sizes like those in our solar system is of order 20 visual magnitudes (a factor of $\sim 10^8$) fainter than the stellar brightness, although the brightness contrast improves by a factor of a thousand (or more) in the planet's thermal infrared, for example, at wavelengths $\lambda \sim 10\,\mu\mathrm{m}$. Diffraction of light by telescope optics and atmospheric variability compound the difficulty of direct detection of extrasolar planets. Technological advances, most critically in the area of adaptive optics on large ground-based telescopes and coronagraphic imaging from space, are enabling direct detection of relatively massive, young, and in most cases self-luminous planets orbiting at substantial distances $a \gtrsim 10\,\mathrm{AU}$ from young, nearby stars with masses $M_\star \gtrsim M_\odot$. These detections leverage planet–star brightness contrasts of order $L_p/L_\star < 10^5$ and angular separations of order $\alpha \sim 1$ arcsec. A high-profile example is illustrated by Beta Pictoris b (Lagrange et al., 2010), with mass $M_p = 8^{+5}_{-2} M_J$ at separation $a = 8^{+1.7}_{-0.4}$ AU from Beta Pictoris, a young A-type star that has long been known to harbor an infrared excess and an extensive debris disk (Smith and Terrile, 1984). Another interesting and somewhat controversial example is provided by Fomalhaut b (Kalas et al., 2008). This curious object, which has been imaged with HST, lies near the inner radius of the dust ring surrounding the young, nearby A-type star Fomalhaut. The imaged light associated with the planetary candidate's position is dust-scattered starlight, associated, perhaps, with a circumplanetary disk (Galicher et al., 2013; Kenyon et al., 2014).

The most startling and remarkable direct-imaging detection to date is that of the system of four companions to the young ($\sim 30\,\mathrm{My}$) A-type star HR 8799 (Marois et al., 2008, 2010). These planets all have masses in the vicinity $M_p \sim 5 - 7 M_J$, with semimajor axes lying at 14.5, 24, 38, and 68 AU, and call to mind a version of our own outer solar system that has been scaled up by a factor of several in both mass and astrocentric distance. The presence of HR 8799's planets at their observed distances presents interesting challenges to both the core accretion (Lissauer et al., 2009) and the gravitational instability (Durisen et al., 2007) models of giant planet formation. The proximity of the system configuration to the dynamical stability boundary is also intriguing and implies either that the system will suffer catastrophe within a time that is much less than the star's main-sequence life or that the planets are dynamically protected by a resonant mechanism (Fabrycky and Murray-Clay, 2010). The pace of detection by direct imaging is proceeding at a rapid clip, with additional examples being those of HD 95086b (Rameau et al., 2013), 2MASS J01033563-5515561(AB)b (Rameau et al., 2013), κ And b (Carson et al., 2013), and GJ504b (Kuzuhara et al., 2013), which tend to be massive planets $M \gtrsim 4 M_J$ orbiting at $R \gtrsim 40\mathrm{AU}$ from young (or relatively young) stars.

Direct imaging is poised for major advances with the advent of the Gemini Planet Imager (GPI), which experienced first light at the Gemini South telescope in late 2013 (Macintosh et al., 2014), and by the SPHERE high-contrast adaptive optics imager at the VLT, which came on line in 2014 (for details on the SPHERE instrument, see Beuzit et al., 2008). The GPI adaptive optics system is designed to detect planetary companions at separations of $\delta = 0.2$–1.0 arcsec and brightness contrast of 10^{-7} in 1–2 h exposures. This observational strategy is sensitive to Jupiter-mass planets within the first several million years of their formation and will enable direct imaging of a variety of planets younger than 1 Gy in age. The GPI system, furthermore, uses an integral field spectrometer to obtain $R \sim 40$ spectra that will give important clues to overall atmospheric compositions and states (see, e.g., Konopacky et al. (2013), who reported on the use of the Keck Observatory's OSIRIS integral field spectrograph to detect CO and H_2O absorption in HR 8799c).

Several other methods can also be used to detect extrasolar planets. Precise timing of eclipses of eclipsing binary stars has the potential of revealing the masses and orbits of unseen companions, and indeed, such timing measurements have been used to confirm the planetary nature of the transiting circumbinary planet Kepler-16b (Doyle et al., 2011). Spectroscopy could be used to identify gases that would be stable in planetary atmospheres but not in stars, and Doppler variations of such signals could yield planetary orbital parameters. As an example, Brogi et al. (2013) had obtained tentative detections of CO and H_2O in the emission spectrum of 51 Peg during superior conjunction of its nontransiting short-period planetary companion. Starlight scattered from a planetary atmosphere will be polarized (for detail, see Seager et al., 2000), and the expected polarization signal lies at the threshold of current detectability (Berdyugina et al., 2008; Wiktorowicz, 2009). Radio emissions similar to those detected from Jupiter could reveal the presence of extrasolar planets, although to date all attempts at detection via this channel have been unsuccessful (see, e.g., Lazio et al., 2010). Finally, the detection of artificial signals from an alien civilization would presumably imply the presence of a habitable terrestrial-sized planet or giant planet satellite.

The *Kepler* spacecraft has broken through the psychologically important threshold of one Earth radius, identifying numerous Earth-sized candidates, and has validated several planets smaller than the Earth, including Kepler-37 b, a planet about the size of the Earth's Moon (Barclay et al., 2013). The Doppler RV technique is approaching the comparable $1M_{\oplus}$ threshold, with the Geneva Extrasolar Planet Search team's detection of an $M_p \sin i \sim 1.1M_{\oplus}$ planet in a short-period orbit about Alpha Centauri B (Dumusque et al., 2012). All of the Earth-sized exoplanets verified thus far, however, have orbital periods of a few weeks or less and are not worlds of astrobiological interest. Nevertheless, it has been unambiguously established that planets of masses somewhat greater than the Earth's mass and larger are *extremely* common in the galaxy, and the emphasis of the field is shifting from the detection of extrasolar planets to their physical characterization. In the same manner that a new branch of astronomy has been created, a new and important subfield of planetary geophysics has also come into being.

10.21.3 An Overview of the Current Planetary Catalog and Census

Including both verified exoplanets and high-quality *Kepler*-detected transiting planet candidates, thousands of planets have now been identified, and the outlines of the galactic planetary census are emerging. Much of the current inventory of planets is shown in Figure 2. In this diagram, which combines planets and planet candidates from several sources, the log of the mass ratio of the planet to the central star, $\log_{10}(M_p/M_\star)$, is plotted on the ordinate, and $\log_{10}P$ is charted on the abscissa. For the case of Doppler detections, we conflate M_p with $M_p \sin i$, and for high-quality candidate transiting planets detected photometrically, we have transformed from planetary radius R_p to M_p using a simple transformation:

$$M_p = \left(\frac{R_p}{R_\oplus}\right)^3 M_\oplus \qquad R_p < R_\oplus \qquad [2]$$

$$M_p = \left(\frac{R_p}{R_\oplus}\right)^{2.06} M_\oplus \qquad R_J > R_p > R_\oplus \qquad [3]$$

$$M_p = M_J \qquad R_J > R_\oplus \qquad [4]$$

In the preceding text, the $M_p/M_\oplus = (R_p/R_\oplus)^{2.06}$ relation (Lissauer et al., 2011a) provides a best-fitting power law to the solar system planets spanned in mass by the Earth and Saturn. That such a simple power law does such a good job in the face of different formation mechanisms for the solar system planets can largely be attributed to the fact that only four planets are involved in the fit and to the substantial similarity between Uranus and Neptune. The $M_p = M_J$ relation is applied to just a handful of candidates that appear in multiple-planet systems and does not affect the overall trends exhibited by the diagram. In the absence of solid information, the relation $M_p = (R_p/R_\oplus)^3 M_\oplus$ simply assumes that a small number of planet candidates with radii smaller than the Earth's have Earth-like densities. As we will discuss in the succeeding text, the results from planets that have had both M_p and R_p independently measured indicate that there is no single planetary mass–radius relation and that the dispersion in radii for

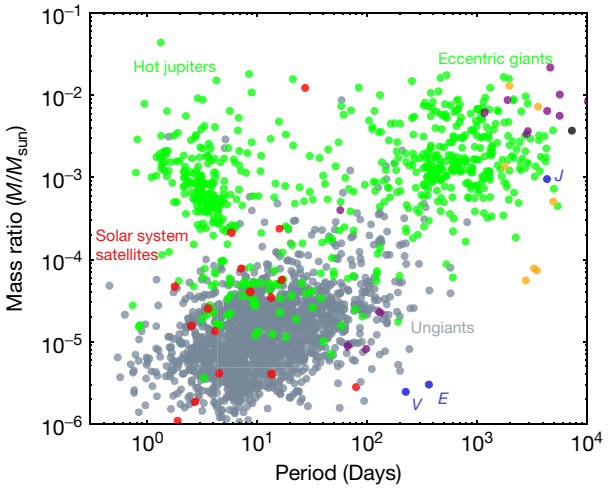

Figure 2 *Green circles*: $\log_{10}(M_{satellite}/M_{primary})$ and $\log_{10}(P)$ for 634 planets securely detected by the radial velocity method, including those first identified via transits. *Red circles*: $\log_{10}(M_{satellite}/M_{primary})$ and $\log_{10}(P)$ for the regular satellites of the Jovian planets in the solar system, along with the Earth's Moon. *Gray circles*: $\log_{10}(M_{satellite}/M_{primary})$ and $\log_{10}(P)$ for 1501 *Kepler* candidates and objects of interest in which *multiple*-transiting candidate planets are associated with a single primary. Radii, as reported in Batalha et al. (2013), are converted to masses using the mass–radius relations described in the text. *Black circle*: Planets detected by direct imaging, with mass ratios estimated from infrared emission detected from the planetary candidate (imaged planets with $P > 10^4$ days, e.g., HR 8799 b, c, d, and e are not shown). *Gold circles*: Planets detected via microlensing. *Purple circles*: Planets detected via pulsar and white dwarf timing. *Blue circles*: Jupiter, Earth, and Venus.

planets of given mass is substantially larger than was generally expected.

The degree of incompleteness that characterizes Figure 2 is somewhat difficult to evaluate, especially in light of the fact that it draws together planets detected by a variety of methods. Nevertheless, a reasonable estimate for the current limiting sensitivity of the Doppler surveys, in the absence of highly focused, high-cadence campaigns on bright nearby stars, is $K = 2\,\mathrm{m\,s^{-1}}$, multiplied by an additional period-dependent term of order unity that favors shorter orbits. A curious and mostly unpredicted feature of the diagram is that the planets fall into three groups. Observational completeness, furthermore, while not perfectly known (see, e.g., Cumming et al., 2008), is sufficient to ensure that the gaps separating the three distinct populations represent real features of the galactic planetary census.

Centered on $M_p/M_\star \sim 1 \times 10^{-3}$ (i.e., $\sim 1M_J$) and $P \sim 3$ days is a population of *hot Jupiters*. The members of this group, on account of their ready detectability, are the best-studied (if still incompletely understood) population of extrasolar planets. In aggregate, hot Jupiters are clearly gas giants dominated by hydrogen–helium compositions, but in nearly every observable property – radii, chemistry, emission properties, density, orbital elements, and so forth – they display a tremendous variability that defies easy categorization.

Hot Jupiters constitute a prominent fraction of the planets in Figure 1 because they are readily detectable, but as a whole, they represent a small fraction of the entire population of

planets. Among a large sample of main-sequence host stars, they are the exception rather than the rule, with an occurrence rate among nearby Sun-like main-sequence stars of only about ~1% (Mayor et al., 2011a; Wright et al., 2012). From the Batalha et al. (2013) catalog of *Kepler* candidate planets, one estimates a hot Jupiter occurrence rate of 0.5%, in contrast to the order-unity occurrence rate of smaller planets with orbital periods $P < 100$ days.

The upper right-hand corner of **Figure 2** shows a second population of planets that have been revealed by the Doppler velocity surveys. In the absence of a consensus terminology, we refer to this group as the *eccentric giants*. Planets in this group are characterized by (1) orbital periods in the range of hundreds to thousands of days; (2) masses that are, on average, several times larger than the mass of Jupiter, with a median value of $M \sin i = 1.94 M_J$, although the mean of the underlying distribution is clearly smaller because more massive planets are easier to detect; and (3) typically substantial eccentricities, with a median value $e = 0.22$ and $e > 0.5$ not uncommon, although a few members travel on nearly circular orbits. HD 114762 b (Latham et al., 1989), with $M \sin i = 11 M_J$ and $P = 114$ days, is a member of this population. Of order $F \sim 5\%$ of the solar types F, G, and K, main-sequence dwarfs in the local galactic neighborhood harbor an eccentric giant, making them roughly ten times more common than hot Jupiters. Like the hot Jupiters, however, the occurrence rate of eccentric giants depends strongly on the metallicity of the parent star (Gonzalez, 1997, 1999). This strong correlation imparts an important, albeit still imperfectly understood, clue regarding the nature of the planet-forming process. The most metal-rich stars, with $[\mathrm{Fe/H}] > 0.3$, that is, more than twice the solar value, are a factor of five to ten times more likely to harbor a hot Jupiter or an eccentric giant than are stars with metallicity less than half that of the Sun (i.e., those with $[\mathrm{Fe/H}] < -0.3$) (Fischer and Valenti, 2005; Santos et al., 2001). Stars with $M_\star > M_\odot$ are also statistically more likely to harbor a hot Jupiter or an eccentric giant.

Jupiter lies near the long-period edge of the currently known population of eccentric giants. Until recently, the natural interpretation of this apparent placement near the tail of the distribution is that it arises from observational incompleteness among genuinely Jovian analogs with Jupiter-like masses and Jupiter-like periods. That is, the apparent dearth of planets with $P \sim 10$ years and $M < 1 M_J$ was thought to be the simple consequence of long required timescales for observation and the difficulty in detecting low-amplitude signals. Such assumptions, however, are increasingly being called into question. As an example, consider the stars in the Keck RV survey as maintained by the Lick–Carnegie Exoplanet Survey (Vogt et al., 2010). As of 2012, the Keck I telescope has been used to obtain 31,910 Doppler measurements in the overall RV database (binned to a minimum cadence of 2 h in the frequently occurring case of multiple back-to-back exposures that average over stellar p-modes) on 1298 individual, primarily solar-type, main-sequence dwarfs. The median-derived instrumental uncertainty on these measurements is $\sigma = 1.45\,\mathrm{ms}^{-1}$ (stellar jitter, depending on the star, generally contributes $\sigma = 1\text{–}5\,\mathrm{ms}^{-1}$ in quadrature to the instrumental uncertainty, and for observations associated with individual stars, the median time baseline $\tau_{\mathrm{base}} = \mathrm{HJD}_{\mathrm{obs.last}} - \mathrm{HJD}_{\mathrm{obs.first}} = 2426$ days). Furthermore, there are 237 stars with time baselines longer than Jupiter's orbital period ($\tau_{\mathrm{base}} > 11.85$ years). The stars in this long-baseline group tend to be similar to the Sun in terms of basic properties and are chromospherically quiet and photometrically stable, averaging 55 Doppler measurements each. A true-Jupiter analog ($P = 11.85$ years and $K = 12 \sin i\ \mathrm{ms}^{-1}$) orbiting almost any of these stars would be immediately evident.

Of potentially equal significance to the concentrations of planets in the mass–period ratio diagram are the regions of parameter space where the number density of worlds is low. Nature tends to avoid sitting giant planets with orbital periods in the 10 days $< P <$ 100 days range; the underlying cause of these broad areas of lower concentration is not fully understood. There appears to be a general dearth of planets of both short and intermediate period with masses ranging from roughly $40 M_\oplus$ to $100 M_\oplus$, consistent with the predictions of rapid growth through this mass range in the core-nucleated accretion model of giant planet formation (Pollack et al., 1996).

Perhaps the most important exoplanet-related discovery of the past 10 years has been the realization that roughly half of the Sun-like stars in the solar neighborhood are accompanied by systems of one or more planets on low-eccentricity orbits with periods ranging from days to months and masses falling in the $1 M_\oplus < M_p < 50 M_\oplus$ range (Mayor et al., 2009, 2011b). These planets are clearly visible as a third population that is distinct from the hot Jupiters and from the eccentric giants. Its members constitute the bulk of the transiting planet candidates in multiple-transiting systems detected by *Kepler*, which are indicated in gray on the mass–period ratio diagram. There is clearly a 'desert' (dearth of objects) between giant planets and these 'ungiants,' the term of art that we will employ for what is largely still *terra incognito* – the planetary mass range $M_p < 30 M_\oplus$.

Whereas the period distribution of giant planets reveals that hot Jupiters are a separate population, distinct from the more distant giants, whose abundance peters out at periods of less than a few months, no such distinction is seen among the ungiants. The population of these planets appears roughly constant in log period space (as would be expected from stability limits imposed by planetary dynamics) for orbital periods between 10 and 100 days. Data are too sparse to extend this conclusion to longer periods. At shorter periods, there is clearly a drop in the abundance of ungiant planets, but this is gradual, with no counterpart to the spike in the 3–4-day range seen for giants. Neptune-sized planets are detected down to orbital periods of 2 days, and planets with $R_p \lesssim 2 R_\oplus$ are observed at periods well under 1 day. The current record holder for ultrashort-period planets is Kepler-78 b, a rocky world (it has been detected both in transit and using RV) slightly larger than the Earth with an orbital period of only 8.52 h (Howard et al., 2013; Pepe et al. 2013).

Little is known about the physical properties of ungiants, apart from that *by mass*, they are composed primarily of elements heavier than helium, in contrast to giant planets, and that they are a diverse lot in terms of dominant constituent *by volume*. It is not clear, for example, whether most of its members are properly described as 'super-Earths' or 'sub-Neptunes' or something else entirely. Curiously, our own solar system, which contains nothing interior to Mercury's 88-day orbit, lacks any of the larger and closer-in planets that dominate this part of the exoplanet diagram; how common terrestrial

planet configurations similar to our solar system are is unknown, although many stars clearly host different and easier-to-detect systems of ungiants Sanchis-Ojeda et al. (2013).

A confounding factor is presented by the fact that very few of the known super-Earth-/sub-Neptune-class planets have been both studied with transit photometry and weighed using Doppler RV and/or transit-timing variations. **Figure 3** shows the current census of planets for which both mass and radius (and hence density) measurements have been made. It provides an interesting high-level synopsis of much of what is currently known regarding the physical properties of extrasolar planets. Even with the log–log scaling, the plot indicates to the eye that planets are subject to a wide variety of structures. For example, within the errors, it appears that planets of $M \sim 6M_\oplus$ range in radii by a factor of at least three. When mass is viewed as a function of radius, the transition in composition appears sharper, with planets with radii $\gtrsim 2R_\oplus$ generally not dominated by rock (including iron) and those with radii $\lesssim 1.6R_\oplus$ and measured masses mostly rocky. While the upper limit to the size of abundant rocky planets within $\sim$0.5AU of their stars seems well established, it is quite possible that many or even most planets smaller than $1.6R_\oplus$ are composed primarily of low-density constituents but that the low masses of such planets make them difficult to measure.

In **Figure 3**, we have overplotted three potential mass–radius relations for ungiants. The first relation is the $M_p/M_\oplus = (R_p/R_\oplus)^{2.06}$ best fit to the solar system planets spanned in mass by the Earth and Saturn. Despite the uncertainties, this relation is seen to provide a reasonable fit to the mass–radius relation of planets smaller in mass than Saturn. The solar system fit is bracketed by two alternate relations. The first, with a steeper slope, is derived from the assumption that low-mass, short-period planets have rocky cores surrounded by hydrogen–helium envelopes, with envelope masses dictated by *in situ* formation, as discussed in Chiang and Laughlin (2013). The second alternate relation, $3M_p/M_\oplus = R_p/R_\oplus$, has a shallower slope and is a fit derived from an ensemble of transit-timing measurements applied to 22 systems within *Kepler*'s multiple-transiting planet candidate population by Wu and Lithwick (2012) (see also Weiss et al., 2013).

Kepler is capable of detecting rocky terrestrial planets analogous to Venus and Earth, but the spacecraft is unlikely to find a statistically robust sample of terrestrial planets similar to those in our solar system. The mass–period diagram is thus still largely incomplete for terrestrial planets with solar system-like masses and orbits and will likely remain so for some time. In the absence of solid data, we can only resort (with an abundance of cautionary disclaimers) to statistical extrapolations to anticipate the inventory of low-mass planets (**Figure 4**).

To construct a concrete (albeit uncertain) extrapolation, we assume that planet formation is highly efficient and that long-distance migration ($\Delta a \gtrsim a$), where a is the current semimajor axis of the planet and Δa is the amount it has migrated, does not regularly occur in the super-Earth population. We then idealize the population of *Kepler* planetary candidates from Batalha et al. (2013) as being composed of solar-composition solids, and we assign each planet a surface density, $\sigma_{solid} = M_p/2\pi a_p^2$,

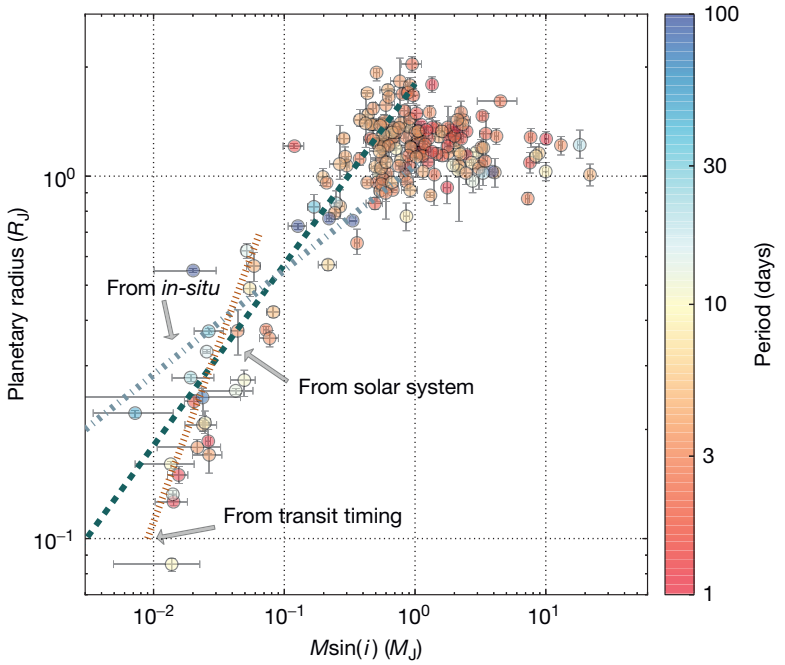

Figure 3 Mass–radius diagram for extrasolar planets. This figure shows all planets for which both mass and radius estimates exist, with orbital period coded to run from 1 day (red) through 100 days (blue). Three sample mass–radius relations are shown. The short dotted line is drawn from a simple *in situ* formation theory as described in Chiang and Laughlin (2013) and is based on rock-iron planets surrounded by hydrogen–helium envelopes and does not include the possible effects of insolation-driven atmospheric mass loss. The long dashed line is the best-fit $M_p/M_\oplus = (R_p/R_\oplus)^{2.06}$ power law appropriate to the solar system planets spanning masses from the Earth through Saturn. The medium dashed line is the $3M_p/M_\oplus = R_p/R_\oplus$ relation derived by Wu and Lithwick (2012) from consideration of the transit-timing variations observed by *Kepler* for 22 multiple-transiting candidate planet pairs in the vicinity of mean motion resonances.

where a_p is the orbital semimajor axis, computed with the approximation that $M_\star = M_\odot$, and $M_p = (R_p/R_\oplus)^{2.06} M_\oplus$. The resulting $N = 1925$ surface densities obtained for low-mass candidates with $R_p < 5R_\oplus$ are plotted in Figure 3. The best-fit power law to the median data can be interpreted to define a 'minimum-mass extrasolar nebula' $\sigma_{solid} = 50(a/1\,AU)^{-1.6}\,g\,cm^{-2}$, which has a very similar power law index, $\alpha = -1.6$ to the canonical minimum-mass solar nebula (MMSN) value of a $\alpha = -1.5$ (Hayashi, 1981), but with a density normalization that is 5 times as large. Extending the power law to a distance $a \sim 1$AU leads to two suggestions or, better, two moderately informed speculations:

- Roughly half of the Sun-like stars in the Sun's neighborhood will harbor a planet as large as (or larger than) the Earth in (or near) an Earth-like orbit.
- Among the planetary systems of single main-sequence stars, the inventory of mass in the solar system's terrestrial planets will lie below the median total planetary mass interior to $a \sim 2$ AU.

10.21.4 Planetary Geophysics

Investigations of extrasolar planets can currently be divided conceptually into (1) analyses of planetary structure and composition, (2) the exploration of planetary orbital dynamics, and (3) the study of planet formation. These three areas closely inform one another. For example, at a given planetary age, τ_p, the radius of a giant planet (a zeroth-order structural property) depends on the mode of formation. A planet that emerges from the process of core accretion will probably be smaller at early τ_p than one that arises from disk gravitational instability (Marley et al., 2007). The planetary radius, in turn, has a strong influence on the tidal dissipation rate, with tidal luminosity obeying $\dot{E} \propto (R_p/a)^5$, and frequently, the long-term dynamical behavior of a compact planetary system is sensitively informed by its tidal evolution, for example, Mardling and Lin (2002). In the remainder of this chapter, we will give an overview of what is known about the 'geophysics' of extrasolar planets, with an eye toward elucidating the connections to theories of dynamical evolution and theories of planetary formation.

The direct characterization of extrasolar planets has been enabled in large part by elaborations on transit photometry, and as a result, our understanding is strongly biased toward short-period planets orbiting close to their parent stars. Most of the well-characterized giant exoplanets were discovered by ground-based transit searches, with most of the ungiants found by the Kepler spacecraft (Lissauer et al. 2014b). With this context, we then provide a synopsis of the theory of planet formation, largely informed by the contents of our own solar system. We argue that a synthesis of the overall picture is most definitely not yet fully in hand, which motivates a look forward at advances that are likely to be made within the next decade.

10.21.4.1 Exoplanetary Systems

RV surveys have detected scores of systems with more than one exoplanet, including more than one dozen nearby stars with three or more planets. In systems with high multiplicity, the planets tend to have low masses and low eccentricities, although a number of systems with three or more giant planets are known. Planets tend to be clustered into systems in the sense that there are more multiple-planet systems than would be the case were planets randomly distributed among stars. Hot Jupiters are an exception to this rule – few of them are known to have companion planets. (Nonetheless, the star υ Andromedae has at least three Jovian-mass planets, one of which is a hot Jupiter.) The remaining planets are far more distant from υ And and travel on eccentric orbits.

The multiple-transiting systems from *Kepler* provide a much larger and very rich dataset of short-period (primarily from a few days to several months) planets that can be used to

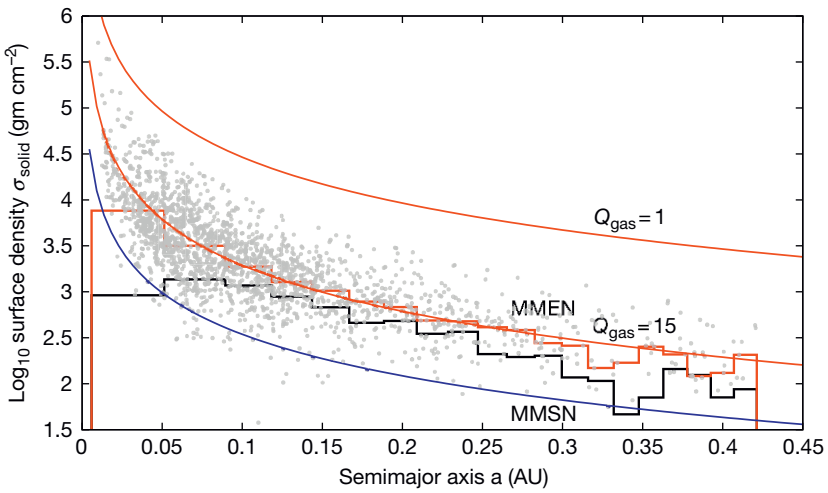

Figure 4 The solid surface density profile of the 'minimum-mass extrasolar nebula' (MMEN) constructed from *Kepler* data (Chiang and Laughlin, 2013). *Gray circles*: $\sigma_{solid,i} \equiv M_i/2\pi a_i^2$, computed from *Kepler* planets with $R_p < 5R_\oplus$ and $P < 100$ days, assuming $M_p/M_\oplus = (R_p/R_\oplus)^{2.06}$ and solar-mass host stars. $Q_{gas} < 1$ implies the nebular surface density in gas required for gravitational instability. For reference, σ_{solid} for the minimum-mass solar nebula (MMSN) – or technically its extrapolation inward, since no planet is present interior to Mercury at $a = 0.4$AU – is plotted as a blue solid curve. As plotted, the MMEN is a factor of five times as massive as the MMSN at these distances.

powerfully test theoretical predictions of the formation and evolution of planetary systems.

The major findings, updated from (Lissauer et al., 2011b), are the following:

1. The large number of candidate multiple-transiting planet systems observed by *Kepler* shows that flat (i.e., nearly coplanar) multiplanet systems are common in short-period orbits around other stars. This result holds for ungiant planets in the size range of $R_p \sim 1-6R_\oplus$, but not for giant planets. Not enough data are yet available to assess its viability for smaller worlds nor for planets with orbital periods longer than a few months.
2. Mean-motion orbital resonances and near resonances are statistically favored over random period ratios, but most planets are neither in nor very near such resonances. First-order resonances (e.g., period ratios of 2:1 and 3:2) dominate, but second-order resonances (with period ratios 3:1, 5:3, etc.) also are manifested. Most near-resonant planet pairs have period ratios from one to a few percent larger than those of the nearby resonance. Few planet pairs have period ratios slightly smaller than those of first-order resonances.
3. Almost all candidate systems survive long-term dynamical integrations that assume circular, planar orbits and the mass–radius relationship given in eqns [2]–[4], derived from planets within our solar system.
4. Attempts to generate a simulated ensemble of planetary systems to match the observed *Kepler* planets do not strongly prefer fits by a single homogeneous population. In particular, there is some evidence for a population or subpopulation of systems that either contains only one detectable planet per star or multiple planets with high relative orbital inclinations that produces the observed excess of singly transiting systems. A single population, whose characteristics are described in the succeeding text, can account for the vast majority of multiple-transiting systems and roughly half of the single planets observed. A third, rarer, group of planar densely packed multiplanet systems also appears to be present. Note that these populations of planetary systems need not be cleanly separated; that is, there may also be significant numbers of intermediate systems.
5. The abundance and distribution of multiply transiting systems imply that the mean number of planets in the $1.5R_\oplus < R_p < 6R_\oplus$ and $3 < P < 125$-day range per star for those stars with at least two such planets of this radius is $\sim$3. According to *Kepler* observations, only $\sim$5% of stars have planetary systems within these size–period limits.
6. The inclination dispersion of most candidate systems with two or more transiting planets appears to have a median of $\sim 2^\circ$ (e.g., Fabrycky et al., 2014), suggesting relatively low mutual inclinations similar to the solar system.
7. Many *Kepler* targets with 1 or 2 identified planet candidates must be multiplanet systems where additional planets are present that are not transiting and/or too small to be detected.

10.21.4.2 The Radii, Densities, and Compositional Structures of Extrasolar Planets

Hot Jupiters, which have $P \lesssim 7$ days and $M_p \gtrsim 100M_\oplus$, represent extrasolar planets at their most alien, but they are nevertheless by far the best studied. The short orbital periods and large masses of these worlds allow for precise and full orbital characterization for cases in which transits occur (transit probabilities are given by $\mathcal{P}_{tr} = 0.0045(1\ \mathrm{AU}/a)(R_\star + R_p/R_\odot)[(1 + e\cos(\pi/2 - \omega))/1 - e^2]$ where ω is the longitude of periastron of the star such that $\omega = 90^\circ$ corresponds to the prospective transit midpoint and e is the orbital eccentricity. In contrast, For a distant observer sited at a random viewing angle, $\mathcal{P}_\oplus = 0.5\%$. $\mathcal{P} \sim 10\%$ for typical hot Jupiters and their high surface temperatures generate infrared planetary fluxes that are readily detectable. Scores of short-period giant planets now have accurate physical measurements, but the spectra and even the radii of these planets have defied straightforward explanation. The origins, furthermore, of the majority of the physically characterizable extrasolar planets are not yet fully clear. It is generally thought that conditions at $a \lesssim 0.1-1$ AU in protostellar disks are not favorable to the successful completion of the core accretion process (Bodenheimer et al., 2000). It is therefore believed that planetary migration, either via quiescent disk processes (Lin et al., 1996; Lubow and Ida, 2011), via planet–planet scattering (Jurić and Tremaine, 2008), or via Lidov–Kozai cycling with tidal friction (Eggleton and Kiseleva-Eggleton, 2001; Fabrycky and Tremaine, 2007), or some combination thereof, plays an important role in delivering the planets to their current locations.

The characterization of extrasolar planets with $M_p < 30M_\oplus$ is difficult, even when the orbital periods are short. Low-mass planets have small transit depths, small RV half-amplitudes, and generally small transit-timing variations, which make it hard to accurately determine their densities. Nevertheless, dedicated follow-up on small-radius transiting planets identified by the *Kepler* mission has begun to yield results (Jontof-Hutter et al., 2014; Marcy et al. 2014), and **Figure 5** shows that the broad outlines of the planetary distribution for $M_\oplus < M_p < 30M_\oplus$ are being delineated. While this diagram is

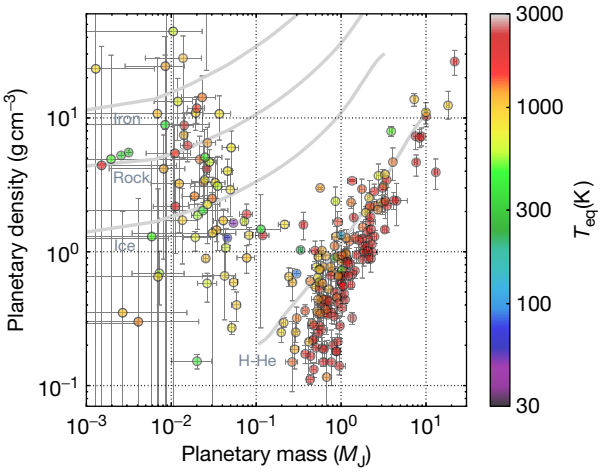

Figure 5 Densities and masses for planets that have individually measured values for R_p and M_p. Theoretical mass–radius relations for planets of various pure compositions are shown for comparison. Note that many of the measurements for low-mass planets were derived from transit-timing variations and these data points tend to have large uncertainties. The six most massive solar system planets (Venus, Earth, Uranus, Neptune, Saturn, and Jupiter) are included on the diagram and can be distinguished on account of their low equilibrium temperatures.

generally consistent with the $\rho(R_p)$ values exhibited by the solar system planets, it is clear that the ungiant regime spanning ($M_\oplus < M_p < 30M_\oplus$) encompasses a very wide range of planetary densities (and by extension, planetary compositions). Frustratingly, there is substantial compositional degeneracy if planetary mass and radius are the only quantities that are measured. Often, a substantial range of admixtures of metallic, rocky, icy, and enveloping gaseous components can jointly contribute to produce a planet of given mass and radius (Adams et al., 2008). The lack of significant concrete physical data for low-mass planets means that guidance must be drawn from theoretical work. The internal structures of planets more massive than Earth are reviewed in Baraffe et al. (2014) and the references therein. The expected properties of 'ocean' planets with large water fractions have been discussed by a number of authors (see, e.g., Sotin et al., 2007, 2011).

Figure 5 suggests that the overall distribution of planetary densities reaches a broad minimum, $\rho_{min} \sim 0.2$ to 1.0 g cm^{-3}, at roughly $M_p \sim 0.1 M_J$. Above this mass, planetary compositions are dominated by hydrogen and helium. Over 130 well-characterized examples of transiting H–He-dominated giant planets (with $M_p/M_\oplus \gtrsim 100$) are now known. It is clear that within this regime, variations in mass and stellar insolation are not the only factors responsible for the observed range in planetary sizes, and *radius anomalies* – observed planetary sizes that are substantially different from those predicted by structural models – have been evident since the discovery of the first transiting extrasolar planets. Early structural evolutionary models for giant planets computed by, for example, Bodenheimer et al. (2001) and Guillot and Showman (2002) suggested that a H–He-dominated planet with HD 209458b's mass, insolation, and age should have a radius of approximately $R_p \approx 1.1 R_J$, a figure that is startlingly at odds with the observed value, $R_p = 1.38 \pm 0.02 R_J$ (Southworth, 2010).

During the last decade, the accumulation of many mass–radius measurements for giant planets has demonstrated that radius anomalies are by no means anomalous (see, e.g., Burrows and Orton (2011) or Baraffe et al. (2010) for overviews). The substantial variation in observed radii for the giant planet population is indicated by Figure 6, which charts the measured radii and uncertainties for the transiting giant planets with accurately measured masses against an insolation-based orbit-averaged planetary equilibrium temperature given by

$$T_{eq} = \left(\frac{R_\star}{2a}\right)^{1/2} \frac{T_\star}{(1-e^2)^{1/8}} \qquad [5]$$

which implicitly assumes that the planet has an albedo of zero and reradiates energy uniformly over its entire surface and depends on the average flux received by the planet over its orbit (incorporating the effect of albedo results in multiplying the right-hand side by $(1-A)^{1/4}$). In eqn [5], $T_\star$ is the stellar effective temperature, e is the planetary orbital eccentricity, $R_\star$ is the host star's radius, and a is the planetary semimajor axis. The actual temperatures in most of the exoplanetary atmospheres are unmeasured and, depending on the atmospheric properties, chemistry, and dynamics, may be higher or lower than T_{eq}.

At a given planetary mass, it is expected that the radius of a mature gas giant planet should primarily be determined by the amount of radiative energy that it receives from its star. This

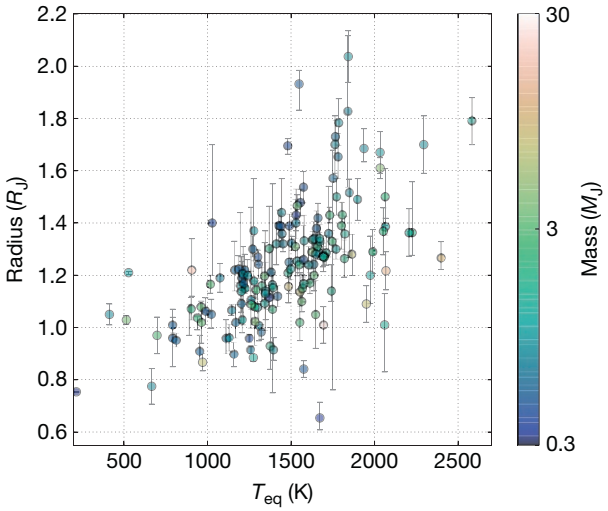

Figure 6 Planetary radii, R_p/R_J, versus insolation-derived planetary equilibrium temperatures, T_{eq} (see eqn [5]), for 130 planets with $M_p \sin i / M_\oplus > 100$ that have both transit and radial velocity characterizations. The planets are color-coded by mass, suggesting that planets substantially more massive than Jupiter are less likely to exhibit significantly inflated radii.

expectation is supported by the clear trend in Figure 6, which indicates that R_p is positively correlated with planetary T_{eq}. The degree of quantitative agreement can be obtained by computing model radii, R_m, for H–He composition planets as a function of M_p and T_{eq} and comparing with those of the observed planets. Figure 7 shows the result of such a comparison to a set of baseline core-free models computed by Bodenheimer et al. (2003) using a Henyey-type planetary structure and evolution code. We define the radius anomaly, $\mathcal{R}$ to be the difference (in Jupiter radii) between the observed planetary radius and the radius predicted by the Bodenheimer et al. (2003) baseline model.

Figure 7 indicates that the structural models explain some, but not all, of the observed variation in planetary radii. For $T_{eq} \gtrsim 1000$ K, planets are usually larger (and sometimes substantially larger) than predicted by the models. At lower temperatures, radii tend to be smaller than what one would expect for a giant planet of solar composition. Several authors, for example, Enoch et al. (2011), have noted the trend that is evident in Figure 7, and a power law fit to the current data suggests an $\mathcal{R} \propto T_{eq}^{1.4 \pm 0.6}$ dependence.

Giant planets with negative $\mathcal{R}$ probably contain a substantial fraction of heavy elements. The majority of observed planets with $T_{eq} < 1000$ K have negative radius anomalies; for this population, $\overline{\mathcal{R}} = -0.12$, which suggests that the average short-period giant planet has a $M_{core} \sim 30 M_\oplus$ core mass. Planets orbiting metal-rich stars are statistically associated with larger core masses (Miller and Fortney, 2011), and there is likely an inverse relation between planetary mass, M_p, and the degree of a planet's enrichment in heavy elements, $Z_p/Z_\star$ (Laughlin et al., 2011).

In order to inflate an H–He-dominated planet to large $\mathcal{R}$, models must appeal to a cryptic source of heating at adiabatic depth, and a wide range of heating mechanisms have been proposed. Those that have received significant attention include dissipation stemming from (1) tidal orbital circularization

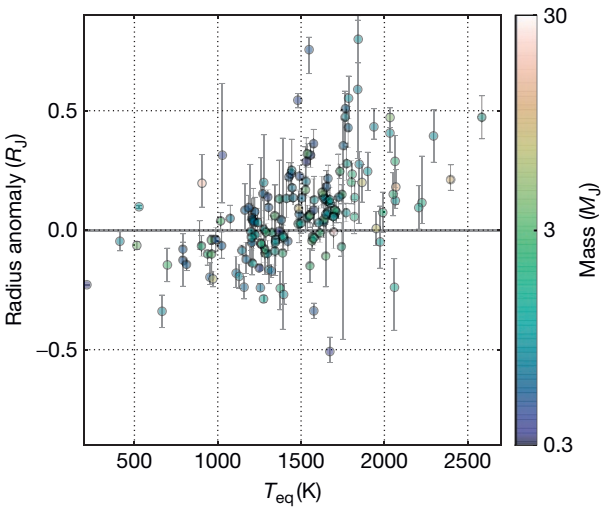

Figure 7 'Radius anomalies,' $\mathcal{R} \equiv R_{obs} - R_{pred}$, versus insolation-based planetary equilibrium temperature, T_{eq}. Planetary models that account for insolation *typically predict radii that are too small* when $T_{eq} > 1200$K.

(Bodenheimer et al., 2001), (2) obliquity tides (Winn et al., 2005) (but see the cautions raised by Levrard et al. (2007) and see Fabrycky et al. (2007) for full-blown arguments against obliquity tides), (3) 'kinetic heating' in which wind energy is converted into heat (Guillot and Showman, 2002), (4) dissipation induced by thermal tides (Arras and Socrates, 2010), and (5) ohmic dissipation (Batygin and Stevenson, 2010).

A clue is provided by the $\mathcal{R} \propto T_{eq}^{1.4}$ dependence. It is difficult to understand this correlation if the radius anomalies stem primarily from tidal heating, for which one would expect the major dependence to be with eccentricity, $\mathcal{R} = \mathcal{R}(e)$. Individual planets, of course, may be significantly affected by dissipation, and there is a wide observed dispersion in planetary size at all T_{eq}.

Arras and Socrates (2010) revived the thermal tidal torque mechanism that was introduced by Gold and Soter (1969) to account for Venus' low-frequency retrograde spin. In Arras and Socrates's (2010) picture, uneven global heating of a short-period planet produces a comparatively cold, high-density bulge that trails the planet–star line. Gravitational torque acting on the bulge spins the planet up into a state of asynchronous rotation, enabling steady-state constant-lag tidal energy dissipation to occur in the planet. Arras and Socrates (2010) suggested that this dissipation may be sufficient to inflate hot Jupiters to their observed radii. Other workers, however, for example, Gu and Ogilvie (2009), argue that rapid isostatic readjustment of the planet will offset the thermal bulges for forcing frequencies (e.g., the planetary mean motion, $n = 2\pi/P$) that are lower than the planetary dynamical frequency (which is of order $\sqrt{\rho/G}$).

The kinetic heating mechanism, as described by Guillot and Showman (2002), posits that a constant fraction, $\eta \sim 0.01$, of the total flux received by a planet is converted into kinetic energy by atmospheric gradients and that this energy is dissipated at adiabatic depth within the planet. While the flow patterns on the surfaces of strongly irradiated extrasolar planets are still a matter of debate (see the succeeding text), an overall $\dot{E} \propto T_{eq}^4$ scaling is implied by the kinetic heating hypothesis, leading to $\mathcal{R} \propto T^{2/3}$, which is somewhat weaker than the observed $\mathcal{R} \propto T^{1.4}$ dependence. As was the case with the evaluation of the viability of tidal heating, this argument does not imply that kinetic heating is absent, but rather, the implication is that kinetic heating is unlikely to be the primary mechanism that is generating the radius anomalies.

Batygin and Stevenson (2010) presented a case that resistive heating (ohmic dissipation) can inflate hot Jupiters. In their model, significant atmospheric electrical conductivity at $T_{eq} \gtrsim 1200$K is enabled by valence electron ionization of alkali metals. The presence of Na in the atmosphere of HD 209458b has been directly observed via transit spectroscopy (Charbonneau et al., 2002). The Batygin–Stevenson model assumes that the atmospheric layers of the swollen planet have rotation-induced zonal jets, which are seen on all four solar system giants and which are a generic feature in two- and three-dimensional hydrodynamic simulations of exoplanetary surface flows (Showman and Polvani, 2011). Conductive atmospheric zonal flows introduce a meridional surface current that, in the Batygin–Stevenson model, flows from the planetary poles to the equator and then closes the circuit by returning poleward through the deep convective interior of the planet. Resistive heating within the planet

$$\dot{E} = \iiint \frac{J^2}{\sigma_r(r)} \mathrm{d}V \qquad [6]$$

where $\sigma_r(r)$ is the conductivity in the near-surface (but still adiabatic) layers, provides an internal energy source. Batygin et al. (2011) found that this heating is sufficient, for reasonable planetary atmospheric and **B**-field values, to provide $\mathcal{R}$ values of order those that are observed.

If one further assumes that the planetary Elsasser number, $\Lambda = \sigma_i B^2 / 2\rho\Omega$, is roughly constant across the aggregate of transiting planets, the Batygin–Stevenson theory implies an $\mathcal{R} \propto T_{eq}^{2.7}$ dependence. This power law index $\alpha = 2.7$ is steeper than the observed value of $\alpha \sim 1.4$. A more sophisticated treatment, however, must account for the back reaction onto the wind velocity, **v**, generated by the Lorentz force:

$$\rho \frac{\mathrm{dv}}{\mathrm{d}t} = \frac{1}{c} \sigma_r (\mathbf{v} \times \mathbf{B}) \times \mathbf{B} \qquad [7]$$

where **B** is the local magnetic field strength and σ_r is the conductivity of the gas parcel. Three-dimensional simulations by Rauscher and Menou (2013) suggest that the Lorentz force provides a drag term to the velocity field, which in turn reduces the current and decreases the dissipation rate, driving the power law index to lower values. In summary, it appears likely that ohmic dissipation may provide the bulk of the explanation for the large radius anomalies that characterize many short-period hot Jupiter-type planets.

The realm of the gas giants has a lower-mass bound of about $50 M_\oplus$. **Figure 5** (which charts masses versus densities) suggests that for $M_p < 50 M_\oplus$, the overall fraction of refractory material increases steadily toward lower masses. This observed trend is in part due to selection effects – the lowest-mass planets for which both R and M can be measured have short periods and therefore very high surface temperatures. As an example, Kepler-78 b (Howard et al., 2013; Pepe et al., 2013) has $M_p \sim 1.7 M_\oplus$, $R_p \sim 1.1 R_\oplus$, and $\rho_p \sim 5.5\,\mathrm{g\,cm^{-3}}$ and must therefore be composed largely of metals and silicates, but its orbital period is only $P = 0.35$ days, and it is so close to its star that it

would have lost any low-density component to its original mass. Indeed, the lower T_{eq}, low $-M_p$ planets shown in Figure 5 whose masses have been determined through analysis of transit-timing variations (and which are thus less sensitive to a bias toward very short periods) have systematically lower densities than those that have had their masses determined via Doppler velocity measurement (Jontof-Hutter et al., 2013).

Bulk densities give an important clue to the overall planetary structures, but, unfortunately, there are a wide range of compositional structures involving admixtures of metals, rocks, ices, and gases that can reproduce a given planetary mass and radius. See, for example, Fortney et al. (2007) for a catalog of planetary structural models spanning a broad range of compositional assumptions.

The tidal Love number, k_2, provides an effective parameterization of the degree of central condensation exhibited by a particular density structure, $\rho(r)$, with lower values for k_2 mapping to higher degrees of central condensation. Specifically, if $\rho_m(r)$ is the mean density of a planet interior to radius r and R_p is the planet's radius, a quantity $\eta_2(R_p)$ can be obtained by integrating the ordinary differential equation

$$r\frac{d\eta_2}{dr}+\eta_2^2-\eta_2-6+\frac{6\rho(r)}{\rho_m(r)}(\eta_2+1)=0 \qquad [8]$$

radially outward from $\eta_2(0)=0$. The Love number k_2 is then calculated as (Sterne, 1939)

$$k_2=\frac{3-\eta_2(R_p)}{2+\eta_2(R_p)} \qquad [9]$$

If a short-period planet in a coplanar, hierarchical ($a_c \gg a_b$) two-planet system has tidally evolved to an *eccentricity fixed point* (see, e.g., Mardling, 2007; Wu and Goldreich, 2002), then the outcome of this dissipative, deterministic process is that the apsidal lines of the two planets are forced to precess at the same rate. To a good approximation, the secular gravitational perturbation from the inner planet, b, fully dictates the precession of the outer planet, c,

$$\dot{\overline{\omega}}_{c\ \mathrm{secular}}=\frac{3}{4}n_c\left(\frac{M_b}{M_*}\right)\left(\frac{a_b}{a_c}\right)^2\frac{1}{\left(1-e_c^2\right)^2}\left[1-\frac{5}{4}\left(\frac{a_b}{a_c}\right)\left(\frac{e_b}{e_c}\right)\frac{1+4e_c^2}{1-e_c^2}\cos\left(\overline{\omega}_b-\overline{\omega}_c\right)\right] \qquad [10]$$

and all of the quantities in the aforementioned expression are potentially measurable through a combination of photometric transit and Doppler-based observations.

The precession rate of the inner planet, however, is dictated by a number of contributions (Batygin et al., 2009):

$$\dot{\overline{\omega}}_{b\,\mathrm{total}}=\dot{\overline{\omega}}_{b\,\mathrm{secular}}+\dot{\overline{\omega}}_{b\,\mathrm{tidal}}+\dot{\overline{\omega}}_{b\,\mathrm{GR}}+\dot{\overline{\omega}}_{b\,\mathrm{rotational}}=\dot{\overline{\omega}}_{c\,\mathrm{secular}} \qquad [11]$$

For an inner planet whose orbital figure, mass, and radius have all been determined via high-quality photometric transit and Doppler-based observations, k_2 constitutes the only unknown in $\dot{\overline{\omega}}_{b\,\mathrm{total}}$. As a consequence, for systems with favorable orbital configurations, one potentially has access to a mechanism that directly probes the interior structure and that can potentially discriminate between 'super-Earth' and 'sub-Neptune' configurations. To date, this method has only been applied to the HAT-P-13 b–c system (Batygin et al., 2009), where the inner planet mass is $M_b=0.85\pm0.038M_J$, well above the $M_p<50M_\oplus$ scale of interest here. Kramm et al. (2012) found $0.265<k_2<0.379$ for HAT-P-13b, which requires that any central core in the planet has mass $M_{core}<27M_\oplus$. The TESS mission (Ricker et al., 2010), which is scheduled for launch in 2017, and the PLATO mission (Barban et al., 2013), selected in February 2014 and planned for launch in 2024, may detect nearby transiting multiple-planet systems for which the orbital properties can be determined with enough precision to enable accurate measurement of k_2. Finally, implicit evidence for the widespread existence of dense planetary cores is provided by large rocky planets such as CoRoT-7b (Léger et al., 2009) and Kepler-10b (Batalha et al., 2011). For a detailed overview of the types of systems for which interior structures can be probed, see Becker and Batygin (2013).

10.21.4.3 Observations of Exoplanetary Atmospheres and their Interpretation

The foregoing discussion makes it clear that the radii and interior structures of the hot Jupiters continue to provide significant challenges to a comprehensive theoretical understanding. An analogous situation also holds for the atmospheric characterization of these planets.

Nevertheless, given the extraordinary difficulties inherent in separating the signal of a faint planet from a bright star, there have been a number of real successes, the majority of which have come from space-based measurements. The Spitzer Space Telescope (Werner et al., 2004) was designed prior to the detection of transiting extrasolar planets, and exoplanetary observations were not part of the mission's scientific requirements. Serendipitously, however, Spitzer has played a key role in probing exoplanetary atmospheres. HST, MOST, CoRoT, and *Kepler* have all also made substantial contributions, as have ground-based telescopes including Keck and the VLT. The literature on the characterization of the atmospheres of short-period planets is now extensive, and space considerations preclude an exhaustive summary here. See Seager and Deming (2010), Perryman (2011), Line et al. (2012), Tinetti et al. (2013), and Madhusudhan et al. (2014) for successively recent overviews. It is important to stress that while the accumulated catalog of measurements is by now impressive, the signal-to-noise ratio of individual measurements is often low; systematic errors may, in general, be significant; and the number of unknowns, including composition, meteorology, and chemistry that characterize an atmosphere, is daunting.

Atmospheric characterization has mostly been carried out for planets that transit. Extant observations divide into (1) occultation studies, (2) transit spectroscopy of varying resolution, and (3) elaborations on full-phase spectrophotometry.

A wavelength-dependent decrease in flux can be measured during *occultation* (also known as secondary eclipse), when a planet passes behind a star as seen from Earth. (Some planets, such as HD 17156 b, with its highly eccentric $e=0.68$, $\omega=112^\circ$ orbit, undergo transit, but *not* occultation.) At visible wavelengths, the occulted light from the planet consists of reflected and scattered starlight and, for hotter atmospheres, emission from the planet itself. The primary conclusion is that short-period, hot Jupiter planets tend to be *dark*. For example, Rowe et al. (2008) used the MOST telescope to find that the geometric

albedo A_g for HD 209458 is $A_g = 0.038 \pm 0.045$ in the $\lambda = 400 - 700$ nm optical band pass. More recently, Evans et al. (2013) used the STIS instrument on HST to obtain an optical and near-UV spectrum (essentially a reflection spectrum) for HD 189733b. They measured a geometric albedo $A_g = 0.40 \pm 0.12$ in the $\lambda = 290$–450 nm region and $A_g < 0.12$ for $\lambda = 290 - 450$ nm (consistent with the Rowe et al. result for HD 208458b). The planet's apparent upturn in reflectivity at short wavelengths is suggestive of a rich blue visual appearance and is interpreted to be formed by starlight reflecting from clouds coupled with high-altitude sodium absorption of red light within the overlying clear air.

At near-infrared and mid-infrared wavelengths, in the Rayleigh–Jeans tail of the star's emission spectrum, a typical hot Jupiter has a flux ratio $F_p/F_\star \gtrsim 10^{-3}$, and Spitzer has proved to be very well suited to detecting exoplanets in occultation. During the cryogenic phase of its mission, Spitzer's IRAC, IRS, and MIPS instruments were used to observe 15 exoplanets in occultation, starting with MIPS detection of HD 209458 b at 24 μm (Deming et al., 2005) and the IRAC detection of TrES-1 at 4.5 and 8 μm (Charbonneau et al., 2005). Following depletion of its liquid helium, Spitzer has continued to observe occultations with IRAC at 3.6 and 4.5 μm, and well over 30 planets now have eclipse depths measured in both of these bands.

Photometric occultation measurements at a range of different band passes amounts to a low-resolution dayside emission spectrum of an extrasolar planet, and a handful of planets have been measured in five or more bands, including J (1.2 μm), H (1.6 μm), and K (2.2 μm) from the ground, for example, Croll et al. (2011b), in addition to the Spitzer channels. For the most favorably detected transiting planets, such as HD 189733b, Spitzer's IRS instrument was used to obtain mid-infrared dayside emission spectra that were resolved into several dozen spectral resolution elements in the 5–14 μm range, with each spectral element having S/N ~ 10 (e.g., Grillmair et al., 2008). Also, for HD 189733b, HST's NICMOS has been used to obtain near-IR spectra presenting 18 spectral resolution elements in the 1.5–2.5 μm range, with S/N in each element also of order 10 (Swain et al., 2009a). These resolved spectra from IRS and NICMOS display significant variations that are strongly suggestive of molecular lines (including H_2O, NH_4, and CO), yet fitted multiparameter models are imperfect, suggesting a substantially incomplete picture of the radiative structure, chemistry, and dynamics of the atmosphere.

Naturally, there has been a vigorous effort to interpret the panoply of occultation results with theoretical models. For example, Fortney et al. (2008) suggested that strongly irradiated atmospheres (corresponding roughly to the half of the observed planets that receive the largest orbit-averaged fluxes) have thermal inversions caused by hardy molecules such as TiO or VO absorbing and reradiating starlight at low pressures high in the atmosphere. Knutson et al. (2010) presented evidence for an empirical correlation showing that chromospheric activity inhibits the formation of such thermal inversions, perhaps by destroying the inversion-producing molecules through an elevated flux of high-energy photons. More recently, Madhusudhan (2012) (see also Madhusudhan and Seager, 2010) had suggested that C/O ratios form an additional dimension by which planets can exhibit planet-to-planet variation in occultation depths.

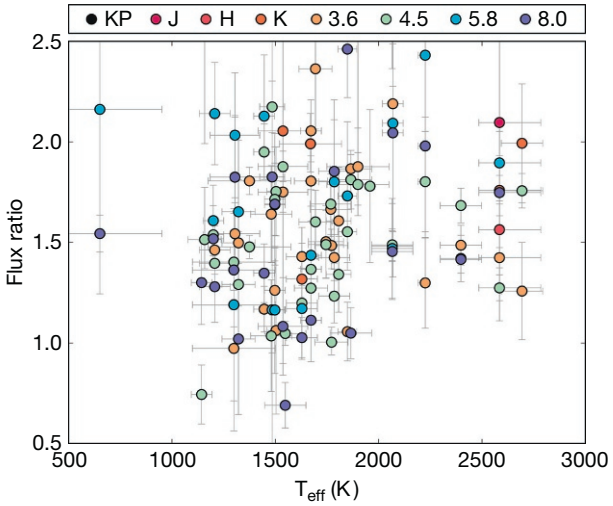

Figure 8 The current collection of broadband occultation measurements. Planets are ordered on the *x*-axis by the equilibrium temperatures, $T_{eq} = (R_\star^{1/2} T_\star)/((2a)^{1/2}(1-e^2)^{1/8})$, that they would have if they were $A_g = 0$ blackbodies reradiating from the full planetary surface area. Measured occultation depths are expressed as ratios of the observed eclipse depth in the band of interest relative to the expected depth in that band if the planet were a uniformly reradiating $A_g = 0$ blackbody. Colors are K (2.2 μm), purple; 3.6 μm, blue; 4.5 μm, green; 5.8 μm, orange; and 8 μm, red.

Figure 8 consolidates a full range of broadband occultation results onto a single plot. The planets are ordered according to specific orbit-averaged received flux, as measured by T_{eq}. Occultation depths in the various infrared bands are transformed to flux ratios, F_λ relative to the expectation for a zero albedo 4π blackbody reradiator. It is clear from the diagram that there is *little or no* systematic degree of similarity among the planets. The data are essentially consistent with random flux ratios relative to $<F_\lambda> = 1.5$, with standard deviation $\sigma_\lambda = 0.5$. This distribution of measurements suggests a complex mix of contributing factors (stemming either from conditions on the planets or from errors introduced in the measurement pipelines), with the attendant applicability of the central limit theorem. The $<F_\lambda> = 1.5$ mean value, however, implies that on the whole, exoplanets are *partially* redistributing their received flux via reradiation from the night side (for further discussion, see Langton et al. (2014)). Certainly, Figure 8 is in concordance with the view expressed by Hansen et al. (2014) that, to the precision of the measurements, the observed emission spectra of exoplanets are consistent with blackbodies.

During transit, starlight flows through the atmosphere of the planet all along the day–night terminator. A stellar spectrum obtained during transit thus contains an admixture of the planet's transmission spectrum, which holds out the possibility of obtaining a detailed probe of the atmospheric column. An early application of transit spectroscopy is found in Charbonneau et al. (2002), who used HST to detect sodium in the atmosphere of HD 209458b by noting that the transit depth associated with a band pass covering the sodium resonance doublet at 589.3 nm was deeper than in adjacent bands. HST has also been used to detect strong evidence of water vapor, methane, and carbon monoxide (e.g., Swain et al.,

2009a,b) in the 1.5–2.5 μm transit spectra of HD 209458b and HD 189733b.

For planets transiting $V > 8$ primaries, a variety of broadband transmission spectra have been obtained for a variety of planets. Interpretation of these spectra is challenging, and, in parallel with the situation for occultations, firm conclusions are hampered by intrinsically low spectral resolution, low signal-to-noise ratio, and the need to adopt a whole range of model assumptions. For more detail, the reader is advised to consult the review by Tinetti et al. (2013). JWST is expected to have significant utility for transit spectroscopy and will be able to usefully probe the atmospheres of planets transiting M-dwarf stars (Deming et al., 2009).

There is an exciting possibility of directly detecting planetary surface winds by observing the Doppler shift of spectral absorption lines that are created by the starlight shining through moving parcels of air at the planet's day–night terminator. Snellen et al. (2010) used the VLT to obtain a high-resolution transit spectroscopy of HD 209458b with $R \sim 100{,}000$ at wavelengths near $\lambda = 2$ μm. By cross correlating on dozens of expected CO lines, these authors were able to produce a time-dependent measurement of the average velocity of the atmosphere at the planetary terminator during the course of the transit. With the orbital motion subtracted out, Snellen et al. (2010) measured a net blueshift of 2 ± 1 km s^{-1} and suggested that this represents a global flow from the dayside hemisphere to the nightside hemisphere at atmospheric levels in the range 0.01 bar $< P <$ 0.1 bar. Showman et al. (2013) found that generic flow patterns with this large net blueshift can be created within current extrasolar planet atmospheric circulation simulations (see, e.g., Showman et al., 2009), by varying the amount of frictional drag in the atmosphere.

For planets in the 'ungiant' regime, atmospheric measurements obtained via transit spectroscopy can potentially help to sort out the compositional degeneracies that prevent strong conclusions being drawn from the measurements of bulk planetary density (e.g., those shown in **Figure 5**). A planet with a refractory core covered by a deep solar-composition atmosphere will have a wavelength-dependent transit depth that can be potentially distinguished, using current observational sensitivity, from the signature produced by a planet with an atmosphere (and an overall structure) dominated by high-molecular-weight species such as water. For example, if the atmosphere of a planet such as Gliese 1214b, with $M_p - 6.6 M_\oplus$, $\rho_p = 0.35 \rho_\oplus$ and $T_p \sim 500$ K (Charbonneau et al., 2009), is primarily composed of H_2, then the resulting atmospheric scale height, $H = k_B T/\mu g$, will be of order $H \sim 200$ km. Given that Gliese 1214b has an M4.5 V primary, this implies that $H/R_\star \sim 0.0014$. For an H to $R_\star$ ratio of this magnitude, ground-based measurements are presently capable of distinguishing between a clear H_2-dominated solar-composition atmosphere, which will show measurable differences in planetary radius as a function of wavelength, $\Delta(R_p/R_\star) \sim 0.005$ (de Mooij et al., 2012), and a high-molecular-weight atmosphere with a small-scale height and a transmission spectrum that presents much smaller variations.

Measurements of $\Delta(R_p/R_\star)$ taken at different band passes during transits by Gliese 1214b have indicated that the transmission spectrum is fairly flat between $\lambda = 0.6$ μm and $\lambda = 5$ μm (Bean et al., 2010, 2011; Berta et al., 2012; Croll et al., 2011a; de Mooij et al., 2012; Désert et al., 2011). As of early 2014, a number of these measurements are in conflict, however, and while a clear solar-composition atmosphere is inconsistent with the data, Gliese 1214b could be presenting either a hazy low-metallicity H–He-dominated atmosphere or a low-scale height atmosphere composed of species (such as H_2O) of high molecular weight. Very recent work by Kreidberg et al. (2013) reports intensive HST observations of Gliese 1214b (15 transits over 60 telescope orbits) that are sensitive enough to reveal absorption features from constituents such as H_2O, CO_2, and NH_4 in a high-molecular-weight atmosphere. A flat transmission spectrum between 1.1 and 1.7 μm was observed, suggesting that Gliese 1214b's atmosphere *must* contain clouds or high-altitude hazes. In addition, other planets with $P < 100$ days and $M_p < 30 M_\oplus$ are nearly certain to be discovered in transit across bright low-mass primaries. For example, Bonfils et al. (2012) had announced the detection of Gliese 3470b, which has $M_p = 14 M_\oplus$, $R_p = 4.2 R_\oplus$, and $T_p \sim 800$ K and which orbits an $R_\star \sim 0.5 R_\odot$ M1.5 V primary. Spectrographic observations of Gliese 3470b by Crossfield et al. (2013) using the Keck telescope are consistent with a flat spectrum between 2.09 and 2.36 μm, which rule out a cloud-free atmosphere in chemical equilibrium and which are again suggestive of high-altitude haze or clouds. The prospects for improved characterization of planets in the 'ungiant' category are especially bright, given that NASA's forthcoming TESS mission will locate a substantial fraction of the transiting short-period planets with radii $R_p \gtrsim 2.0 R_\oplus$ orbiting stars with $V < 12$.

Transit and occultation measurements act as effective bookends to *full-phase* photometric measurements, in which planetary emission is monitored through the course of an orbit. The most frequently cited example of this type of observation was published by Knutson et al. (2007), who presented a high-quality 8 μm light curve for HD 189733b that spans the 29 h interval from just before the planet's primary transit to just after its secondary eclipse. Adopting the assumption that the planet is in a spin-synchronous rotation with its orbit, Knutson et al. (2007) derived a global temperature distribution for the planetary photosphere as a function of longitude and found that the hottest region of the planet is shifted east of the substellar point (see Cowan and Agol (2008) for the details of the mapping technique). The longitudinal shift of the planet's temperature maximum is attributed to superrotating $v \sim 1$ km s^{-1} equatorial winds, which are a robust feature that emerge from a wide variety of hydrodynamic models of the surface flows on tidally locked close-in extrasolar planets (see, e.g., Showman and Polvani, 2011; Showman et al., 2009). In the past several years, a number of additional infrared phase curves in assorted band passes have been produced for a variety of strongly irradiated planets. Examples include Knutson et al. (2009b)'s follow-on partial-orbit MIPS 24 μm and Knutson et al. (2012)'s full-orbit 3.6 and 3.5 μm IRAC phase curves for HD 189733 (which corroborate the basic picture inferred by Knutson et al., 2007) and a full-orbit optical phase curve from the Kepler satellite for HAT-P-7b (Borucki et al., 2009) that shows evidence of both dayside thermal emission and reflected light. Full- or partial-orbit near-IR phase curves have also been published for HD 149026b (Knutson et al., 2009a), WASP-18b (Maxted et al., 2013), and WASP-12b (Cowan et al., 2012), all of which are hot, short-period planets on nearly

circular orbits. The phase curves for these systems suggest that the selection of planets surveyed have a large range of efficiency in their ability to equilibrate day–night temperature distributions.

Figure 9 shows phase curves in several band passes for the eccentric planet HAT-P-2b, as presented by Lewis et al. (2013). The location of the substellar point (high noon) must move on planets with eccentric orbits (if the rotation period equals the orbital period, rotation is referred to as synchronous, e.g., the Moon) and hence, their atmospheres are virtually certain to display strong time-dependent meteorology. Phase-curve observations of such planets can potentially determine atmospheric radiative time constants, tidal luminosities, and pseudosynchronous rotation rates, as well as the global manifestation of time-dependent storms (e.g., Langton et al., 2014).

10.21.5 Planet Formation

The vast majority of work on planetary formation has been done to explain the properties of our solar system, for which we have the most detailed data. We begin with a synopsis of these models and then discuss some recent models of the formation and migration of exoplanets that travel on short-period orbits.

10.21.5.1 An Overview Informed by the Solar System

Models of the solar system formation are based upon data from our own solar system and observations of the circumstellar environments of young stars. The nearly planar and almost circular orbits of the planets in our solar system argue strongly for planetary formation within flattened circumstellar disks. When a molecular cloud core undergoes gravitational collapse, an occurrence triggered by loss of magnetic field and turbulent velocity support, its spin angular momentum leads to the formation of pressure-supported protostars surrounded by rotationally supported disks, for example, Terebey et al. (1984). Molecular cloud cores are subcondensations of mass, $M \gtrsim M_{\odot}$, characteristic size $r \sim 0.25$ pc, and rotation rate typically $\sim 10^{-13}$ Hz that are found within giant molecular cloud complexes in the galactic disk that typically contain 10^4 to $10^5 M_{\odot}$.

Circumstellar disks are commonly observed in association with newly formed stars (Mamajek, 2009) and are analogous to the primordial solar nebula that was initially conceived by Kant and Laplace to explain the observed properties of our

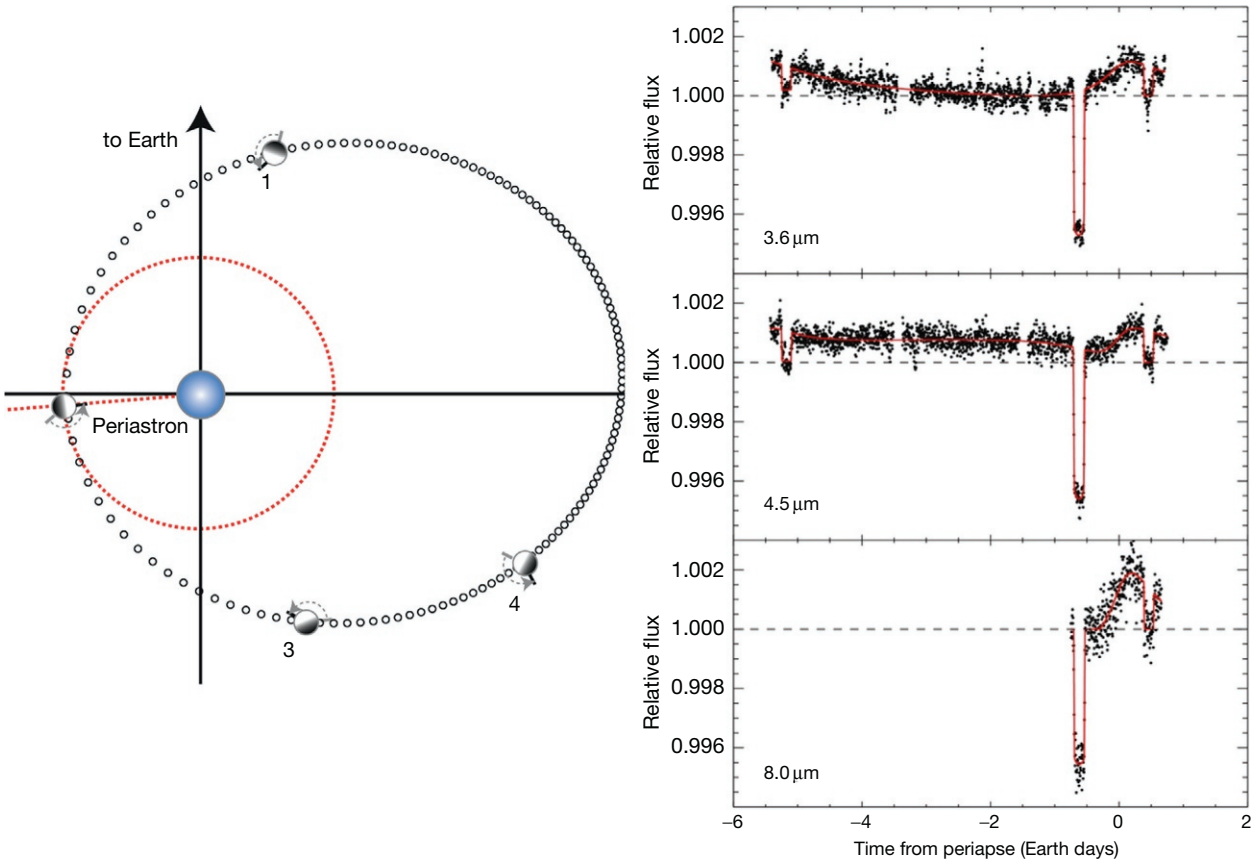

Figure 9 Photometric IR phase curves for the eccentric planet HAT-P-2b, with orbital period, $P = 5.633$d; eccentricity, $e = 0.511$; and $M_p = 9M_J$ (adapted from Lewis NK, Knutson HA, Showman AP, et al. (2013) *Astrophysical Journal* 766: 95). The left panel shows the geometry of the HAT-P-2b orbit, with periastron passage occurring 14 h after the primary transit. The panels on the right display the light curves for the 3.6 (top), 4.5 μm (middle), and 8.0 μm photometry. Optimized phase, transit, and secondary eclipse fits are overplotted as red line (see Lewis et al. (2013) for details). The dashed line represents the stellar flux level.

solar system. For a more detailed historical background, see Woolfson (1993). Planets form within such disks and play a major role in the later stages of disk evolution. Terrestrial planets grow via pairwise accretion of solid bodies. In the generally favored core accretion paradigm, giant planets begin their growth as do terrestrial planets, but they become massive enough to accumulate substantial amounts of gas before the protoplanetary disk dissipates. Under some circumstances, as described, for example, by Gammie (2001), giant planets may form directly from the protostellar disk via gravitational instability (see, e.g., Boley, 2009; Durisen et al., 2007), especially at large ($d \gtrsim 40$AU) from the parent star.

Within the solar system, bodies up to the mass of the Earth consist almost entirely of condensable (under reasonable protoplanetary disk conditions) material, and the fraction of highly volatile gas increases with mass above that of the Earth. The most massive planets contain a considerable fraction of light gases. About 90% of Jupiter's mass is H and He, and these two light elements make up $\sim$75% of Saturn. In both cases, these planets contain $\sim 30 M_{\oplus}$ in elements other than hydrogen and helium. The large amounts of H and He contained in Jupiter and Saturn imply that these planets must have formed within $\sim 10^7$ years of the collapse of the solar system's natal cloud, before the gas in the protoplanetary disk was swept away. The two largest planets in our solar system are generally referred to as *gas giants*, even though these elements are not gases at the high pressures that most of the material in Jupiter and Saturn is subjected to. Analogously, Uranus and Neptune are frequently referred to as *ice giants*, even though the astrophysical 'ices' such as H_2O, CH_4, H_2S, and NH_3 that models suggest make up the majority of their mass (Hubbard et al., 1995) are in fluid rather than solid form. Note that whereas H and He *must* make up the bulk of Jupiter and Saturn because no other elements can have such low densities at plausible temperatures, it is possible that Uranus and Neptune are primarily composed of a mixture of 'rock' and H/He, although the high observed CH_4/H_2 ratio in their atmospheres (30–40 $\times$ the solar value) makes this somewhat unlikely. This ambiguity in basic structure also holds for the majority of the ungiant exoplanets whose mass and radius have both been measured.

Lithium and heavier elements constitute $< 2\%$ of the mass of a solar-composition mixture. The *atmospheric* abundances of volatile gases heavier than helium (excluding neon, which is thought to be substantially depleted through gravitationally induced settling) are $\sim 3 \times$ solar in Jupiter (Young, 2003), a bit more enriched in Saturn, and substantially more for Uranus and Neptune. The *bulk* enhancements in heavy elements relative to the solar value are roughly 5, 15, and 300 times for Jupiter, Saturn, and Uranus/Neptune, respectively. Thus, all four giant planets accreted solid material substantially more effectively than gas from the surrounding nebula. Moreover, the total mass in heavy elements varies by only a factor of a few between the four planets, while the mass of H and He varies by about two orders of magnitude between Jupiter and Uranus/Neptune.

There is a vast observational literature that details the presence, the properties, and the evolution of disks of the solar system dimensions around pre-main-sequence stars (Williams and Cieza, 2011). The existence of disks on scales of a few tens of astronomical units is inferred from the power law spectral energy distribution in the infrared over more than two orders of magnitude in wavelength (Andrews et al., 2010; Chiang and Goldreich, 1997; Haisch et al., 2001; Megeath et al., 2004). Observations of infrared excesses in the spectra of young stars suggest that the lifetimes of protoplanetary disks span the range of 10^6–10^7 years (Alencar and Batalha, 2002; Ercolano and Koepferl, 2012; Strom et al., 1993). Much lower-mass second-generation debris disks composed of dust eroded from larger solid objects that accreted within protoplanetary disks are observed around main-sequence stars, with younger stars typically (but far from always) possessing more massive debris disks (Krist et al., 2012; Meyer et al., 2004). Many debris disks appear to have inner holes, and lower-mass stars typically retain their debris disks for more time (Wyatt, 2008).

Although to a first approximation the gas in the disk is centrifugally supported in balance with the star's gravity, negative radial pressure gradients provide a small outwardly directed force that acts to reduce the effective gravity, so the gas rotates about the star at slightly less than the Keplerian velocity. Small solid bodies (dust grains) rotate with the gas. Large solid bodies orbit at the Keplerian velocity, and medium-sized particles move at a rate intermediate between the gas velocity and the Keplerian velocity; thus medium-sized and larger bodies are subjected to a headwind from the gas (Adachi et al., 1976). This headwind removes angular momentum from the particles, causing them to spiral inward toward the star. This inward drift can be very rapid, especially for particles whose coupling time to the gas is similar to their orbital period; smaller particles drift less rapidly because the headwind they face is not as strong, whereas large particles drift less because they have a greater mass to surface area ratio. Orbital decay times for meter-sized particles at 1 AU from the Sun have been estimated to be only $\sim$100 years (Weidenschilling, 1977). The large radial velocities of bodies in this size range relative to both larger and smaller particles imply frequent collisions, so most solid bodies may pass through the critical size range quickly without substantial radial drift. However, it is also possible that a large amount of solid planetary material is lost from the disk in this manner. Solid bodies larger than $\sim$1 km in size face a headwind only slightly faster than meter-sized objects, and because of their much greater mass to surface area ratio, they suffer far less orbital decay from interactions with the gas in their path. Thus, kilometer-sized or larger planetesimals appear to be reasonably safe from loss (unless they are ground down to smaller sizes via disruptive collisions) until some of these planetesimals grow into planetary-sized bodies.

The initial composition of the protoplanetary disk is assumed to still be essentially identical to that of the protosun. Dust within a protoplanetary disk initially agglomerates via sticking/local electromagnetic forces that produce inelastic collisions. Particles gradually settle toward the disk midplane as they grow.

The conceptual bottleneck created by the short residence times of meter-sized particles in protoplanetary disks is perhaps the least well-understood phase of solid planet formation. It is not yet clear how agglomeration from cm-sized pebbles to km-sized or larger bodies that are referred to as planetesimals occurs. Collective gravitational instabilities (Goldreich and Ward, 1973; Safronov, 1969) might be important, although turbulence may prevent protoplanetary dust layers from becoming thin enough to be gravitationally unstable (Weidenschilling and Cuzzi, 1993). The interactions

between small particles and gas in a rotating disk involve complicated fluid-particle interactions, and planetesimal formation is a very active research area. Recent work suggests that the answer may lie in the joint action of aerodynamic and gravitational instabilities to agglomerate particles (see the review of Chiang and Youdin (2010)). Some models suggest that pebble-sized particles accumulated into planetesimals more than 100 km in size (Johansen et al., 2012).

The primary perturbations on the Keplerian orbits of kilometer-sized and larger bodies in protoplanetary disks are pairwise gravitational interactions and physical collisions (Safronov, 1969). These interactions lead to accretion (and in some cases erosion and fragmentation) of planetesimals. Gravitational encounters are able to stir planetesimal random velocities up to the escape speed from the largest common planetesimals in the swarm (Safronov, 1969). The most massive planets have the largest gravitationally enhanced collision cross sections and accrete almost everything with which they collide. If the random velocities of most planetesimals remain much smaller than the escape speed from the largest bodies, then these 'planetary embryos' grow extremely rapidly (Greenzweig and Lissauer, 1992). The size distribution of solid bodies becomes quite skewed, with a few large bodies growing much faster than the rest of the swarm in a process referred to as runaway accretion (Greenberg et al., 1978; Wetherill and Stewart, 1989). If embryos dominate the stirring, then $\dot{M} \propto M^{2/3}$; in this circumstance, if individual embryos control the velocity in their own zones, larger embryos take longer to double in mass than do smaller ones, although embryos of all masses continue their runaway growth relative to surrounding planetesimals; this phase of rapid accretion of planetary embryos is known as *oligarchic growth* (Kokubo and Ida, 1998). Eventually, planetary embryos accrete most of the (slowly moving) solids within their gravitational reach, and the runaway/oligarchic growth phase ends.

The self-limiting nature of runaway and oligarchic growth implies that massive planetary embryos form at regular intervals in semimajor axis. The agglomeration of these embryos into a small number of widely spaced terrestrial planets necessarily requires a stage characterized by large orbital eccentricities, significant radial mixing, and giant impacts. At the end of the rapid-growth phase, most of the original mass is contained in the large bodies, so their random velocities are no longer strongly damped by energy equipartition with the smaller planetesimals. Mutual gravitational scattering can pump up the relative velocities of the planetary embryos to values comparable to the surface escape velocity of the largest embryos, which is sufficient to ensure their mutual accumulation into planets. The large velocities imply small collision cross sections and hence long accretion times.

Once the planetary embryos have perturbed one another into crossing orbits, their subsequent orbital evolution is governed by close gravitational encounters and violent, highly inelastic collisions. Terrestrial planets continue to grow by pairwise accretion of solid bodies until the spacing of planetary orbits becomes sufficient for the configuration to be stable to gravitational interactions among the planets for the lifetime of the system (Chambers, 2001; Hansen and Murray, 2012; Laskar, 2000; Lissauer, 1995; Safronov, 1969). This process has been studied using N-body integrations of planetary embryo orbits. Many of the simulations of this type have endeavored to reproduce our solar system; they generally begin with about $2M_{\oplus}$ of material spread through the terrestrial planet zone, typically divided (not necessarily equally) among hundreds or thousands of bodies. These simulations generally display a high efficiency of converting seed embryos into terrestrial planets, and the end result is generally the formation of 2–5 terrestrial planets on a timescale of about 10^8 years. Some of these systems look startlingly similar to our inner solar system, with the caveat that the emergent planets often travel on more eccentric orbits than those of the terrestrial planets, although the simulations that begin with the largest numbers of bodies yield eccentricities more similar to those in our solar system (O'Brien et al., 2006). It is possible that the solar system is by chance near the quiescent end of the distribution of terrestrial planets, but more likely, a damping process of some type plays a role. Processes such as fragmentation and gravitational interactions with a remaining population of small debris and interactions with a remnant gas disk (Ogihara et al., 2007) have been invoked to lower the characteristic eccentricities and inclinations of the ensemble of terrestrial planets.

An important result of these N-body simulations is that planetary embryo orbits execute a random walk in semimajor axis as a consequence of successive close encounters. The resulting widespread mixing of material throughout the terrestrial planet region diminishes any chemical gradients that may have existed when planetesimals formed, although some correlations between the final heliocentric distance of a planet and the region where most of its constituents originated are preserved in the simulations. Nonetheless, these dynamical studies imply that Mercury's high iron abundance is unlikely to have arisen from chemical fractionation in the solar nebula.

The mutual accumulation of numerous planetary embryos into a small number of planets must have entailed many collisions between protoplanets of comparable size. Mercury's original silicate mantle was probably partially stripped off by one or more of such giant impacts, leaving behind an iron-rich core. Accretion simulations also lend support to the giant impact hypothesis for the origin of the Earth's Moon; during the final stage of accumulation, an Earth-sized planet is typically found to collide with several objects as large as the Moon and frequently one body as massive as Mars (Chambers, 2001).

Models for the formation of gas giant planets were reviewed by Wuchterl et al. (2000) and Helled et al. (2013). Starlike direct quasispherical collapse is not considered viable, because of both the observed brown dwarf desert mentioned in the preceding text and theoretical arguments against the formation of Jupiter-mass objects via fragmentation (Bodenheimer et al., 2000). The theory of giant planet formation that is favored by most researchers is the *core-nucleated accretion model*, in which the planet's initial growth resembles that of a terrestrial planet but eventually becomes sufficiently massive (several $M_{\oplus}$) that it is able to accumulate substantial amounts of gas from the surrounding protoplanetary disk. The only other hypothesis receiving significant attention is the *gas instability model*, in which the giant planet forms directly from the contraction of a clump that was produced via a gravitational instability in the protoplanetary disk (Durisen et al., 2007). Formation of giant planets via gas instability has never been demonstrated for realistic disk conditions. Moreover, this model has difficulty explaining the supersolar abundances of heavy

elements in Jupiter and Saturn, and it does not explain the origin of planets like Uranus and Neptune. Nonetheless, it is possible that some giant planets form via disk instability.

The core-nucleated accretion model (Mizuno, 1980; Pollack et al., 1996) has been reviewed by Lissauer and Stevenson (2007), with further details given in D'Angelo et al. (2011). The model relies on a combination of planetesimal accretion and gravitational accumulation of gas. In this theory, the core of the giant planet forms first by accretion of planetesimals, while only a small amount of gas is accreted. Core accretion rates depend upon the surface mass density of solids in the disk and physical assumptions regarding gas drag, etc. (Inaba et al., 2003; Lissauer, 1987). The escape velocity from a planetary embryo with $M > 0.1M_{\oplus}$ is larger than the sound speed in the gaseous protoplanetary disk. Such a growing planetary core first attains a quasistatic atmosphere that undergoes Kelvin–Helmholtz contraction as the energy released by the accretion of planetesimals and gas is radiated away at the photosphere.

During the runaway planetesimal accretion epoch, the protoplanet's mass increases rapidly. The internal temperature and thermal pressure increase as well, preventing substantial amounts of nebular gas from falling onto the protoplanet. When the planetesimal accretion rate decreases, gas falls onto the protoplanet more rapidly. The protoplanet accumulates gas at a gradually increasing rate until its gas mass is comparable to its heavy element mass. The key factor limiting gas accumulation during this phase of growth is the protoplanet's ability to radiate away energy and contract (Hubickyj et al., 2005; Pollack et al., 1996). The rate of gas accretion then accelerates more rapidly, and a gas runaway occurs. The gas runaway continues as long as there is gas in the vicinity of the protoplanet's orbit. The protoplanet may cut off its own supply of gas by gravitationally clearing a gap within the disk (Lin and Papaloizou, 1979). Lissauer et al. (2009) used a three-dimensional adaptive mesh refinement code (D'Angelo et al., 2002, 2003) to follow the flow of gas onto an accreting giant planet, allowing the determination of final planetary mass as a function of the time-varying properties (density, temperature, viscosity, longevity, etc.) of the surrounding disk. Such a self-regulated growth limit provides a possible explanation to the observed mass distribution of extrasolar giant planets.

Core-nucleated accretion also offers an explanation for the formation of low-density ungiant exoplanets. These bodies could be cores that grew massive enough to accrete some H_2 and He from their planetary disks but were unable to accrete enough light gases to become giants (Rogers et al., 2011).

10.21.5.2 How Did Short-Period Planets Arrive at their Observed Locations?

Quite aside from the zeroth-order questions related to their atmospheric properties and internal structures, the origins of the short-period planets are not fully explained. It is clear from **Figure 2** that the hot Jupiters represent a population distinct from the short-period ungiants, and so it is reasonable to consider their formation scenarios separately.

It is generally assumed that hot Jupiters were formed through the core accretion process, with assembly occurring at distances at least a few AU from their host stars, where more solids, especially water ice, were available. As discussed in the preceding text, in this standard core accretion scenario for giant planet formation, a protoplanetary core composed largely of ices and rock reaches a mass of $\sim 10M_{\oplus}$, at which point it begins to rapidly accrete gas from the surrounding nebular disk. Thereafter, as a result of dynamical or hydrodynamic processes, the planet is delivered into a short-period orbit. It is worth noting, however, that while disfavored, *in situ* formation for hot Jupiters has not been strictly ruled out. Detailed calculations by Bodenheimer et al. (2000), for example, suggest that hot Jupiters can form in place under certain conditions.

The 'classical' formation scenario for hot Jupiters was outlined by Lin et al. (1996), shortly after the discovery of 51 Peg b. In this picture, the planet grows to near its original mass at a distance several AU from the star. A planet with 51 Peg b's mass is large enough to maintain a well-cleared annular gap in the disk that brackets the planet's radial location. Once formed, the planet spirals inward via the process of type II migration (Lin and Papaloizou, 1986) on the parent protoplanetary disk's viscous timescale, $\tau_{\nu} = r_{\mathrm{d}}^{1/2}\nu \sim 10^6$ years. The final location is controlled either by disk truncation at an inner magnetospheric cavity or via tidal interaction with the young, rapidly spinning parent star. This basic picture has been elaborated substantially during the past two decades. For recent overviews, see Lubow and Ida (2011) and Kley and Nelson (2012).

The disk migration scenario avoids the serious problems associated with *in situ* formation, but is not itself without problems. One difficulty lies with the so-called type I migration (Ward, 1997), which is thought to affect planets that have insufficient mass to clear and maintain a gap in the protostellar disk. The timescale for type I migration $\tau_1 \sim (M_{\mathrm{p}}/M_{\star})$ $c_{\mathrm{s}}\Omega \sim (M_{\mathrm{p}}/M_{\oplus})10^5$ years is substantially shorter than the timescale that appears to be required to assemble a core large enough to initiate rapid gas accretion (Movshovitz et al., 2010). The mismatch hints at the possibility that a fundamental process is either missing or is not fully understood. A further problem arises from observed statistics of systems with massive, short-period planets. Hot Jupiters appear almost exclusively in single-planet configurations (Steffen et al., 2012) (with the υ Andromedae planets providing a notable exception).

Purely dynamical mechanisms have received increased attention in connection with the production of hot Jupiters. An early and influential study was carried out by Rasio and Ford (1996), who attributed hot Jupiters to the outcome of catastrophic planet–planet scattering. In their picture, extant short-period planets are survivors of strong gravitational encounters, in which one planet was either ejected or placed in a long-period orbit and the other is left in a high-eccentricity orbit with modest semimajor axis. Given a sufficiently close periastron distance, a high-eccentricity planet will subsequently undergo orbital circularization.

The process of Lidov–Kozai migration with tidal friction has grown rapidly in popularity during the last several years. In the Lidov–Kozai scenario (see, e.g., Eggleton and Kiseleva-Eggleton, 2001; Fabrycky and Tremaine, 2007; Wu and Murray, 2003), a planet destined to become a hot Jupiter forms at a distance of several AU from its parent star in an orbit that is substantially inclined at angle I_{b} to the orbit of a distant binary companion of mass $M_{\mathrm{b}\star}$. If the mutual orbital inclination between the stellar binary companion is larger or,

better, substantially larger than the Lidov–Kozai critical angle, $I_c = \arccos[(3/5)^{1/2}] \sim 40^\circ$ (assuming $M_{b\star} \gg M_p$ and an initially circular orbit for b), the planet is compelled to undergo *Lidov–Kozai cycles* in which the Jacobi energy $E_J = (1-e^2)^{1/2}\cos I$ is conserved, in which the planet experiences periodic cycling between successive states of high orbital eccentricity and high mutual inclination. The timescale for these cycles is

$$\tau_{LK} = \frac{2P_C^2}{3\pi P_B}\frac{M_\star + M_B + M_c}{M_c}\left(1-e_c^2\right)^{3/2} \quad [12]$$

For large initial I_B, the planet's periastron distance during the high-eccentricity phase of the cycle can be small enough so that dynamical tides acting on the planet are capable of efficiently turning orbital energy into heat, thereby shrinking the semimajor axis, a, of the planetary orbit. The Lidov–Kozai cycles are eventually destroyed when the general relativistic precession rate

$$\dot{\omega}_{GR} = \frac{3G^{3/2}(M_\star + M_B)^{3/2}}{a_B^{5/2}c^2(1-e_B^2)} \quad [13]$$

exceeds the Lidov–Kozai cycling timescale, that is, $2\pi/\dot{\omega}_{GR} < \tau_{LK}$. At this point, the planet shifts to a secular evolution characterized by steady orbital decay and circularization, with the end product being a hot Jupiter.

The Lidov–Kozai process delivers planets into orbits in which the planetary orbital angular momentum and the stellar spin angular momentum are initially largely uncorrelated.

A slew of measurements of the sky-projected angle, λ, between the stellar rotation and planetary orbital angular momentum vectors using the Rossiter–McLaughlin spectroscopic technique (McLaughlin, 1924; Rossiter, 1924) indicate that a substantial fraction of hot Jupiter orbits are badly misaligned with the equators of their parent stars.

10.21.6 Questions for the Next 10 Years and Beyond

There are few precedents in the history of science in which a discipline moves so rapidly from shaky disrepute through a golden age of discovery and into a mature field of inquiry. In less than two decades, the study of extrasolar planets has accomplished all of this – answering questions that were posed at the dawn of the scientific era, while affording tantalizing glimpses of revelations to come. This rapid progress partially obscures the fact that the extrasolar planets are *fundamentally alien*. Virtually none of their properties, either statistical or physical (aside from the scarcity of planets with $30M_\oplus < M_p < 100M_\oplus$), were predicted or anticipated (Lissauer, 1995, 2006), and theorists struggle to understand the zeroth-order features of the planetary distribution. At the current moment, it is thus useful to conclude by listing some of the most important unsolved questions.

- *Why is our inner solar system empty*? The *Kepler* mission and the high-precision Doppler velocity surveys have shown that the default mode of planet formation generates multiple super-Earth-mass planets with orbital periods $P < 100$ days. Our own solar system, however, contains nothing interior to Mercury's 88-day orbit. Furthermore, given the *presence* of Jupiter, with a mass and period combination that appears to be at least somewhat unusual, is there a possible connection between these two abnormal solar system attributes? Recent work of Walsh et al. (2011) suggests that both Jupiter and Saturn experienced significant radial migration, and the so-called Nice model (Gomes et al., 2005; Morbidelli et al., 2005; Tsiganis et al., 2005) posits that substantial migration of the outer planets occurred during the solar system's formation phases. A provocative, and as yet unanswered, question is whether such a process – generated, for example, via sweeping secular resonance – could have thwarted planet formation in our inner solar system.
- *Where in the protostellar disks did the observed planets form*? Our solar system has long been thought to be the product of planet formation that occurred more or less *in situ*, via core accretion for the giant planets and via planetesimal accretion for the terrestrial planets. The detection of 51 Peg b, along with other early extrasolar planet discoveries, led to the suggestion, which soon became a paradigm, that long-distance planetary migration can and does occur. At present, there are substantial arguments both in favor and against *in situ* formation of close-in ungiants. For hot Jupiters, where initial formation at large astrocentric distance seems more probable, it is not clear whether the Lidov-Kozai Cycles with Tidal Friction mechanism or quiescent long-distance type II disk migration is the dominant process.
- *What are the bulk compositions of the ungiants*? If one considers $\log_{10}M$, the most prominent mass gaps among all the bodies populating the solar system are those between Jupiter and the Sun, with $\log_{10}M_\odot/M_J = 3.02$, and between Earth and Uranus, with $\log_{10}(M_{Ura}/M_\oplus) = 1.16$. While it has long been possible to explore the properties of objects in the Sun–Jupiter gap through observations of low-mass stars and, more recently, brown dwarfs (Chabrier and Baraffe, 2000), the mere presence of extrasolar planets with $M_\oplus < M_p < M_{Ura}$ orbiting main-sequence stars has been known only since the discovery of Gliese 876 d, with $M_p = 7.5M_\oplus$ (Rivera et al., 2005), and the first density estimate became available only with the unveiling of Gliese 1214b, which has $M_p = 6.3M_\oplus$, $R_p = 2.7R_\oplus$, and $\rho_p = 1.67\,g\,cm^{-3}$ (Charbonneau et al., 2009). Structural models, as calculated by, for example, Rogers and Seager (2010), can easily reproduce Gliese 1214b's mass and radius with configurations drawn from three board classes of models, (i) rock and iron planets with massive H/He or H_2 atmospheres, (ii) rock–ice cores surrounded by H–He envelopes of solar nebular composition, and (iii) the so-called water worlds composed primarily of H_2O.

As we have described, attempts to characterize the atmosphere of Gliese 1214b have been met with ambiguity. It is likely that only when high-quality transmission spectra and interior mass distribution measurements are obtained will a clear understanding of the true range of compositions and structures of the ungiants emerge.

- *What (if any) is the observable role of magnetohydrodynamics*? The Earth and the four larger planets in our solar system all

harbor intrinsic magnetic fields that are generated by dynamo action in the planetary interiors. It is therefore natural to expect that many, perhaps most, short-period extrasolar planets with $M_p >$ several $M_\oplus$ also have magnetic fields, and to first approximation, these fields can be estimated by assuming that the *Elsasser number*, $\Lambda = \sigma_i B^2/2\rho\Omega$, is roughly constant across the aggregate of transiting planets ranging from Earth-like to Jupiter-like worlds. If we further assume synchronous rotation (which should hold for hot Jupiters on circular orbits), then $1/\Omega \propto a^{3/2}$. The upper atmospheres of planets with $P \lesssim 5$ days are hot enough ($T \gtrsim 1200$ K) that alkali metals (e.g., Na and K) have ionization fractions that are sufficient to couple the planetary magnetic field to the atmospheric hydrodynamic flow (see, e.g., Shu, 1992). Studies, such as those by Batygin and Stevenson (2010), suggest that ohmic dissipation is responsible for heating planetary interiors, thereby explaining much of the observed radius anomaly trend. Do MHD-mediated influences have a zeroth-order effect on exoplanet atmospheres and can some of the bewildering variation in atmospheric emission be understood as arising from magnetohydrodynamic phenomena?

10.22.1 Scientific Rationale and Present Status of Planetary Exploration Missions

For centuries, major advances in planetary science had to rely on ground-based observations. The increasing size of telescopes up to the present 8 m class observatories (e.g., VLT and Keck) and the increasing sophistication of focal plane instruments have made major advances possible in terms of wavelength coverage and spectral and spatial resolution for observing solar system bodies. Two developments have much enhanced the potential of ground-based observations over the last 20 years: the development of adaptive optics (Beckers, 1993), which brings telescopes close to their diffraction limits by correcting for atmospheric turbulence, and interferometry, which increases the effective aperture, improving spatial resolution. New results can therefore be expected from the next generation of ground-based observatories in the 2010–20 time frame, in particular ALMA (in the sub-mm wavelength range, first light in 2012), extremely large telescopes (aperture 30–40 m, scheduled for 2020), and the Square Kilometer Array (at radio wavelengths). Space observatories are not limited to the transmission windows of the Earth atmosphere. The most prominent examples for planetary science have been the Hubble Space Telescope in the visible and near-IR range, ISO and SIRTF in the IR range, Herschel (launched in 2009) in the sub-mm wavelength range, and FUSE in the UV range. The next major step will be the launch of JWST, the successor to Hubble with a wavelength range extending to the middle IR, in 2018.

An important perspective for planetary science that goes beyond our solar system is the detection and characterization of other planetary systems, which cannot yet be considered for in situ investigations (**Chapter 10.21**). Two space observatories dedicated to exoplanetary transits, COROT (CNES–ESA, launched in 2006) and Kepler (NASA, launched in 2009), have been highly successful in discovering exoplanets down to a few Earth masses. GAIA (ESA), successfully launched in December 2013, should identify thousands of giant planets through the displacement of the central star. The next steps are already being prepared, with three transit missions selected in 2013 and 2014. A small ESA mission, Cheops, approved in October 2013, will accurately determine the radius of exoplanets orbiting bright stars. Plato (ESA) will combine long-duration transit observations with ground-based radial velocity determinations so as to determine the radius and mass of exoplanets, hence their density. TESS is a NASA mission dedicated to finding targets for transit spectroscopy, the next step in exoplanet characterization, which is one of the goals of JWST (launch now scheduled in 2018).

While recognizing the importance of these contributions, it is however clear that most breakthroughs in solar system science have resulted and will continue in the future to result from space missions to other solar system bodies, starting from the landmark Luna 3 mission to the Moon, which revealed for the first time its hemisphere facing away from the Earth. Similarly to space observatories, remote-sensing planetary missions are not limited to the transmission windows of the atmosphere of the Earth. They can achieve much higher spatial resolutions even with relatively small optical devices (a typical planetary mission payload ranges from 50 to 150 kg in mass) as they get very close to the target body. Let us consider a 10 m class telescope operating at 1 μm. Its maximum resolution is 10^{-7} rad assuming that the diffraction limit is reached using adaptive optics. The best observing conditions are at quadrature for Mercury and Venus (maximum angular distance from the Sun) and at opposition for outer bodies. Distances therefore range from 55 million km (Mars at the best oppositions) to

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00180-9

several hundred million km. With a space mission, one can easily implement a camera with an aperture of at least 10 cm (a 70 cm aperture camera, HiRISE, is orbiting Mars since November 2006), corresponding to a diffraction-limited resolution of 10^{-5} rad or better. The closest distance for a flyby or an orbiter is typically 300 km for most planets and asteroids, 30 000 km for Jupiter, and 80 000 km for Saturn (outer edge of the A ring). For Mars, the resolution of a camera with a 10–20 kg mass is in the meters range instead of at best 5.5 km from the Earth. Therefore, flyby missions (over a short time interval) and orbiter missions provide improvements by several orders of magnitudes over the best ground-based or Earth-orbiting facilities. Orbiter missions make it possible to monitor temporal variations at high spatial resolution. Such missions also provide unique opportunities for characterizing the environment of planetary bodies in terms of particles, fields, and their interactions with the solar wind. By implementing in situ missions (landers, rovers, and airborne modules if there is an atmosphere), it is possible to bring to bear the full range of techniques used in Earth sciences: chemical and mineralogical analysis, seismology (which is best implemented with a network of stations), atmospheric sensors, etc. A comprehensive review of experimentation for planetary missions is provided in the next chapter (**Chapter 10.23**). Eventually, sample return missions make it possible to implement powerful analysis techniques, which are still required today for very high-precision measurements of trace elements and isotopic compositions (radiochronology and isotopic anomalies). This may change in the future considering the remarkable improvements of in situ analysis techniques over the last 20 years (e.g., mass spectrometry with a resolution of 1000 or more, implemented on the Rosetta comet rendezvous mission of ESA only 20 years after it became available in the laboratory).

As discussed in, for example, Langevin (2001), the sequence of missions to a given planetary body in terms of increasing complexity is therefore the following:

- First, exploration by a flyby mission
- Comprehensive characterization by remote-sensing techniques on orbiter missions
- In situ investigations (landers, rovers, descent probes, balloons, airplanes, etc.)
- Sample return missions

Possibly even more so than the 1st edition in 2006, the 2nd edition of this book corresponds to a timely period for assessing the status of planetary exploration and outlining the next perspectives. All classes of solar system bodies with the exception of Kuiper Belt objects (KBOs, beyond Neptune) have been visited at least once by flyby missions. The last gap will be filled by the New Horizons NASA mission, which will encounter Pluto, one of the largest KBOs, in 2015. Similarly, the remote-sensing phase is well under way, with the highly successful missions to Mars (MGS, Mars Odyssey, and Mars Reconnaissance Orbiter (MRO) for NASA and Mars Express for ESA), the Cassini–Huygens mission to the Saturn–Titan system (NASA–ESA), the Venus Express mission to Venus (ESA), and the Messenger mission (NASA, launched in 2005, orbiting Mercury since March 2011) and the more ambitious BepiColombo mission to Mercury (ESA/JAXA, launch scheduled in 2016). Five lunar orbiter missions launched from 2007 to 2010 (Kaguya, Japan; Lunar Reconnaissance Orbiter, NASA; Chandrayaan, India; and Chang'e 1 and 2, China) provided a comprehensive remote-sensing coverage of the Moon. The outstanding results of this extensive set of ambitious planetary exploration missions are discussed in other sections of Volume 10, in particular **Chapters 10.02** and **10.05** for the terrestrial planets, **Chapter 10.16** for the giant planets, and **Chapter 10.18** for icy satellites. The JUICE mission selected by ESA in 2012 for a launch in 2022 will perform a comprehensive remote-sensing investigation of Jupiter, its environment, and its satellites, in particular Ganymede and Callisto. For small bodies, one can mention the rendezvous missions toward comet Churyumov–Gerasimenko (Rosetta, ESA, rendezvous in mid-2014), near-Earth asteroids Eros (NEAR, NASA) and Itokawa, and a primitive NEA (Hayabusa and Hayabusa 2, Japan). The Dawn mission (NASA), launched in 2007, has successfully orbited asteroid 4 Vesta for more than 1 year (July 2011–September 2012), and it is now on its way to Ceres, the largest main belt asteroid, which will be reached in 2015. With this impressive set of orbital remote-sensing missions (in operation or approved), comprehensive information has been or will be obtained on six of the eight planets (Uranus and Neptune being left out), four of the seven planet-sized satellites (the Moon, Ganymede, Callisto, and Titan), one cometary nucleus, the two largest main belt asteroids, and three near-Earth asteroids.

In situ investigations suffered some setbacks in the first years of the twenty-first century (failure of the Beagle 2 Mars lander and descoping of a Mercury lander on BepiColombo). However, remarkable successes have been obtained by the Huygens descent probe in the atmosphere of Titan (ESA), which provided information all the way down to the surface in January 2005, and the Mars Exploration Rovers of NASA, 'Spirit' and 'Opportunity,' which started their investigations in early 2004 and much exceeded their 3 months' lifetime (Opportunity was still operating in late 2012). A very large Mars rover ('Curiosity,' 800 kg) was launched in November 2011 by NASA, and it has been investigating the interior of the Gale crater since its successful deployment in August 2012. ExoMars, the rover mission to Mars in the framework of the exploration program of ESA, initially scheduled in 2013, is now considered for a 2018 launch at the earliest. The Rosetta lander, Philae, has landed in November 2014 as the first lander ever on a cometary nucleus. China, Japan, and India are presently studying lunar lander and rover missions for the 2014–20 time frame.

For 30 years, lunar dust and rocks from Apollo and Luna had remained the only samples brought back from another planetary body. Samples of cometary dust have been successfully recovered in early 2006 from comet Wild-1 (Stardust, NASA), with intriguing results on early mixing in the protosolar nebula. The Japanese Hayabusa mission has succeeded in bringing back dust grains from asteroid Itokawa, and a reflight to a primitive asteroid has been launched in December 2014. Mars sample return missions are now considered beyond the 2020 time frame.

Given the remarkable success and breadth of scope of presently flying and approved remote-sensing missions, it is likely that planetary missions beyond the 2020 time frame will focus on in situ investigations and sample returns. Orbiter missions will, however, continue to be useful as relays for in situ modules, specific science objectives, and extended time coverage. These considerations are important for the purpose of this chapter, as the resources required are increasingly larger for

each step in planetary exploration, even if the presence of an atmosphere around the target body can in part alleviate for these higher energy requirements. The following sections present the major constraints on mission design for planetary exploration. The basic issues of astrodynamics are presented in a reference textbook (Bate et al., 1971). More recent textbooks have been published by Battin (1999) and Vallado (2001). A discussion of these questions focused on mission design techniques is also available (Langevin, 2005). A review of the most recent advances in mission analysis is provided by Marsden and Ross (2006).

10.22.2 Energy Requirements and Mass Budgets for Planetary Missions

10.22.2.1 Leaving the Gravitational Influence of the Earth

Apart from missions to the Moon, all planetary missions have to leave the gravitational influence of the Earth. So as to compare the different types of missions, one can consider as a starting point a near-circular orbit around the Earth at an altitude of ~330 km, which lies beyond the upper reaches of the Earth atmosphere. A large velocity increment can then be provided in as short a time as possible by an upper stage, so as to exceed the escape velocity. This strategy was used for both Mars Express (June 2003) and Venus Express (November 2005) with the Soyuz launcher and its Fregat upper stage.

At this altitude, the velocity on a circular orbit (circular velocity, V_c) 7.71 km s^{-1} and the escape velocity V_{esc}, which is always $\sqrt{2}$ times larger than V_c, are 10.90 km s^{-1}. Velocity increments lower than 3.19 km s^{-1} provided by the upper stage will therefore result in bound orbits, and velocity increments larger than 3.19 km s^{-1} will result in interplanetary trajectories. The interplanetary departure velocity V_{inf} can easily be derived from energy conservation arguments:

$$V_{inf}^2 = V_{per}^2 - V_{esc}^2 \quad [1]$$

where V_{per} is the velocity at pericenter after the upper-stage burn.

The resources required for each class of trajectory can then be compared from the velocity increment ('ΔV'), which is required in addition to that that would be needed to reach a bound orbit with a semimajor axis of 320 000 km, which goes much beyond that of the Moon (Table 1).

It is important to note that the ΔV required from the upper stage to reach the Moon (3.14 km s^{-1}) and to leave the Earth with a 3 km s^{-1} relative velocity (3.61 km s^{-1}) are similar (460 m s^{-1} difference). Very large departure velocities (9 km s^{-1}) require additional velocity increments similar to the 3.19 km s^{-1}, which are already needed to escape from a circular orbit.

These considerations have a major impact on the mass available for interplanetary modules. This directly derives from the basic physical constraints on rockets, first discussed by K. Tsiolkovky in the last years of the nineteenth century. An upper stage, similarly to any rocket, ejects exhaust gas at a large velocity V_{ej} (~3.25 km s^{-1} for the Fregat upper stage and ~4.1 km s^{-1} for the Centaur cryogenic upper stage). From the momentum balance, we can write

$$M(t)\mathrm{d}v = \mathrm{d}M V_{ej} \quad [2]$$

where $M(t)$ is the mass at a given time during the thrust. Integrating eqn [2] over the full duration of the thrust results in the basic constraint of spaceflight, the 'rocket equation' (Tsiolkovsky, 1903):

$$\Delta V = V_{final} - V_{initial} = V_{ej}\, In(M_i/M_f) \quad [3]$$

where M_i and M_f are the initial and final masses of the upper stage with its payload and ΔV is the total velocity increment.

In the case of the Soyuz–Fregat launch strategy used for Mars Express and Venus Express, the equivalent mass, which could be injected in a near-circular orbit, is 7200 kg, while the dry mass of the Fregat stage with the payload attachment device is 1150 kg. It should be noted that this 'useless' dry mass ends up with the same velocity as the spacecraft itself; hence, it has to be subtracted from M_f so as to obtain the 'useful' mass injected into a given orbit.

Figure 1 provides the useful mass as derived from the rocket equation, which can be launched at a given departure velocity

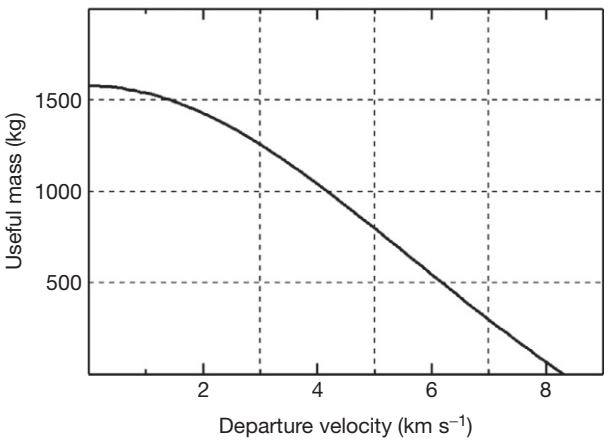

Figure 1 Useful mass as a function of departure velocity with the Soyuz–Fregat combination used for the launch of Mars Express in 2003, not taking into account gravity losses. The departure velocity of Mars Express was ~3 km s^{-1}; hence, the available useful mass was ~1250 kg.

Table 1 ΔV requirements on the upper-stage burn for each class of trajectories

Type of trajectory	V_{per} *(km s^{-1})*	*Upper stage* ΔV *(km s^{-1})*	ΔV *over bound orbit (km s^{-1})*
Moon-crossing orbit	10.85	3.14	0.00
Marginal escape	10.90	3.19	0.05
Departure at 3 km s^{-1}	11.31	3.61	0.46
Departure at 5 km s^{-1}	12.00	4.29	1.15
Departure at 7 km s^{-1}	12.96	5.25	2.11
Departure at 9 km s^{-1}	14.14	6.43	3.29

from the Earth–Moon system with Soyuz–Fregat in its Mars Express configuration. It is clear that there is very little available mass for escape velocities larger than 6 km s^{-1}, while departure velocities lower than 3.5 km s^{-1} result in significant mass budgets even with a relatively small (and cheap!) launcher. This is a slightly optimistic view, as it considers that the Fregat burn is performed at a 330 km altitude. However, even with the powerful thruster of Fregat (20 000 N, providing an acceleration of 2.8 m s^{-2} at full load and 10 m s^{-2} at the end of the thrust arc), the thrust extends over several hundred seconds so as to reach escape velocity. Part of the thrust is therefore provided when the upper stage is at higher altitudes. Close to escape, the energy provided by each m s^{-1} of ΔV is proportional to the local escape velocity. At an altitude of 2000 km, the local escape velocity is 9.75 km s^{-1} instead of 10.90 km s^{-1} at an altitude of 330 km s^{-1}; hence, the efficiency of the thrust in terms of energy has been reduced by 10%. This penalty incurred with extended thrust arcs is called a 'gravity loss.' It is increasingly severe for very large velocity increments, which require longer thrust arcs. As an example, the actual performance of the Soyuz–Fregat drops to zero slightly below 8 km s^{-1}, instead of 8.15 km s^{-1} as in Figure 1. In practical terms, a single stage such as Fregat can provide at best a velocity increment that is ~1.5 times larger than the exhaust velocity. For spacecraft propulsion systems, the practical limit is lower, in the range of the exhaust velocity, as the initial mass is that at departure and some useful mass must remain for the scientific mission.

Two alternative launch strategies with an intermediate bound orbit can be considered:

- For low departure velocities, it is possible to effectively use the Moon, which is a very large satellite when compared to its primary. A Moon gravity assist (MGA, see Section 10.22.6) from a bound orbit can provide a departure velocity close to 1.4 km s^{-1}. If the Moon is in a favorable location, this strategy provides for free the launch capability of the Moon-crossing orbit (1610 kg) instead of 1500 kg as in Figure 1. There are severe limitations to this strategy, as the departure direction must be close to the orbit plane of the Moon. The 7% improvement in the mass budget is therefore only of interest in very specific cases (ion propulsion missions, see Section 10.22.7)
- For large departure velocities, it is not effective to carry along the large dry mass of the Fregat upper stage (1150 kg), which then exceeds the useful mass. It is interesting to consider launching as much mass as possible (1610 kg) into a Moon-crossing elliptical orbit. The spacecraft thruster (or a dedicated propulsion stage) can then be used as a new stage at the next perigee. This indirect launch strategy is discussed by Farquhar and Dunham (1999). The required ΔV at perigee can be derived from the fourth column in Table 1, which indicates the difference between the perigee velocity of the Moon-crossing orbit and that required for departure at a given velocity. Interplanetary spacecraft thrusters provide typically 400 N, much less than the 20 000 N of Fregat. The exhaust velocity is only slightly smaller (3.1 km s^{-1} instead of 3.28 km s^{-1}). For large departure velocities, the thrust arc extends far before and after perigee, and gravity losses begin to offset the advantage of jettisoning the large Fregat upper stage. For Mars Express (departure at 3 km s^{-1}), the spacecraft thruster has to provide 460 m s^{-1} (actually 500 m s^{-1} due to gravity losses). The final mass after the spacecraft thruster burn is then 1370 kg, 130 kg more than with a direct injection with Fregat. One should, however, take into account that 240 kg of additional fuel has to be carried, with a spacecraft mass at separation of 1610 kg. This requires larger tanks and a more robust structure than the 'direct injection' spacecraft with its 1240 kg mass. For each additional kg of fuel, 0.1–0.14 kg of tanks and structure have to be added to the spacecraft (this ratio is called the 'tankage factor'). With 240 kg of additional fuel, the penalty in dry mass is ~30 kg; hence, the benefit of such a launch strategy is reduced to 100 kg, which is still quite significant. For a departure velocity of 6 km s^{-1}, the bound orbit launch strategy increases the available mass after departure from 500 to 700 kg, even taking into account gravity losses. For departure velocities ranging from 3 to 6 km s^{-1}, there is therefore a complex trade-off between mass budget, complexity, cost, and risk: The 'direct injection' spacecraft is lighter, hence cheaper, and a major maneuver 1 month after launch may not be desirable. A bound orbit launch extends the mission duration by 1–2 months, but extending the launch window and coping with launcher errors become very cheap. Finally, it is important to note that there is a practical limit of ~3 km s^{-1} on onboard ΔV, as this corresponds to the ejection velocity; hence, more than 70% of the spacecraft mass would consist of fuel, tanks, and the corresponding structural mass. Therefore, the bound orbit launch strategy cannot be considered for missions requiring large ΔV capabilities after departure.

Soyuz–Fregat has been launched from Kourou starting in 2011, and new versions of Fregat have been developed. A Moon-crossing orbit capability of 2140 kg with Soyuz–Fregat was considered as the initial baseline for the BepiColombo mission to Mercury (launched in 2013), before this mission exceeded the capability of the Soyuz–Fregat launcher due to major mass increases. For missions requiring more mass, one has to use a more capable launcher. Ariane 5 (ECA version), Atlas 5 (421), Delta 4 (M+), or Proton provides a Moon-crossing orbit capability larger than 4500 kg (3500 kg or more for a departure at 3 km s^{-1}). With such launchers, a direct injection is therefore likely to meet the mass requirements of most solar system exploration missions. The departure velocity is, however, still limited to ~7 km s^{-1} if the upper stage is not cryogenic (Ariane 5 and Proton), as the same equations as those for the Fregat upper stage of Soyuz apply. NASA has a major asset for high-energy missions as it was able to develop a cryogenic upper stage (Centaur) as early as 1963. The ejection velocity of a H_2/O_2 engine is larger than 4 km s^{-1}, compared with 3.1 km s^{-1} for bipropellant thrusters such as that of Fregat, and the decrease in useful mass with departure velocity is slower. This made it possible to implement direct missions to Jupiter, which require departure velocities of at least 9 km s^{-1}: Pioneer 10/11, launched by Atlas/Centaur in 1972/1973, and Voyager 1/2, launched by Titan/Centaur in 1977. Such direct missions to Jupiter have a very short cruise time (1.75 years to Jupiter). However, the useful mass is low: The mass of Pioneer 10 was only 270 kg; hence, this strategy

has until now only been used for flyby missions to the outer solar system, the most recent being 'New Horizons' (NASA), launched in 2006 toward Pluto and the Kuiper Belt.

10.22.2.2 Flyby Missions

Flyby missions only require that the spacecraft leaving Earth crosses the path of the target body. The Moon is a specific case, as it orbits the Earth. It can be visited by a spacecraft on a bound geocentric orbit, with a velocity at perigee lower than the escape velocity (see Table 1). Near-Earth asteroids and several comets have orbits that come quite close to that of the Earth. The velocities relative to the Earth, which are required to reach these bodies (albeit at a high flyby velocity), can be so low (<1.5 km s^{-1}) that a simple lunar swingby from a bound orbit is adequate. The mass budget is then similar to that of a lunar flyby mission. The best example of such a cheap flyby mission is the magnetospheric mission ISEE-3 of NASA, retargeted and renamed ICE (International Comet Explorer) after a lunar flyby, which made it possible to encounter comet Giacobini–Zinner in 1991 (Farquhar, 2001).

Multiple flybys of comets and asteroids can cheaply be implemented using gravity-assist strategies (see Section 10.22.6), thereby enhancing the scientific return (Farquhar et al., 2002). This usually requires retargeting the spacecraft by flying close to a planet. When this planet is the Earth, the period of each successive orbit has to be close to a simple fraction of 1 year. As an example, the trajectory of the ESA probe Giotto on its way to the flyby of comet Halley in 1986 had an orbital period close to 0.75 years, which brought the spacecraft back to the Earth after four orbits and 3 years. It was then possible to adjust the Earth swingby so as to visit comet Schwassmann–Wachmann 3 in 1991. Similarly, USSR's VEGA-1 and VEGA-2 missions used a swingby of Venus (with the deployment of balloons in the atmosphere) to reach comet Halley at nearly the same time as Giotto. The most comprehensive mission of this type was expected to be NASA's CONTOUR. Four flybys of comets and asteroids were planned in the nominal mission, three intermediate Earth swingbys retargeting the spacecraft toward the next target. This mission unfortunately failed at launch in 2001.

All other planetary bodies of interest (planets, natural satellites apart from the Moon, main belt asteroids, and most comets) do not come close to the orbit of the Earth. A transfer trajectory is then required, with a significant departure velocity. Apart from near-Earth objects, minor bodies consist of three main groups: comets, main belt asteroids, and KBOs, which orbit beyond Neptune. Pluto is not a planet, but one of the largest representatives of KBOs. Most minor bodies have large eccentricities and large inclinations. Such characteristics much increase the cost of a flyby mission and even more so that of a rendezvous mission. Some large main belt asteroids, such as 4 Vesta, have relatively low eccentricity and inclination, which is also the case for the seven major planets. Visiting a large natural satellite with a flyby mission has very similar requirements to that of a mission to the planet itself.

A first approximation of the relative complexity of solar system exploration missions can be made by assuming that all planetary orbits are circular, with an orbit in the same plane as the orbit of the Earth. The problem in this coplanar, circular approximation becomes very simple: the cheapest transfer between the Earth and such an idealized planet is an ellipse, which is tangent to the two circles (Hohmann transfer). This applies to both a flyby mission and a rendezvous mission. All velocities in the solar system can be scaled to the orbital velocity of the Earth, $V_e = 29.78$ km s^{-1}, if the semimajor axis of the Earth is considered as the unit of distance (astronomical unit or AU). If R_p is the semimajor axis of the planet in these units, we have

$$A = (1 + R_p)/2 \qquad [4]$$

where A is the semimajor axis of the transfer orbit. The cruise time is one-half of the period of the orbit, which is equal to $A^{1.5}$ (in years) if A is expressed in astronomical units. From Kepler's laws, it is then easy to derive the heliocentric velocities at departure (V_1) and arrival (V_2):

$$V_1 = V_e(2 - 2/A)^{0.5} \quad V_2 = V_e\left(2/R_p - 2/A\right)^{0.5} \qquad [5]$$

The orbital velocity V_p of a planet in a circular orbit is $V_e R_p{}^{-0.5}$. The relative velocity at departure (V_{dep}) and arrival (V_{arr}) is therefore

$$V_{dep} = V_1 - V_e \quad V_{arr} = V_2 - V_e R_p{}^{-0.5} \qquad [6]$$

Table 2 presents the required departure and arrival velocities for selected solar system bodies in the circular and coplanar approximation. Mercury and Vesta depart very significantly from this hypothesis in terms of inclination (Table 2, column 2), and the eccentricity of the orbit of Mercury is large (Table 2, column 3). When comparing Table 2 to Table 1 and Figure 1, Venus and Mars stand out as targets, which are relatively easy to reach, with optimum departure velocities in the range of 2.5–3 km s^{-1} (respectively, backward and forward relative to the orbital motion of the Earth at departure). Even a simple flyby to Vesta is already a challenge, as the departure

Table 2 Orbital elements of selected solar system bodies and main characteristics of the corresponding transfer orbits

Target	*Inclination*	*Eccentricity*	*Semimajor axis (AU)*	*Departure (km s^{-1})*	*Arrival (km s^{-1})*	*Cruise (years)*
Mercury	7.01°	0.206	0.387	−7.53	9.61	0.29
Venus	3.39°	0.007	0.723	−2.50	2.71	0.40
Mars	1.85°	0.093	1.524	2.94	−2.65	0.71
Vesta	7.13°	0.090	2.365	5.51	−4.43	1.09
Jupiter	1.31°	0.049	5.203	8.80	−5.64	2.73
Saturn	2.49°	0.056	9.539	9.60	−5.44	6.04

The relative velocities are evaluated assuming all planetary orbits to be circular, in the same plane as the orbit of the Earth. In this table, relative velocities are positive if the spacecraft goes faster than the planet or asteroid and negative if the spacecraft goes slower than the planet or asteroid. The departure and arrival conditions further assume that the Earth and the target body are at the appropriate relative positions in the solar system.

velocity in this optimistic hypothesis is not far from the upper limit in Figure 1. Direct transfer missions to Mercury, Jupiter, Saturn, and even more so Uranus and Neptune are out of reach of medium-class launchers such as Soyuz if any significant mass is to be brought to destination. Another important conclusion of this preliminary analysis is that missions to Mars and Venus require relatively short transfer times, while missions to the outer solar system require relatively long cruise durations, apart from being energetically more demanding.

10.22.2.3 Rendezvous Missions

For a rendezvous mission, the spacecraft has to be captured in orbit around the target body. The simplest way to get into orbit is to brake closest to the target body using the spacecraft thruster. This is the exact counterpart of the launch strategy from a highly elliptical orbit, which was considered in Section 10.22.2.1. The same issues arise on the length of thrust arcs, with a possible impact in terms of gravity losses if one has to thrust at higher altitudes. The closest possible altitude for an orbit insertion maneuver depends on the target body: If it has no atmosphere (Mercury and Vesta), 200 km is a safe distance. If with an atmosphere (Mars and Venus), 300 km is a reasonable choice. If there are rings (Saturn) or intense radiation belts (Jupiter), larger distances may be required due to safety constraints, for example, 80 000 km for Saturn so as to be outside of the rings (one can get closer by flying above the rings, as was done by Cassini). At a given distance from a planet, the local escape velocity V_{esc} defines the orbits, which have a total energy of 0 in the reference frame of the primary. The relationship between the ΔV required for a marginal capture and the arrival velocity V_{arr} can then be derived from energy conservation:

$$(V_{esc} + \Delta V)^2 = V_{esc}^2 + V_{arr}^2 \quad \Delta V = \left(V_{esc}^2 + V_{arr}^2\right)^{0.5} - V_{esc} \qquad [7]$$

From eqn [7], the required ΔV increases with the arrival velocity and decreases with the local escape velocity; hence, it is easier to capture around a large solar system body. The actual orbit insertion maneuver is not much larger than that required for a marginal capture, as the first orbit around the target has always a much longer period than the operational orbit. The 8 days' initial orbit of Mars Express costs 60 m s^{-1} more than a marginal capture around Mars, and the 115 days' initial orbit of Cassini around Saturn costs 140 m s^{-1} more than a marginal capture around Saturn with the same approach velocity.

From Table 3, the large gravity fields of Jupiter and Saturn compensate for the relatively large arrival velocity (Table 2), so that the capture ΔV is in the same range of that required for Venus and Mars (0.34–0.68 km s^{-1}). Conversely, orbiter missions around Mercury or an asteroid such as Vesta require extremely large orbit insertion maneuvers. Once again, it is useful to go back to the rocket equation [3]: with an exhaust velocity of 3.1 km s^{-1}, the mass in orbit can be larger than 80% of the mass during approach for 'easy' rendezvous targets such as Venus, Mars, Jupiter, and Saturn. Conversely, orbiter missions to Mercury and Vesta are out of reach of a single-stage onboard propulsion system unless the relative velocity can be reduced to more reasonable values using gravity-assist strategies (see Section 10.22.6).

Table 3 Capture ΔV requirements for a rendezvous mission

Target	*Arrival (km s^{-1})*	*Local escape velocity (km s^{-1})*	*Capture ΔV (km s^{-1})*
Mercury	9.61	4.09	6.35
Venus	2.71	10.36	0.35
Mars	−2.65	4.81	0.68
Vesta	−4.43	0.3	4.14
Jupiter	−5.64	35.0	0.45
Saturn	−5.44	24.0	0.61

10.22.2.3.1 Rendezvous missions to natural satellites of giant planets

Among the 15 largest solar system bodies (excluding the Kuiper Belt), 7 are in orbit around a planet: the Moon and the six largest natural satellites of giant planets (Io, Europa, Ganymede, and Callisto around Jupiter, Titan around Saturn, and Triton around Neptune). It has already been indicated that a flyby mission to a Galilean satellite has very similar requirements to a flyby mission to Jupiter, and the Voyager 1 and 2 missions did combine these two objectives. The situation is drastically different for orbiter missions: the large gravity fields of giant planets, which make it relatively easy to capture into a highly elliptical orbit, result in very large orbital velocities and local escape velocities at the distances of large natural satellites. As an example, the orbital velocity of Europa is 13.7 km s^{-1}, and the local escape velocity is 19.4 km s^{-1}. Capturing a spacecraft in an orbit with its pericenter at the distance of Europa requires a minimum ΔV of 0.8 km s^{-1} (one can do somewhat better by capturing at a lower altitude and then raising the pericenter, but this extends the mission duration). Matching the orbit of Europa for a rendezvous would require an additional 5.7 km s^{-1}. Therefore, orbiter missions to satellites of giant planets cannot be achieved simply with a chemical propulsion system. Much more complex methods must be implemented, such as satellite gravity-assist methods (Longman and Schneide, 1970) or nuclear electric propulsion (NEP), or a combination of both (see Sections 10.22.6 and 10.22.7).

Apart from Mercury, all planets have a substantial atmosphere. Among natural satellites, this is the case only for Titan. It is then possible to dip into the atmosphere so as to lose energy and lower the orbit (French and Cruz, 1980). This has to be done in one pass if one wants to use the atmosphere for the insertion maneuver (aerocapture) or for a landing module (atmospheric entry). Once in orbit, it is possible to lower the orbital period by dipping into the outer regions of the atmosphere during many successive orbits (aerobraking). In situ missions to planetary bodies with an atmosphere have a close relationship with flyby missions, as an entry module with a heat shield can quite effectively dissipate the arrival energy for a wide range of arrival velocities.

10.22.2.3.2 Rendezvous missions to comets and Earth-crossing asteroids

Comets and Earth-crossing asteroids are very specific as flyby missions and rendezvous missions have completely different characteristics, contrarily to solar system bodies in nearly circular orbits. As has already been mentioned, flyby missions can

be very cheap if the encounter location is not too far from the orbit of the Earth. Unfortunately, such encounters occur at a very high relative velocity (more than 70 km s^{-1} for the flybys of Halley's comet in 1986), which makes it impossible to consider a rendezvous. Two conditions must be met for a rendezvous mission to be feasible with chemical propulsion:

- The inclination must be relatively small ($\leq 12°$), which eliminates most candidates.
- The perihelion must range between 0.65 and 1.5 AU.

Asteroid 433 Eros, the largest near-Earth asteroid, meets these criteria with a perihelion at 1.13 AU and an inclination of 10.8°. It was studied by the Near Earth Asteroid Rendezvous (NEAR) mission of NASA from rendezvous in February 2000 to a programmed touchdown on Eros in February 2001 (Cheng et al., 1997). Comet Churyumov–Gerasimenko, the target of the Rosetta rendezvous mission, is a typical good candidate among comets, with an inclination of 7.1° and a perihelion at 1.29 AU.

The lowest relative velocity at arrival is achieved by departing from the Earth close to the perihelion of the target body, hence arriving close to aphelion. Again, considering the case of Churyumov–Gerasimenko, the minimum arrival velocity is a reasonable 1.2 km s^{-1}, but the departure velocity is close to 10 km s^{-1}, which is out of reach for a direct launch. Similarly to giant planets, gravity-assist strategies (Section 10.22.6) or an advanced propulsion system (Section 10.22.7) is required.

10.22.3 Remote-Sensing and In Situ Missions to Venus and Mars

The simplified analysis in Section 10.22.2 demonstrated that Venus and Mars stand out as the easiest targets for a rendezvous mission apart from the Moon. They are also surrounded by an atmosphere, which is a major asset for implementing in situ modules (landers, rovers, balloons, etc.). It is therefore no surprise that until 1972, all planetary missions were sent toward one of these two planets. However, not all opportunities are equal, due to the nonnegligible inclination of Venus (3.39°) and Mars (1.85°) and the significant eccentricity of the orbit of Mars ($e = 0.093$).

The first issue to consider is how often can one send a spacecraft to Venus and Mars. Arrival occurs nearly 180° away from departure. During the required cruise time from Earth to Venus on a Hohmann transfer trajectory (0.399 years), Venus travels 233°. Therefore, the appropriate departure time is when Venus is 53° behind the Earth on its orbit. For Mars, the cruise time is 0.709 years, during which Mars travels 135.6°. The appropriate departure time is when Mars is 44.4° ahead of the Earth on its orbit (this assumes that the orbit of Mars is nearly circular, which is not the case). How often does such a favorable configuration repeat? This period P_{syn} (called the synodic period) is such that the angle traveled by the innermost planet (which moves fastest) exceeds by one full turn the angle traveled by the outermost planet. If P_1 and P_2 are the periods of the innermost and outermost planets, we have

$$P_{syn}/P_1 = P_{syn}/P_2 + 1 \quad P_{syn} = P_1P_2/(P_2 - P_1) \qquad [8]$$

If one considers the orbital period of Venus (0.615 years) and Mars (1.881 years), this gives a repeat interval of 1.6 years for transfers to Venus and 2.135 years for transfers to Mars. The position of the Earth at launch moves forward by 216° for Venus and by 48.6° for Mars. After 8 years (5 synodic periods, 13 Venus 'years'), the windows to Venus repeat almost perfectly, as Venus is then only 1.5° ahead of its position 8 years before. For Mars, the best match is after 15 years (7 synodic periods), but Mars lags by 9° behind its position 15 years before, and the windows do not repeat. Intermediate launch dates can be obtained by inserting 'phasing' orbits in the transfer, so that the spacecraft travels close to 540° instead of 180°. This increases the cruise time by 0.8 years for Venus and 1.4 years for Mars. A 540° transfer to Venus requires launching 6 months earlier than the direct window. Such opportunities can be useful, in particular when Venus or Mars is used for a gravity assist (see Section 10.22.6).

The significant eccentricity of the orbit of Mars (0.093) has an impact on transfer orbits. The minimum velocity at infinity required to reach Mars is 3.5 km s^{-1} when it is reached at aphelion (1.665 AU) and only 2.3 km s^{-1} when it is reached at perihelion (1.38 AU). Conversely, the minimum arrival velocity is much higher at perihelion (3.3 km s^{-1}) than at aphelion (2.1 km s^{-1}). The range of departure velocities corresponds to a difference of only 300 m s^{-1} of ΔV from the upper stage. The range of arrival velocities corresponds to a difference of 640 m s^{-1} for the insertion maneuver (actually somewhat larger as gravity losses also increase), which is quite significant (20% less mass budget for an orbiter with an insertion at perihelion, if one does not use aerocapture or aerobraking). Venus has a nearly circular orbit, so that in this respect, all Venus windows should be equivalent. The Earth itself has a small eccentricity (0.0167), so that an outbound launch in January (when the Earth is closest to the Sun) and an inbound launch in July require slightly smaller departure velocities.

However, a much more important problem results from the small but significant inclination of the orbit of Mars (1.83°) and even more so Venus (3.39°) with respect to the orbit plane of the Earth (the ecliptic). The plane of the transfer orbit contains the Sun, the Earth at departure, and the target planet at arrival. The planet at arrival is in the ecliptic only at one of the two intersections of the orbit plane and the ecliptic (nodes): $L_s \sim 76.8°$ and $L_s \sim 256.8°$ for Venus and $L_s \sim 49.5°$ and $L_s \sim 229.5$ for Mars (L_s: heliocentric longitude, measured from the Sun–Earth direction at the fall equinox). In most cases, this forbids a perfect Hohmann transfer, as a 180° orbit would have to fly directly over the Sun. For Mars, angles of 160° (type I transfers) or 200° (type II transfers) bring the transfer orbit plane much closer to the ecliptic. The in-plane departure and arrival velocities are suboptimal compared to the Hohmann transfer, but the out of ecliptic component of the departure velocity drops from the staggering values (>30 km s^{-1}) required for a 180° transfer to 2 km s^{-1} or less (when Mars at arrival is close to one of the nodes).

As a conclusion of this analysis, a good window to Mars (Venus) occurs when Mars (Venus) can be reached close to one of the nodes. For Venus, both nodes are equivalent, as they are at nearly the same distance from the Sun (0.7205 and 0.7261 AU for L_s 76.8° and L_s 256.8°, respectively), but

only the latter lies conveniently close to one of the five possible arrival locations in the 8 years' cycle. For Mars, arriving close to L_s 49.5° (at 1.4715 AU) is slightly better than arriving close to L_s 229.5° (at 1.5515 AU) for flyby and in situ missions and slightly worse for orbiter missions relying only on chemical propulsion.

The situation is further complicated as the performances of Ariane 5 from Kourou strongly depends on the declination (angle of the departure velocity to the equatorial plane of the Earth). At the low latitude of Kourou (5° N), the launcher can take full advantage of the rotational velocity of the Earth (461 m s^{-1} instead of 463 m s^{-1} at the equator) by launching due east if the departure velocity lies close to the equatorial plane. For larger declinations, one has to launch away from the optimum direction (avoiding Brazil for the fall of the boosters), and the thrust must be applied at an angle to the velocity ('dogleg') as the third stage of Ariane 5 cannot be restarted. When the launch pad is at a higher latitude (Kennedy Space Center, 28.5° N and Baikonur, 46° N), the rotational velocity is lower (407 m s^{-1} for Kennedy, 322 m s^{-1} for Baikonur), but the launch capability is the same for all declinations (N or S), which do not exceed the latitude. The spacecraft is first set on a circular orbit with a declination equal to the latitude by launching due east (which is optimum). The upper stage (Centaur, Fregat) is then restarted at the position on the circular orbit, which is adequate for reaching the departure declination. Soyuz–Fregat can be launched from Kourou since late 2011. The circular orbit has then a declination equal to that of departure, with a much smaller mass penalty than for Ariane 5 (the same as for a launch at the corresponding latitude). As there is an angle of 23.45° between the ecliptic and the equator, the declination is a complex combination of the departure date and the out of ecliptic component.

Tables 4 and 5 provide useful comparisons for all remote-sensing and in situ missions to Mars and Venus. They show the major impact of the 3.39° inclination of Venus on the approach velocity, which never gets close to the lower limit derived from the coplanar assumption. Conversely, several Mars windows have overall performances that are very close to that of the coplanar assumption. The departure or arrival velocity for Mars can even be smaller than the coplanar estimate, as Mars (0.093) and the Earth itself (0.0167) have non-circular orbits. The similarity between the Venus Express transfer orbit (2005/08) and that of the 2013 window illustrates the 8 years' cycle of windows to Venus (5 synodic periods of 1.6 years). With Soyuz from Baikonur (Mars Express), many windows are relatively similar for an orbiter mission. With Ariane 5, specific strategies must be considered for all windows from 2009 to 2020 due to declination (25° N or 46° S is not accessible). Inserting a 1-year orbit before departure or using a favorable type III window (2017) results in a cruise time of 1.7–2.2 years.

10.22.3.1 Orbiter Missions Not Implementing Aerocapture

Orbiter missions that do not implement aerocapture have to use their propulsion system to insert into orbit around the planet. The simplest way to compare windows is to consider as a baseline for all missions the launch strategy from a Moon-crossing orbit described in Section 10.22.2.1, which provides the best mass budget on Mars and Venus transfer trajectories. The spacecraft propulsion system is used both to leave Earth orbit and for orbit insertion. Therefore, high departure or arrival velocities have a comparable impact in terms of total ΔV (next to last column of Tables 4 and 5). Assuming a 3.1 km s^{-1} ejection velocity for the spacecraft thruster, this can be translated into an available mass in orbit by applying the rocket equation [3], to the launch capability in a large bound orbit for a given launcher (Soyuz–Fregat for the last column in Tables 4 and 5).

After capture in a long-period orbit (8 days for Mars Express), it is possible to reduce the period of the orbit by implementing thrust at pericenter. 2.96 km s^{-1} of additional ΔV is required to go down to a circular orbit around Venus at an altitude of 300 km, and 1.41 km s^{-1} of additional ΔV is required to reach a circular orbit around Mars at an altitude of 300 km. Splitting the maneuver over many pericenters (eight for Mars Express) limits gravity losses to a few m s^{-1}, as each thrust arc is short, close to the optimum altitude.

From Table 4, the 2005 window to Venus was attractive in terms of departure velocity, but it was relatively poor in terms of arrival velocity. This was not a major issue as the orbital period could not be shorter than 1 day due to constraints on eclipse duration imposed by the reuse of the Mars Express spacecraft.

From Table 5, the 2003 window to Mars stands out as one of the best over 20 years. With a direct injection by Soyuz–Fregat, the Mars Express spacecraft (1050 kg after releasing the 70 kg

Table 4 Launch windows to Venus for Venus Express (10/2005) from 2013 to 2018

Launch	V_{dep} (km s^{-1})	*Launch declination*	*ΔV/Moon*	*Arrival position*	*Arrival date*	V_{arr} (km s^{-1})	*ΔV/V_{esc}*	*ΔV, total*	*Mass (kg)*
Coplanar approximation	2.500		0.338			2.710	0.357	0.695	1287
2005/10/31 (II)	2.780	26.4° S	0.404	L_s 249°	2006/04/07	4.653	1.019	1.423	1017
2013/10/30 (II)	2.795	26.6° S	0.408	L_s 250°	2014/04/06	4.730	1.052	1.459	1006
2015/05/21 (II)	2.480	9.7° N	0.333	L_s 78°	2015/10/27	3.780	0.683	1.017	1160

The type of transfer (I or II) is indicated. The ΔV at departure is evaluated assuming an indirect launch from a Moon-crossing orbit. The ΔV at arrival is evaluated for a marginal capture at an altitude of 300 km. The mass in orbit is evaluated for a Venus Express-type launch (Soyuz–Fregat from Baikonur: no penalty for declination up to 46° N or S).

Beagle II module) could brake down to a 6.7 h polar orbit, which required 1.5 km s^{-1} of ΔV including a plane turn, leaving 70 kg of reserve fuel in the tanks on top of the 570 kg dry mass. The 2005 window is among those delivering the lowest mass in Mars orbit (20% less than in 2003, representing, e.g., 170 kg of fuel). This was one of the arguments against flying a new mission to Mars as a follow-up to Mars Express, selecting instead Venus Express, successfully launched in October 2005. The exploration program of ESA was initially considering a rover mission in the 2013–15 time frame (it has since then been significantly delayed). As the present design is based on a large rover ('ExoMars'), this mission belongs to the category of in situ missions, which will be considered next. Orbiter missions may be required after 2010 so as to provide relay capability. In this respect, 2013 is poor and 2016 is bad, and the next good window after 2011 is in 2018.

The mass budget of orbiter missions can be markedly improved by aerobraking. This method involves shallow atmospheric passes, which slowly reduce the semimajor axis starting from a highly elliptical capture orbit. The impact on spacecraft design is significant, but far less severe than for aerocapture. Solar panels pick up most of the strain. They have to be symmetrical and relatively robust, but no heat shield is required. This method was first implemented for the Mars Global Surveyor (MGS) mission of 1998 (Albee et al., 2001), then for Mars Odyssey in 2000 (Smith and Bell, 2005), and in late 2006 for the MRO mission, which was launched in August 2005. Aerobraking was definitely required for MRO as it is a large spacecraft, while the 2005 window is poor. If one goes all the way down to a circular orbit, which is the case for both MGS and MRO, nearly 1.4 km s^{-1} of ΔV is saved, which corresponds to a factor of 1.57 in terms of mass budget (actually closer to 1.7 if one takes into account the additional mass of tanks and structure). There is a drawback: as each pass has to be gentle, the orbit reduction takes a long time. The science phase of the mission was therefore delayed by 6 months for MRO, and it was delayed by 1 year for MGS, due to a nonnominal configuration of one of the solar panels. There is some risk involved, and the aerobraking phase requires a high level of monitoring, with a significant impact on operational cost. Aerobraking has yet to be implemented by ESA, but it should definitely be considered for large orbiters in low orbits around Mars or Venus.

10.22.3.2 In Situ Missions and Orbiter Missions Implementing Aerocapture

For in situ missions (landers, rovers, balloons, etc.) or orbiter missions implementing aerocapture, an entry module with a heat shield dissipates the approach energy. The control of a trajectory deep in an atmosphere is a complex problem, which is beyond the scope of this chapter. It is extensively discussed for Earth reentry trajectories (see, e.g., Vinh and Kuo, 1997; Willcockson, 1999; Wu et al., 2001) and for other planetary bodies (see, e.g., Justus et al., 2005; Scoon et al., 1991; Tu et al., 2000. There is a narrow entry corridor for aerocapture: If the minimum altitude is too high, the velocity remains above escape, and the spacecraft leaves the planet. If the minimum altitude is too low, the velocity drops below the circular velocity, and the spacecraft falls on the planet. The latter case is what is required for an in situ mission. However, if the entry is too steep, the heat flux may overcome the dissipation capability of the shield, and the mission is lost. The energy corresponding to the escape velocity at the surface (10.3 km s^{-1} for Venus and 5.1 km s^{-1} for Mars) has to be dissipated anyway; hence, the mass that is required for the heat shield depends only weakly on the approach velocity: the range of specific energies to be dissipated is 57–64 MJ kg^{-1} for Venus (see, e.g., Craig and Lyne, 2005) and 16.5–20.5 MJ kg^{-1} for Mars for the full range of approach velocities in Tables 4 and 5. Therefore, for such missions, the most important parameters are the departure performances, which can be defined from columns 3 (declination) and 4 (ΔV at departure from a bound orbit) of these tables. For such types of missions, a window with a low departure velocity and a high arrival velocity becomes attractive, and the type I window to Venus in 2018 would be selected (3.1 km s^{-1} at departure) instead of the type II window (3.7 km s^{-1} at departure), while the latter would provide more mass for an orbiter with chemical insertion. ESA has

demonstrated its capability to deliver a surface station to Titan with the Huygens mission, with an entry velocity of 6 km s^{-1} very similar to Mars entry velocities. Typically, half of the mass of an entry module is available as useful mass on the surface, as demonstrated by missions such as Huygens (ESA) or the 2004 Mars rovers (NASA). Launchers such as Atlas/Centaur (NASA) or Ariane 5 (ESA) can deliver 4000 kg to Mars, making it possible to deploy a large surface module. The Mars Science Laboratory (MSL) mission of NASA, launched in 2011, is an example of such ambitious undertakings with its 800 kg 'Curiosity' rover. A combination of a large relay orbiter (1 t) and test descent module launched in 2016 and a larger entry and descent module launched in 2018 is now the baseline for the ExoMars mission of ESA's exploration program, to be implemented in collaboration with Russia. Similarly to Venus and Mars, aerocapture provides the most effective strategy for other planetary bodies with a significant atmosphere. It is in particular likely that a post-Cassini mission to Titan will have to implement such a strategy (e.g., Spilker, 2005).

10.22.4 Orbit Evolution Around Planetary Bodies

For all orbiter missions, the evolution of the orbit with time is a critical aspect of science operations, as it defines which regions can be observed and the local time (a critical parameter for cameras and near-IR spectrometers, which rely on solar photons).

The perturbations of the orbit by the Sun play only a minor role except for highly eccentric orbits. The main effect is a change in the minimum altitude, which has to be compensated if it decreases so as to avoid impacting the planet. When approaching a planet at a low velocity, the combined gravitational pull of the Sun and the planet can provide for free a capture in a weakly bound orbit. These three body effects are important for planetary systems, in particular for the Earth–Moon system (Belbruno and Miller, 1993; Knezevic and Milani, 1998).

High-order terms of the gravity field of the planetary body are most important for orbits closest to the target body. They result in a precession of the intersection of the orbit plane with the equatorial plane (defined by the position of the ascending node Ω) and a precession of the pericenter (defined by the angular distance from the ascending node to the pericenter ω) for elliptical orbits. The quadrupolar term of the gravity field, J_2, plays the most important role. It is linked to the oblateness of the planetary body. The evolution of Ω and ω as a function of J_2 and orbital elements (see, e.g., Hechler et al., 2005) is the following:

$$p = a\left(1-e^2\right) \quad [9]$$

$$\dot{\Omega} = -\frac{3}{2} n J_2 \left(\frac{R_m}{p}\right)^2 \cos i$$
$$\dot{\omega} = \frac{3}{4} n J_2 \left(\frac{R_m}{p}\right)^2 \left(4 - 5\sin^2 i\right) \quad [10]$$

where R_m is the radius of the planetary body, a is the semimajor axis, e is the eccentricity, n is the mean motion of the spacecraft on its orbit (inversely proportional to $a^{1.5}$), and i is the inclination. For circular orbits, the parameter (p in eqn [9]) is equal to a, and the precession of the plane is inversely proportional to the semimajor axis$^{3.5}$.

A specific case of interest is the Sun-synchronous orbit, with a full rotation of the orbit plane in exactly one orbital period of the planetary body around the Sun. With such an orbit, the local time remains approximately constant. This is a desirable feature for cameras and IR imaging spectrometers as observations on successive orbits are made with the same illumination conditions. With the value of J_2 for the Earth (0.001082), an inclination of 97.8° is needed for a circular orbit at 600 km altitude from eqn [9]. A Sun-synchronous orbit has been selected for NASA missions orbiting Mars on a low circular orbit, such as MGS and MRO. The J_2 value for Mars (0.001965) is larger than that of the Earth and the orbital period of Mars is 687 days, so that a lower value of $\cos(i)$ is required for Sun-synchronous orbits. The inclination of MGS (altitude ~400 km) is 92.9° and that of MRO, which reached a circular orbit at an altitude of ~300 km in November 2006, is 92.7°. MRO crosses the equator in mid-afternoon (3 PM) on average. However, the rate of precession is constant, while the angular motion of Mars is 45% larger at perihelion (1.382 AU) than at aphelion (1.666 AU) due to Kepler's 2nd law. As a consequence, the local time at the equator varies from 2 h15 to 3 h 45 PM during one Martian year. The variations in local time are only 2 min for Sun-synchronous orbits around the Earth due to the low eccentricity of its orbit (0.0167).

The precession of the pericenter of an elliptical orbit around Mars such as that of Mars Express is defined by eqn [10]. This precession provides opportunities for observing each latitude range at the highest possible resolution. However, combining the rotation of the planet around the Sun, the precession of the orbit plane and the precession of the pericenter so as to optimize the science return are a complex problem (Hechler et al., 2005), in particular when both dayside observations (for imaging experiments) and nightside observations (for the MARSIS radar) are required at low altitude. The orbit evolution of the selected orbit is presented in **Figure 2**. It provides deep excursions of the pericenter over the sunlit side (L_s 135°, L_s 315°, and L_s 90° in 2006) and shallow excursions of the pericenter beyond the terminator (L_s 90° and L_s 225°).

Venus has a very small oblateness, which can be attributed to its very slow rotation rate. Therefore, precession was neither an issue nor an asset for orbiter missions to Venus such as Magellan (NASA) or Venus Express (ESA). The pericenter of the highly elliptical orbit of Venus Express will therefore remain at high northern latitudes for the full science mission. The value of J_2 for Mercury as measured by Messenger (NASA) from orbit is significantly higher than that inferred from the Mariner 10 flybys. The resulting precession is negligible for the highly eccentric orbit of Messenger of that of the Mercury Magnetospheric Orbiter of BepiColombo (ESA/JAXA). Due to this revised evaluation of the gravity field, the mission profile of the Mercury Planetary Orbiter of BepiColombo, which has a low eccentricity (0.16), had to be redesigned so as to optimize observation conditions and to prevent collision with the planet.

10.22.5 In Situ Missions to Atmosphereless Bodies

In situ missions to atmosphereless bodies represent a specific challenge, as one cannot rely on an atmospheric entry module. The only solution for landing safely on the surface consists in

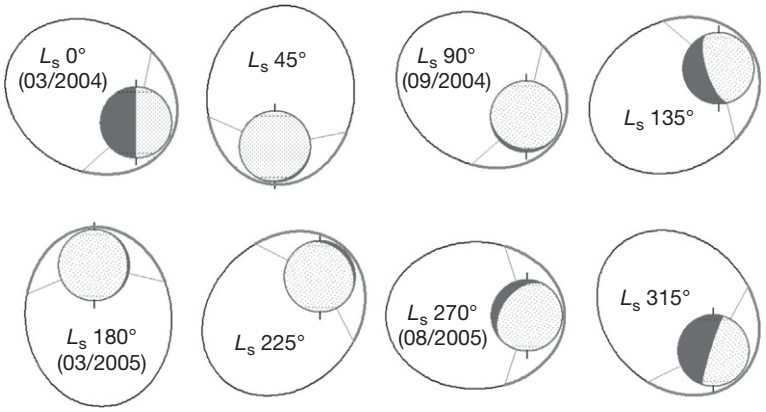

Figure 2 Evolution of the orbit of Mars Express during the first Martian year of science operations (nominal mission). For each heliocentric longitude L_s, Mars is shown as seen from a direction perpendicular to the orbit, the dotted regions being sunlit. The pericenter rotated 1.22 times around the planet during one Martian year, so that each band of latitude was observed at least twice at the lowest altitude (~280 km) at different local times.

Table 6 Escape velocity and surface gravity of large atmosphereless bodies

	Mercury	*Moon*	*Io*	*Europa*	*Ganymede*	*Callisto*	*Vesta*	*Ceres*
Size (km)	4880	3470	3640	3120	5280	4820	540	945
V_{esc} (km s^{-1})	4.257	2.376	2.560	2.030	2.741	2.440	0.370	0.515
g (m s^{-2})	3.700	1.622	1.800	1.320	1.430	1.235	0.260	0.280

using an onboard propulsion system. A soft landing is in many ways similar to a launch in reverse. There is one piece of good news: contrary to a launch, the mass decreases as the landing module gets near the surface; hence, the acceleration from the thrusters increases, while the acceleration from gravity remains nearly constant. Again, similarly to a launch, a landing requires a ΔV that is larger than the escape velocity (or the orbital velocity at pericenter if the lander is released from orbit). The propulsion system has to land itself. A large thrust level requires more mass for thrusters. Conversely, if the thrust is low, there are gravity losses and a larger fraction of the thrust is wasted in the final stages fighting the local gravity.

Atmosphereless solar system bodies of interest are comets, asteroids, KBOs (among them Pluto and probably Triton), small natural satellites, six of the seven largest natural satellites (the Moon, Io, Europa, Ganymede, Callisto, and Triton), and one planet (Mercury). Landing on a cometary nucleus a few km across is a difficult navigation problem, but it is not a mass budget issue, as escape velocities are only in the range of meters per second. There is no survey mission planned yet for Pluto or Triton; therefore, an in situ mission to KBOs is far in the future. The most relevant issues are therefore that of landing on Mercury, the Moon, Galilean satellites, and large asteroids such as Vesta.

Table 6 shows the escape velocity and surface gravity of relevant large atmosphereless bodies. From this table, it is clear that in terms of total ΔV, there is not much difference between a soft lander (a few m s^{-1}), a semihard lander with airbags (~50 m s^{-1}), and a penetrator (up to 100 m s^{-1}), with the exception of asteroids such as Vesta or Ceres.

From Table 6, Mercury, while not the largest atmosphereless body, is in a class by itself in terms of landing: The surface gravity is more than twice that of any other atmosphereless body, and the energy to be dissipated is 2.35–4 times larger than that required for Galilean satellites. The mass budget required for a lander is therefore very large.

With its ion propulsion stage (see Section 10.22.7), BepiColombo approaches Mercury on a weakly bound orbit. The chemical propulsion stage sets the composite into the orbit of the eccentric orbiter (MMO). A release of a landing module was considered at this stage during the early study phases. The key issue is the fraction of the mass of the landing module, which can reach the surface, and the smaller fraction, which is left for lander systems and payload ('useful mass'). A simple landing strategy, close enough to optimum for this order of magnitude analysis, consists in tilting the thrust toward the center of the planet so that the vertical component balances gravity together with the remaining centrifugal force. The remaining horizontal component is used to reduce the orbital velocity. The critical parameter is the acceleration level at approach. Table 7 indicates the thrust time, total ΔV (evaluated from approach), and mass breakdown of a landing module using this strategy with initial acceleration levels between 0.75 and 2 m s^{-2}.

As expected, a larger thrust level provides a larger landing mass as less time is spent fighting the 3.7–3.8 m s^{-2} of local gravity. A useful mass of 50 kg for 5–10 kg of science payload can be considered as a minimum. With an initial acceleration level of 1.5 m s^{-2}, the useful mass has to be multiplied by ~16 (1/0.064) to obtain the initial mass. Therefore, a minimum mass of 800 kg (margins excluded) is required for the landing module and the corresponding fuel for orbit insertion. The results of this simplified analysis are fully consistent with that of the ESA study for the BepiColombo mission to

Table 7 Elements of a mass budget trade-off for a Mercury lander resulting from the simple landing strategy presented in the text

Initial acceleration	0.75 m s^{-2}	1 m s^{-2}	1.5 m s^{-2}	2 m s^{-2}	∞
Thrust time (s)	3660	2640	1650	1200	0
Total ΔV (km s^{-1})	6.70	5.88	4.99	4.62	4.24
Mass on the surface	0.115	0.150	0.200	0.227	0.255
Propulsion system	0.028	0.038	0.056	0.075	NA
Tanks and structure	0.089	0.085	0.080	0.077	NA
Useful mass	−0.002	0.026	0.064	0.075	NA

The total mass on the surface, the mass of the propulsion system, the mass of tanks and structure, and the useful mass are expressed as a fraction of the mass of the landing module at approach.

Mercury. The large mass allocation required was a key element in the decision to descope the landing module in mid-2003.

Other large atmosphereless bodies provide much more favorable constraints for a lander. It turns out that a 1 m s^{-2} acceleration level at approach is adequate for all these bodies. Table 8 provides the minimum mass of a landing module for a 50 kg smart lander, which controls its trajectory to the ground.

The important role of surface gravity is demonstrated by the slightly more favorable mass budget for Ganymede than for Io, while its escape velocity is significantly larger (2.74 km s^{-1} instead of 2.65 km s^{-1}, Table 6). Even with more conservative assumptions, it is clear that a landing module on these bodies (in particular Europa) can be considered for a mass budget not exceeding 200–250 kg at approach. This mass budget has of course to be multiplied by the proper factor from the rocket equation [3], to account for ΔV expenditures from Earth departure to approach at a low velocity.

Table 8 Mass of the landing module on a low-velocity approach to four medium-sized atmosphereless bodies of interest, which is needed to implement a smart lander with a useful mass of 50 kg, assuming a 1 m s^{-2} acceleration level at approach on a weakly bound orbit

	Moon	*Io*	*Europa*	*Ganymede*
Impulsional ΔV (km s^{-1})	2.37	2.57	2.03	2.75
Actual ΔV (km s^{-1})	2.93	3.17	2.40	3.12
Mass on the surface	0.387	0.359	0.460	0.365
Propulsion system	0.038	0.038	0.038	0.038
Tanks and structure	0.061	0.064	0.054	0.063
Useful mass	0.289	0.257	0.368	0.264
Mass of landing module	173 kg	194 kg	136 kg	189 kg

Similarly to **Table 7**, masses are expressed as a fraction of the initial mass on such an orbit.

10.22.6 Gravity-Assist Missions: Giant Planets, Mercury, Asteroid, and Comet Rendezvous

As demonstrated in Section 10.22.2.1, flyby missions to giant planets and Mercury and rendezvous missions to comets require departure velocities higher than 7 km s^{-1}, which are difficult to reach with large useful masses by a direct launch or an indirect launch strategy. A wide range of missions to these bodies became possible by using gravity-assist strategies.

A planetary gravity assist consists in passing close to a planet so as to change the trajectory of a spacecraft. In the planetary referential, energy must be conserved; hence, the relative velocity at departure is the same as the relative velocity at arrival. However, the planetary encounter can rotate this relative velocity by an angle that increases with the mass of the planet and decreases with the distance at closest approach. The benefit appears in the heliocentric referential: passing behind a planet significantly increases the heliocentric velocity (Figure 3). In such a case, the planet has provided additional orbital energy to the spacecraft in the heliocentric referential. Similarly, passing in front of the planet reduces the orbital energy without expenditure of onboard fuel.

The geometry of the swingby is defined by the relative velocity at arrival V_{rel} and the minimum approach distance R_p compared to the radius R of the planetary body and the circular velocity V_c at the surface (a factor of $\sqrt{2}$ smaller than the escape velocity V_{esc}). V_c is directly linked to the gravitational potential of the planet GM. The determination of the semimajor axis (a) and eccentricity (e) of the hyperbolic trajectory around the planet is straightforward from Newton's equations of motion:

$$GM/R^2 = V_c{}^2/R$$
$$a = -GM/V_r^2 = R(V_c/V_{rel})^2$$
$$e = 1 - R_p/a$$

The true anomaly v of the asymptote is defined by

$$1 + e\cos(v) = 0$$

The angle of rotation θ is

$$\theta = 2v - \pi$$

The relationship between the rotation angle θ, the minimum distance R_p, and the relative velocity V_r can then be established, as well as the change in velocity ΔV:

$$\theta = 2a\sin(1/e) = 2a\sin\left(1/\left(1 + R_p/R(V_{rel}/V_c)^2\right)\right) \quad [11]$$

$$\Delta V = 2V_{rel}/\left(1 + R_p/R(V_{rel}/V_c)^2\right) \quad [12]$$

From eqn [12], the maximum theoretical ΔV provided by the planet is equal to V_c. It is obtained for $V_{rel} \sim V_c$ and $R \sim R_p$. From Table 9, any planetary encounter can provide a large ΔV for free. This is also the case to a lesser extent for large natural satellites (Table 6).

The first approach that can be considered is the ΔV gravity assist (ΔVGA), which increases the effectiveness of the available onboard ΔV by a large factor by combining a deep space maneuver with a gravity assist by the Earth (see, e.g., Casalino et al., 1998). ΔVGA strategies can also be used with other

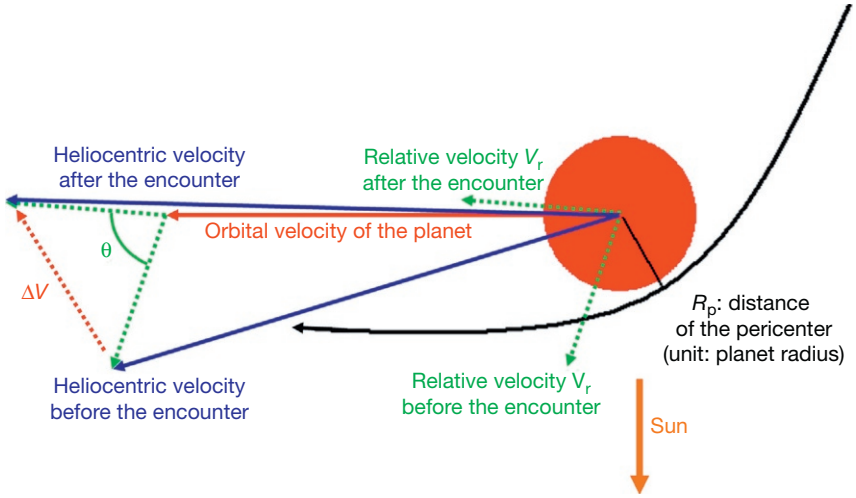

Figure 3 Example of a planetary gravity assist, which increases the orbital energy of a spacecraft in the heliocentric referential. The spacecraft passes over the trailing side. The gravitational pull of the planet rotates the relative velocity at arrival (mostly inbound) in the forward direction at departure, when it adds up to the orbital velocity of the planet. The resulting heliocentric velocity is therefore larger. Such an encounter is included in any ΔVGA strategy.

Table 9 Equatorial radius and circular velocity of planets, corresponding to the orbital velocity on a grazing circular orbit

	Mercury	*Venus*	*Earth*	*Mars*	*Jupiter*	*Saturn*	*Uranus*	*Neptune*
Radius (km)	2440	6050	6380	3400	71 000	60 000	25 500	25 000
V_c (km s^{-1})	3.01	7.33	7.91	3.55	42.1	25.1	15.1	16.6

planets or natural satellites. A ΔVGA strategy can be associated to any resonant orbit that goes back to the Earth after a given number of revolutions. The departure velocity is parallel to the Earth velocity (either forward or backward). The deep space maneuver is performed close to aphelion, reducing the semimajor axis for orbits with periods larger than 1 year, and close to perihelion, increasing the semimajor axis for orbits with periods smaller than 1 year. As a result of this maneuver, the relative velocity when returning to the Earth increases by a much larger amount than the ΔV spent in the maneuver. This is due to the relationship between energy (E) and angular momentum (M) at pericenter ($p = 1$ AU) and apocenter (q). The heliocentric velocity at departure V_p is tangential to the orbit of the Earth. As a function of the eccentricity e, we have for an outbound orbit, following the presentation of Langevin (2005),

$$\begin{aligned} a &= 1/(1-e) \\ q &= (1+e)/(1-e) \\ \Delta M &= q\Delta V = (1+e)/(1-e)\Delta V \\ V_p &= V_e(1+e)^{0.5} = V_e + V_{rel} \end{aligned} \quad [13]$$

where V_e is the heliocentric velocity of the Earth and V_{rel} is the departure velocity:

$$\begin{aligned} V_q &= V_p(1-e)/(1+e) \\ \Delta E_q &= V_q\Delta V = -V_p(1-e)/(1+e)\Delta V \end{aligned} \quad [14]$$

When returning to 1 AU (assuming a resonant orbit, so that the Earth is at the right place), the large reduction in angular momentum at aphelion results in a large reduction of the tangential velocity V_t with respect to its initial value (V_p):

$$V_t = V_p - (1+e)/(1-e)\Delta V$$

As the radial velocity is 0 at departure, if V_r is the radial velocity upon return, we have

$$\Delta E_p = 0.5\left(V_t^2 + V_r^2 - V_p^2\right)$$

For maneuvers that are small with respect to the heliocentric velocities, we can write

$$0.5\left(V_t^2 - V_p^2\right) = -V_p(1+e)/(1-e)\Delta V \quad [15]$$

There is an energy deficit at this stage, when comparing [15] and [14], which must be compensated by the radial component of the velocity V_r. Energy conservation leads to

$$\begin{aligned} \Delta E_p &= \Delta E_q \\ V_r^2 &= 2V_p\Delta V((1+e)/(1-e) - (l-e)/(1+e)) \\ V_r &= \left(8V_p\Delta Ve/(1-e^2)\right)^{0.5} \end{aligned} \quad [16]$$

As an example, for a 3 years' resonant orbit with a departure in January at 6.84 km s^{-1}, the eccentricity is 0.527, and the initial heliocentric velocity V_p is 37.14 km s^{-1}. The radial velocity at return is 2.16 km s^{-1} for a 22 m s^{-1} maneuver at aphelion and 4.60 km s^{-1} for a 100 m s^{-1} maneuver, close to the results of eqn [16]: 2.19 km s^{-1} and 4.67 km s^{-1}, respectively. These small differences can be attributed to the slight eccentricity of the Earth orbit. When evaluating the relative

velocity at Earth return, we have to combine this radial velocity with the tangential relative velocity, which is reduced by the same amount as the tangential heliocentric velocity. As long as V_r remains small with respect to V_{rel}, we have

$$dV_{rel}/\Delta V \sim 4V_p/V_{rel}\, e/\left(1-e^2\right) - (1+e)/(1-e) \qquad [17]$$

The relative velocity at return for a 22 m s^{-1} maneuver is 7.104 km s^{-1}, a velocity increment of 260 m s^{-1}, while eqn [17] would result in a velocity increment of 277 m s^{-1}. Even with such a small maneuver, the radial velocity upon return V_r (2.16 km s^{-1}) is already not that small with respect to V_{rel} (6.84 km s^{-1}). The efficiency of the maneuver decreases as the radial velocity at the Earth increases. Therefore, the ratio between the velocity increment and the ΔV (leverage factor) increases with the eccentricity of the orbit, and it decreases with the velocity gain, which is to be obtained.

A similar derivation for inbound orbits yields

$$V_p = V_e(1-e)^{0.5} = V_e - V_{rel} \qquad [18]$$

$$dV_{rel}/\Delta V \sim 4V_p/V_{rel}e/\left(1-e^2\right) - (1-e)/(1+e) \qquad [19]$$

For the same eccentricity e, an inbound ΔVGA is less favorable than an outbound ΔVGA, as V_p is now smaller than the heliocentric velocity of the Earth [18], contrary to the outbound case [13]. The negative impact of the lower V_p/V_{rel} ratio is not compensated by the reduced value of the second term of [19] compared with that of [17].

Flying over the trailing side of the Earth (for outer solar system missions) or the leading side of the Earth (for inner solar system missions) rotates the relative velocity so that it is nearly aligned with the orbital velocity of the Earth after the encounter (**Figure 3**). This is most effective for reaching distant targets. The increment or decrement in heliocentric velocity over that of the Earth is the effective velocity, as it is equivalent to the departure velocity, which would be provided by a direct launch in the direction of the heliocentric velocity of the Earth (or opposite to it for inner solar system missions). When the relative velocity is very large (9 km s^{-1} or more), a flyby at the lowest acceptable altitude (~250 km) is not able to fully rotate it to the optimum direction (see eqn [11]). The resulting effective velocity is then lower than the relative velocity, and the leverage factor decreases correspondingly. The most relevant examples are provided in **Table 10**. The launch ΔV is that that would have to be spent at the perigee of a Moon-crossing orbit so as to obtain the required departure velocity. For the cheapest orbit, an MGA can provide the required 1.1 km s^{-1} departure velocity (Farquhar, 1991), so that no additional ΔV is required.

The comparison between **Table 10** and **Table 1** demonstrates the potential of gravity-assist methods for the most demanding missions: a 9 km s^{-1} departure velocity required a velocity at perigee 3.29 km s^{-1} higher than that of a Moon-crossing orbit, which could not be achieved by a Fregat upper stage, and only marginally so with a Centaur upper stage. For such a high ΔV, a spacecraft engine burn around perigee (indirect launch strategy) would incur a staggering gravity loss. With a 2:1 ΔVGA, only 1.81 km s^{-1} is needed, with 1.26 km s^{-1} on the bound orbit so as to leave the Earth with a relative velocity of 5.28 km s^{-1} and 0.552 km s^{-1} as a deep space maneuver (for which there is no gravity loss). Using a 2:3 ΔVGA, only 1.71 km s^{-1} is needed to reach the 7.5 km s^{-1} negative velocity required for a direct Mercury flyby mission. With this approach, a spacecraft with a useful mass of about 1000 kg can be sent to Jupiter, a comet, or Mercury with the 2010 version of the Soyuz–Fregat (launched from Kourou). There is a penalty of 2 years in cruise time (hence a 5 years' cruise to Jupiter), which is a small price to pay as such missions are now feasible with classical propulsion methods.

It would seem possible to further improve the mass budget by using a series of ΔVGA maneuvers. However, for departure velocities lower than 4 km s^{-1}, there is not much to be gained from a ΔVGA. The total ΔV budget required for a departure at 3.41 km s^{-1} starting from a Moon-crossing orbit is 0.48 km s^{-1} for a 5:4 ΔVGA and 0.47 km s^{-1} for a 4:3 ΔVGA, a 100 m s^{-1} improvement over the 0.57 km s^{-1} ΔV required for a direct departure from a bound orbit (the gravity loss is small at such low departure velocities). The 3% improvement of the mass budget is definitely not appealing considering the 4–5 years' penalty in cruise time. Using a sequence of a 3:2 ΔVGA followed by a 2:1 ΔVGA for a Jupiter mission instead of a direct 2:1 ΔVGA is more attractive, as the ΔV reduction is now 0.42 km s^{-1} (1.26–0.84 km s^{-1}), actually ~600 m s^{-1} as gravity losses become quite significant for departure velocities in the range of 4 km s^{-1} or more. The improvement of the mass budget is ~20%, still a marginal proposition when considering the 3 years' penalty in terms of cruise time. The 1:1 ΔVGA is specific as the departure velocity can be provided by a Moon

Table 10 Characteristics of relevant ΔV gravity-assist launch strategies

Resonance	*Departure velocity (km s^{-1})*	*Launch ΔV (km s^{-1})*	*Eccentricity*	*Maneuver (km s^{-1})*	*Effective velocity (km s^{-1})*	*Total ΔV (km s^{-1})*	*Leverage factor*	*Additional cruise time (years)*

gravity assist. However, its leverage factor is low, and it is interesting only for low-thrust missions such as BepiColombo (see Section 10.22.7).

With ΔVGA strategies, missions to Jupiter, comets, and Mercury would be within reach even if there was no other planet in the solar system. As we have seen in Section 10.22.2, Venus and Mars are relatively easy to reach. Tapping the gravity-assist potential of these two planets much improves the mass budget for more difficult targets, but there are additional constraints as now the Earth, Venus or Mars, and the target body must be in the proper relationship.

Venus is particularly attractive as a stepping stone to the inner solar system as this planet is nearly as large as the Earth. Furthermore, it lies nearly halfway to Mercury in terms of both its semimajor axis (0.723 AU, when Mercury is at 0.387 AU) and its orbit plane (inclination of 3.39°, to be compared with the 7° inclination of Mercury's orbit). A close swingby of Venus changes the velocity by as much as 7 km s^{-1}, which is more than what can be provided by a single rocket stage. All missions to Mercury therefore include at least one swingby of Venus, with departure velocities from the Earth in the 3.5–4 km s^{-1} range, much lower than the 7.5 km s^{-1}, which would be required for a direct transfer. Indeed, the Mariner 10 flyby mission to Mercury was the very first mission to use a planetary gravity assist, with a launch in November 1973, a flyby of Venus in February 1974, and three flybys of Mercury in 1974 and 1975 (Shirley, 2003).

For rendezvous missions, two Venus swingbys are required (Yen, 1989). The shortest solutions involve the 1:1 resonance (period of 0.615 years); the cheapest solutions use the 3:4 resonance (period of 0.461 years, coming back to Venus after 1.84 years). A second swingby then sends the spacecraft to Mercury, which is reached after 1.5–3.5 full orbits around the Sun (Mercury is usually not at the best position for a transfer, which requires inserting 'phasing' orbits). The arrival velocity is ~5.8 km s^{-1} in the best cases. This is still far too high for an orbiter mission: the corresponding capture maneuver would be in the 3 km s^{-1} range and could not be accommodated in the short time available close to this small planetary body (2450 km in radius). Fortunately, a sequence of gravity assists can also be used for reducing the arrival velocity, with the same leverage factors as for pumping up the departure velocity.

This strategy is particularly effective for Mercury, which has a short orbital period (0.24 years). Mercury mission strategies developed by Yen (1989) involve a series of three ΔVGA (2:1, 4:3, and 6:5) with a total cost of 500 m s^{-1} and a duration of 12 Mercury periods (slightly < 3 years), which reduce the relative velocity at arrival from 5.8 km s^{-1} down to 2.2 km s^{-1}, at which stage an insertion maneuver to a highly elliptical orbit requires only 500 m s^{-1}. Mercury has no atmosphere. Therefore, one has to rely on the spacecraft engine to further reduce the orbital period. The total ΔV cost of a Mercury orbiter on a 10 h elliptical orbit is now in a manageable range (1.5–2 km s^{-1}), which brings more than 50% of the launch mass into orbit, but cruise durations now range from 5.6 years to more than 9 years depending on the Venus window and the Venus–Mercury relative positions. This strategy is that used by the Messenger mission of NASA (McAdams et al., 2006; Santo et al., 2001), launched in 2005 and orbiting Mercury since 2011 (Figure 4).

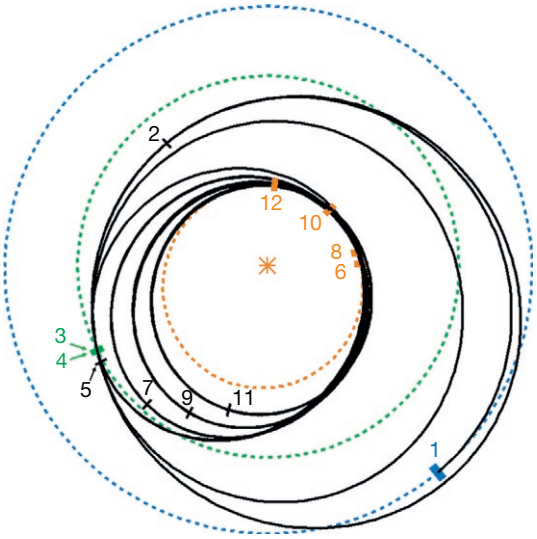

Figure 4 Messenger mission to Mercury, launched in August 2005, with an insertion in Mercury orbit in March 2011. After the launch at 4.05 km s^{-1} (1) and a deep space maneuver (2) that increases the relative velocity to Venus, two Venus swingbys are implemented (3,4). A small maneuver (5) is needed to reach Mercury (6). After the first flyby of Mercury (6) with a relative velocity of 5.8 km s^{-1}, a 3:2 ΔVGA (6–7–8), a 4:3 ΔVGA (8–9–10), and a 6:5 ΔVGA (10–11–12) are implemented. These three maneuvers lower the relative velocity to 2.2 km s^{-1} at a cost of only 500 m s^{-1} in ΔV (but more than 3 years in cruise time). The insertion maneuver into Messenger's elliptical orbit is now at an acceptable level (870 m s^{-1}).

Mars is not a very useful stepping stone to the outer solar system, as its mass is much smaller than that of Venus (the maximum ΔV available from a Mars gravity assist is ~3 km s^{-1}). Furthermore, the orbit of Mars is much closer to that of the Earth than to that of Jupiter. Conversely, Jupiter has such a large circular velocity (42 km s^{-1}) that it can sling the spacecraft toward any target in the outer solar system if the relative position is favorable. The Voyager 1 mission, launched in 1977, took advantage of a perfect configuration to visit Jupiter, Saturn, Uranus, and Neptune from 1980 to 1989, using each planet as a stepping stone to the next target. This favorable configuration repeats only once in 170 years. Given the relative periods of Jupiter (11.9 years) and Saturn (29.6 years), a favorable configuration between Jupiter and Saturn repeats every 19.8 years. The next visit to Saturn, the Cassini–Huygens mission, was launched in 1997, 20 years after Voyager, and the next programmatically realistic opportunity corresponds to launches in 2035–36. In the 18 years' intervals without Jupiter stepping stone opportunities, missions to Saturn must rely on gravity assists of inner planets combined with deep space maneuvers.

Indeed, the best use of the gravity potential of Venus and Mars for outer solar system missions is to replace the deep space maneuver by a gravity assist in an Earth–Earth ΔVGA. One can then reach large departure velocities from the Earth without expending any onboard ΔV, which much improves the mass budget (see, e.g., Longuski and Williams, 1991; Petropoulos et al., 2000).

A Mars flyby is most effective when providing the deep space maneuver in a 3:2 Earth ΔVGA scenario. The cheapest opportunity, with a departure velocity of ~3.2 km s^{-1}, occurs every 2.1 years, and the Earth return is 2.8 years later at a relative velocity of 9 km s^{-1} (Hechler, 1997). A 2 years' intermediate orbit can be needed so as to adjust the inclination. The cruise time is then increased by 5 years. A version of this strategy was used for the 2004 launch of Rosetta by Ariane 5. An initial 1:1 ΔVGA was added so as to optimize the launch declination while increasing the relative velocity from 3.4 to 3.85 km s^{-1} (**Figure 5**). With this strategy, the total ΔV is only 1.68 km s^{-1}, and the useful mass in rendezvous is 1400 kg, which makes it possible to implement a large orbiter and a lander on the comet nucleus. The drawback is a very long cruise time (10.5 years). This trade-off between mass budget and cruise time, already encountered for Mercury orbiter missions, is inherent to gravity-assist strategies: given enough time, very little is impossible.

A Venus gravity assist can provide for free a very large ΔV (up to 7 km s^{-1}). Therefore, a Venus flyby is already quite effective when used as the maneuver in a 1:1 Earth ΔVGA. Indeed, every 1.61 years, it is possible to depart to Venus with a velocity of 3.2–3.7 km s^{-1}, swing by Venus at a very safe distance, and then return to the Earth after 1–1.3 years with a relative velocity of 7.5–10 km s^{-1}, which is in the range required for reaching Jupiter and Saturn (see **Table 2**). The period of the return orbit is very close to 1 year. Hence, this large relative velocity is nearly perpendicular to the orbital velocity of the Earth, when the maximum rotation angle from an Earth flyby at this velocity as derived by eqn [11] is only 40°–50°. Therefore, a first Earth gravity assist is used to transfer the spacecraft to an orbit with a 2 years' period, during which a small maneuver can be implemented so as to further increase the relative velocity (2:1 ΔVGA). The second Earth gravity assist sets the spacecraft on its way to Jupiter or to the target comet. The cruise time is 3 years longer than for a direct transfer, but the low departure velocity provides large mass budgets (5 t approaching Jupiter with Ariane 5). This strategy was first implemented for sending the Galileo spacecraft into orbit around Jupiter (Damario et al., 1992), as it was much larger (1.6 t dry mass and 2.55 t at departure) than Pioneer or Voyager. Another example of such a scenario is the JUICE mission to the system of Jupiter launched in June 2022, which has been selected as the next large mission of the science program of ESA (**Figure 6**). Ariane 5 has strongly reduced launch capabilities away from the optimum declination (0°–5° South) as its third stage cannot be reignited. This increases the cruise time of JUICE by 1 year (up to 7.6 years) as one has to launch in June 2022 on a 1-year orbit at the optimum declination and then return to Earth 1 year later so as to rotate the relative velocity to the departure declination of 20.2° S required for reaching Venus in late November 2023. Europe approved in November 2012 the development of a restartable third stage for its new generation of launchers, which will much improve the capabilities of this launcher for planetary missions.

A different type of Venus–Earth gravity-assist strategy followed by a Jupiter swingby was used for the Cassini–Huygens mission to Saturn and Titan launched in 1997 (Peralta and Flanagan, 1995). A mission to Saturn ('Tandem') was considered as an alternative to JUICE in the selection process of ESA.

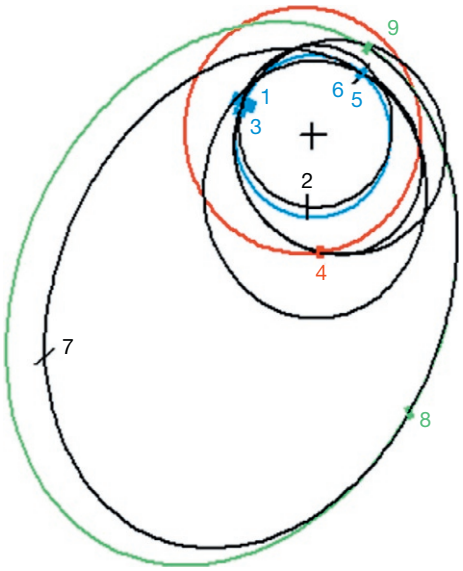

Figure 5 Trajectory of the Rosetta spacecraft to comet Churyumov–Gerasimenko (green orbit). After a launch by Ariane 5 in late February 2004 with a departure velocity of 3.4 km s^{-1} (1), a 1:1 ΔVGA maneuver (2) increased the relative velocity at the Earth to 3.85 km s^{-1} (3); a 3:2 Earth–Mars–Earth gravity assist (3–4–5) increased the velocity of the Earth encounter to 9.35 km s^{-1} (5); a sequence of 2 Earth flybys (5 and 6) is required to tilt the orbit so as to match the inclination of the comet. Two deep space maneuvers (7 and 8) totaling 1.45 km s^{-1} implement the rendezvous at 3.7 AU from the Earth in September 2014 (8). The comet is followed until perihelion (9) in October 2015 in the nominal mission.

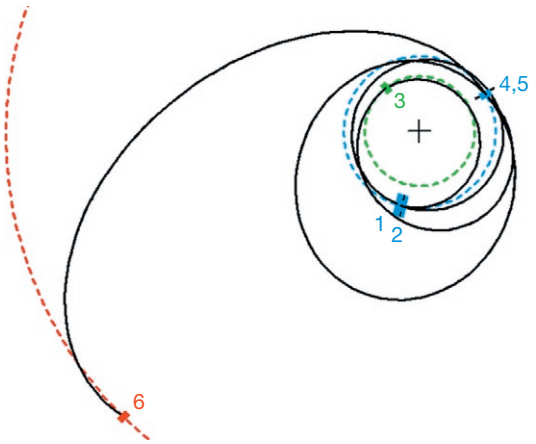

Figure 6 Nominal trajectory (Earth–Venus–Earth–Earth gravity assist) for JUICE, a mission to the Jupiter system selected in April 2012 as the large mission of the 'Cosmic vision' program of ESA. The launch at 3.32 km s^{-1} in June 2022 (1) is performed at the optimum declination for Ariane 5. A first swingby of the Earth 1 year later (2) sends the spacecraft to Venus. The Venus swingby (3) increases the relative velocity to 9.41 km s^{-1} when returning to the Earth (4). A third Earth flyby after 2 years (5) sends the spacecraft to Jupiter, which is reached in February 2030 after 7.6 years (6). Reproduced from Boutonnet A and Schoenmakers J (2012) Mission analysis for the JUICE Mission. *Advances in the Astronautical Sciences* 143: 1561–1578.

For launches in the 2020–25 time frame, Jupiter is too far ahead on its orbit to be of any use, and 'direct' Earth–Venus–Earth–Earth ΔVGA strategies to Saturn had to be considered. A small ΔVGA maneuver on a 4 years' orbit following the 2 years' orbit makes it possible to reach Uranus (Arridge et al., 2012) with a large spacecraft without relying on a Jupiter gravity assist, but the actual departure from the Earth is then 7.6 years after launch and the cruise time becomes extremely long (~15 years).

Gravity assists provide very effective means of exploring the environment of a planet if one or more large natural satellites are present. A remarkable example is the 4 years' tour of the Saturn system by Cassini (Wolf and Smith, 1995), with its 50 flybys of Titan, the largest satellite of Saturn. All other major satellites are visited, the rings are observed at close range, and high latitudes in the magnetosphere are explored. This tour has been extended until 2017, with more than 50 additional flybys of Titan and other satellites. The Jupiter system provides outstanding opportunities (Longman and Schneide, 1970) with its four Galilean satellites (Io, Europa, Ganymede, and Callisto), all with a large gravity-assist potential as escape velocities are larger than 2 km s^{-1} (**Table 6**); hence, velocity changes of 1 km s^{-1} or more can be achieved at no cost other than navigation corrections. This was already demonstrated by the Galileo mission of NASA (Damario et al., 1992). A complex sequence of ΔVGA and gravity-assist strategies between Galilean satellites can be implemented in relatively short times, as the period of Ganymede (third from Jupiter) is only 7.16 days instead of 365.25 days for the Earth (third from the Sun). Io, Europa, and Ganymede are tied by the Laplace resonance (periods close to 1:2:4), while the orbital period of Callisto is 16.7 days, 2.35 times that of Ganymede. The issue of windows from Ganymede to Callisto and back (an essential element of the JUICE strategy, as demonstrated by **Figure 6**) was addressed by Langevin (2010). An important constraint for designing the JUICE strategy (Boutonnet and Schoenmakers, 2012) was the integrated radiation dose, which increases very fast when the trajectory gets significantly closer to Jupiter than the orbit of Ganymede near the equatorial plane of the system.

An effective scenario has been designed (Boutonnet and Schoenmakers, 2012) for inserting the JUICE spacecraft in orbit around Ganymede after visiting Europa and then Callisto (Io flybys could not be considered due to the impact on radiation dose). This 2.6 years' tour (**Figure 7**) implements 11 Ganymede flybys, 13 Callisto flybys, and 2 Europa flybys before insertion in an elliptical orbit around Ganymede with an acceptable radiation budget. The available dry mass is 1800 kg (including 20% of system margins) with an Ariane 5 launch.

10.22.7 Advanced Propulsion Systems: Solar Sail and Ion Propulsions

Gravity-assist techniques presented in **Section 10.22.6** have made possible a wide range of missions, which would have been out of reach of a direct launch strategy. It is therefore interesting to present the arguments for new propulsion

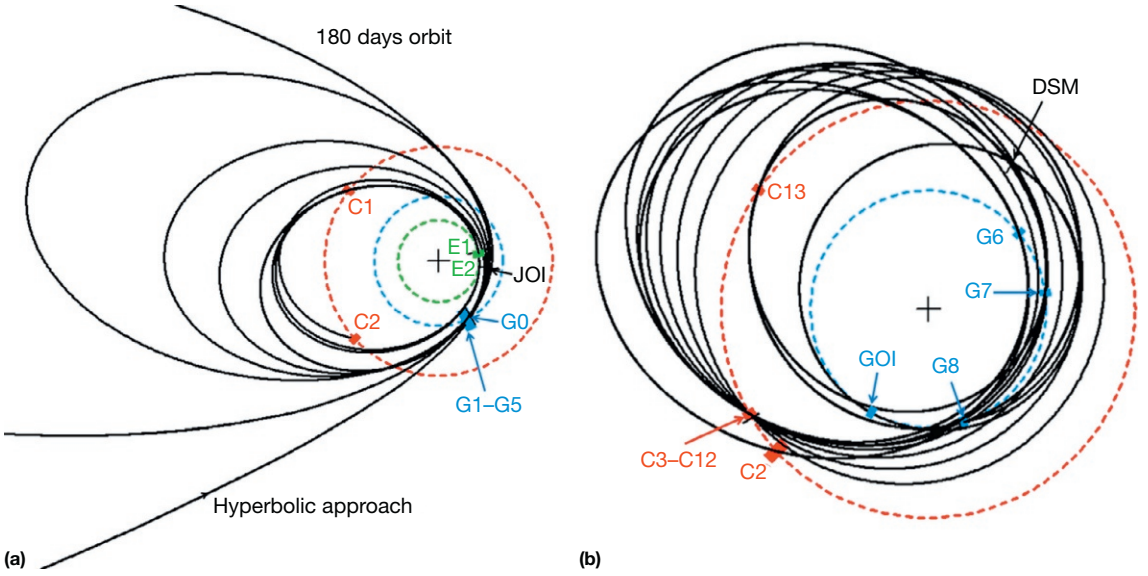

Figure 7 (a) Early stages of the Jupiter satellite tour of JUICE: a Ganymede swingby (G0) before Jupiter orbit insertion (JOI) reduces the JOI ΔV from 1.2 to 0.9 km s^{-1} for reaching a 180-day orbit. 5 Ganymede swingbys (G1–G5) and a small apocenter maneuver reduce the period of the orbit to $<$20 days. A sequence of two flybys of Europa (E1 and E2) bracketed by two flybys of Callisto (C1 and C2) can then be implemented. (b) Late stages of the tour: A Ganymede gravity assist (G6) reduces the relative velocity at Callisto from 4.9 km s^{-1} (C2) to 4.4 km s^{-1} (C3); a series of 10 polar swingbys (5 over the South pole and then 5 over the North pole) crank the inclination of a 16.7 days orbit (1:1 resonance with Callisto) up to 30° and then back to the orbital plane of the satellites; gravity assists by Ganymede (G7) and then Callisto (C13) reduce the relative velocity to $<$1.7 km s^{-1} at return to Ganymede (G8). A Ganymede–Ganymede ΔVGA approach ('DSM') on a 4:3 resonant orbit (G8 → GOI) is presented, which reduces the ΔV cost of Ganymede Orbit Insertion (GOI). A more complex strategy with two additional Ganymede flybys saves even more fuel. Reproduced from Boutonnet A and Schoenmakers J (2012) Mission analysis for the JUICE Mission. *Advances in the Astronautical Sciences* 143: 1561–1578.

techniques. It should first be noted that several missions of interest remain nearly impossible or require very long cruise times:

- Rendezvous with a small body (asteroid or comet) if the perihelion is not close to 1 AU or if the inclination exceeds 15° (the rendezvous maneuver exceeds the 3 km s^{-1} limit); this is the case for all main belt asteroids and all but a few comets.
- Rendezvous missions to Uranus, Neptune, and KBOs (including Pluto).

An additional problem is the exceedingly long cruise time, with an impact on the risk/reliability trade-off (hence cost). The relevance of missions designed 20 years before the science return is obtained is also an issue. Such missions cannot benefit from the latest advances in instrument design. They cannot adjust to new discoveries from other solar system exploration missions. Furthermore, there is an important programmatic risk, as other space agencies may try to steal the fire out of the mission with a smaller, faster mission. As an example, NASA programmed and then canceled a comet lander mission, which would have arrived 5 years earlier than the lander of Rosetta. The complexity of the Rosetta mission strategy (**Figure 6**) and that of the JUICE mission strategy (**Figure 7**) demonstrates that gravity-assist techniques have reached their limit with classical propulsion systems.

The only solution for improving this situation is a major increase in onboard ΔV capability, which requires increasing the ejection velocity V_{ej}. There is, however, a catch. The thrust T is

$$T = \mathrm{d}m/\mathrm{d}t \cdot V_{ej} \quad [20]$$

where $\mathrm{d}m/\mathrm{d}t$ is the mass flux in kg s^{-1}. The corresponding power W is

$$W = 0.5\,\mathrm{d}m/\mathrm{d}t \cdot V_{ej}^2 \quad [21]$$

hence,

$$W = 0.5 V_{ej} T \quad [22]$$

For a given thrust, the required power is therefore proportional to the ejection velocity. Large ejection velocities are appealing as they reduce the fuel mass for a given ΔV, but one must be aware of the larger corresponding energy requirements.

10.22.7.1 Solar Sail Propulsion

The 'photon drive' (e.g., a laser) is popular in science fiction novels, and it provides the highest possible ejection velocity (c, the speed of light). At relativistic speeds, the relationship between energy and thrust is less favorable than that given in eqn [22], as we have

$$W = cT \quad [23]$$

From eqn [23], an effective power of 300 MW would be required for a modest 1 N thrust (420 MW onboard power if the conversion efficiency is ~70%). Unless one considers direct mass–energy conversion (yet another science fiction favorite), the only realistic propulsion method using photons consists in implementing a solar sail, which reflects solar photons. This looks very appealing, in particular for very demanding missions such as sample returns (Hughes et al., 2006), as the photons are provided for free by the Sun; hence, there is no mass expenditure whatever the total ΔV. However, the available power at 1 AU is 1400 W m^{-2}; hence, a 200 000 m^2 sail (nearly 500 m × 500 m) is required for a 1 N thrust level. A maximum of 2 g m^{-2} for the sail and structure is required so as to keep the mass of the sail below 1000 kg. Furthermore, reflective properties must be maintained against high radiation levels for the full cruise phase (Edwards et al., 2004). Due to these difficulties, no solar sail mission has yet been flown. Several test missions have been considered by NASA and ESA, but the first test of solar sail propulsion is yet to be approved.

10.22.7.2 Ion Propulsion

Accelerating ions instead of molecules (ion propulsion) provides ejection velocities in the 15–100 km s^{-1} range, which are much higher than that provided by chemical thrusters (3.1 km s^{-1} for onboard systems). The best propellant is a heavy noble gas, such as Xenon. There are two methods for accelerating ions: the expansion of a hot plasma generates ejection velocities in the lower part of the range (15–20 km s^{-1}). With a high-voltage grid, it is possible to accelerate individual ions to velocities in the 30–100 km s^{-1} range. Higher ejection velocities require less propellant for a given ΔV. However, the required installed power increases with ejection velocity, which has an impact on the mass of the power subsystem. Electric energy can be obtained in space either from solar panels (solar electric propulsion, SEP) or from a small nuclear reactor (nuclear electric propulsion, NEP).

At 1 AU, a solar panel provides ~280 W m^{-2} with a 20% efficiency, which is already quite good. This corresponds to 26 mN with a 15 km s^{-1} ejection velocity and 8 mN with a 50 km s^{-1} ejection velocity, assuming an efficiency of 70% for the ion acceleration process. A SEP propulsion system is therefore limited to relatively small thrusts (in the range of 100–200 mN at 1 AU); otherwise, the solar panels become very large, which has an impact in terms of mass and cost. A 200 mN thrust seems very small, but if it is sustained over 1 year, it can provide 3.15 km s^{-1} of ΔV to a 2000 kg spacecraft. SEP missions are therefore characterized by very long thrust arcs.

SEP systems have been successfully tested by NASA (DS-1, which encountered comet Borelly), ESA (Smart-1, in orbit around the Moon from early 2005 to 2006; Racca et al., 2002), and Japan (Hayabusa, which performed a rendezvous with asteroid Itokawa in 2005 then returned to Earth in 2010). Two major missions have already been programmed: Dawn, launched in 2007 by NASA, has successfully reached 4 Vesta in July 2011 and has departed in September 2012 to Ceres after 1 year of observations of Vesta from orbit. BepiColombo (ESA/Japan) is a dual-orbiter mission to Mercury, which will be launched in 2016 (Benkhoff et al., 2010).

Even if onboard ΔV is more plentiful than with chemical missions, gravity-assist strategies can also be quite interesting for SEP missions, as demonstrated by the evolution of the mission scenario for BepiColombo, which initially included two orbiters and a lander. The very first studies considered a

direct spiral from the orbit of the Earth down to the orbit of Mercury of a large composite spacecraft with all three science modules. Even with an Ariane 5 launch, this required more than 16 km s^{-1} of ΔV with relatively high thrust levels (400 mN) and a 2.5 years' cruise time. These requirements exceeded the lifetime of thrusters, so that full spares were needed with a drastic impact on the cost and mass budgets, and this option was abandoned. Inserting a double Venus swingby reduced the ΔV by ~7 km s^{-1}, and a final 180° transfer from Mercury to Mercury, followed by a 1:1 ΔVGA, saved an additional 1.5 km s^{-1} (Langevin, 2000), so that the ΔV budget went down to a manageable level of ~7.5 km s^{-1} (Figure 8).

The mass requirements of subsystems rose much faster than usual during the early phases of the study (in particular for a Mercury lander; see Section 10.22.5), and cost became an issue. Two Soyuz–Fregat launches were considered, one for the lander and one for the two orbiters. The largest mass is then obtained by launching on a Moon-crossing orbit (~2200 kg).

The cost restrictions on cornerstone missions led in 2003 to the cancelation of the lander, which required a full Soyuz launch with a dedicated cruise module and ion propulsion module (see Section 10.22.5). The new configuration of the mission consisted of two orbiters launched by a single Soyuz–Fregat. Unfortunately, subsystem mass (in particular that of the SEP stage) continued to grow, which led to a major mass crisis, and ESA had to switch to an Ariane 5 launch (4100 kg launch capability, to be compared with 2200 kg for Soyuz–Fregat). New scenarios had to be considered so as to further reduce ΔV (hence fuel mass) with a thrust to mass ratio much less favorable than for early mission profiles. The present class of trajectories (Figure 9) looks quite similar to a ballistic mission such as Messenger (Figure 4) as more work is done by gravity assists (Earth, Venus, and Mercury) than by SEP thrust. Actually, 35% of the ΔV is spent accelerating the spacecraft (green arcs) instead of braking it (red arcs) contrary to the spiral-like approach initially considered (Figure 8). Thanks to the low fuel consumption of electric propulsion at the selected ejection velocity (45 km s^{-1}), more than 3400 kg of the 4000 kg launched in a Moon-crossing orbit can be delivered at a very low relative velocity to Mercury, but the cruise time ranges now from 6.4 to 7.8 years (it was only 2.6 years with Ariane 5 when the mass budget was much more favorable).

The evolution of BepiColombo illustrates the remarkable flexibility of electric propulsion: contrary to chemical propulsion missions, the large onboard ΔV capability makes it possible to adjust to major changes in mass budgets or launch dates. The combination of gravity assists with low thrust is extremely effective, as the initial ΔV budget of 16 km s^{-1} could be reduced to ~4.5 km s^{-1}, albeit with a significant increase in cruise time (from 2.6 to 6.4 years). Additional information on SEP optimization methods can be obtained from Chesta et al. (2006), while the navigation aspects of BepiColombo are addressed by Yarnoz et al. (2006) and Alessi et al. (2012).

SEP is only effective relatively close to the Sun. The Dawn mission, which implements a rendezvous with Vesta, at

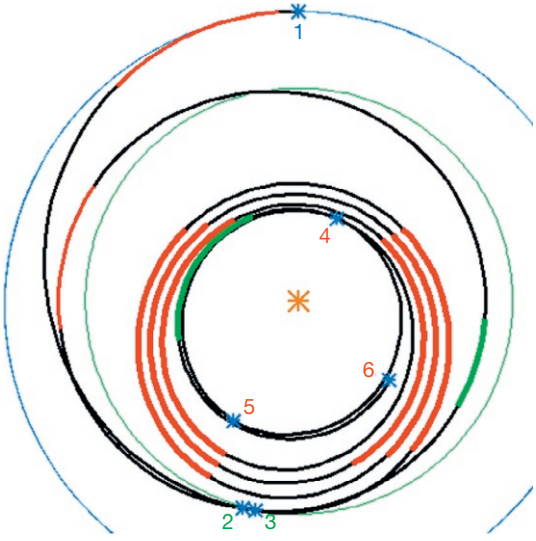

Figure 8 Direct launch option by an Ariane 5 for the BepiColombo mission to Mercury in late 2009. The departure velocity of 2.5 km s^{-1} is increased by early thrusting with the ion engine, so as to reach Venus with a relative velocity of 4.5 km s^{-1} (2). A 1:1 Venus ΔVGA increases the relative velocity to 5.7 km s^{-1} (3). After a three-orbit spiral, Mercury is reached at a relative velocity of 2.7 km s^{-1} (4). A 180° transfer (4–5) and then a 1:1 Mercury ΔVGA (5–6) reduce the relative velocity to $<$400 m s^{-1}. Red arcs correspond to thrust against the orbital velocity; green arcs correspond to thrust along the orbital velocity. The cruise time is 2.6 years. Reproduced from Langevin Y (2000) Chemical and solar electric propulsion options for a cornerstone mission to Mercury. *Acta Astronautica* 47: 443–452.

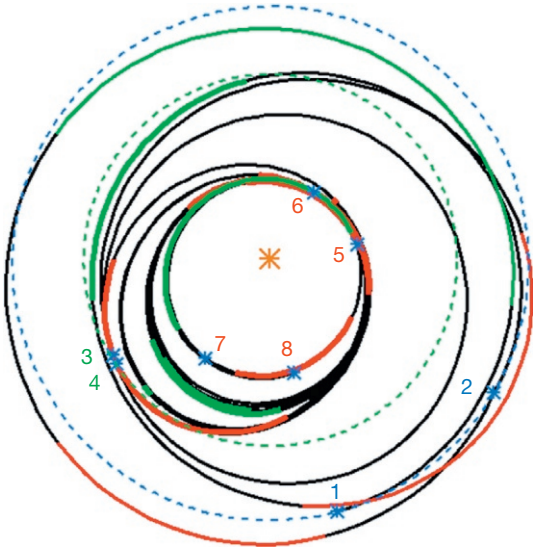

Figure 9 Example of a class of low ΔV SEP transfers to Mercury with an Ariane 5 launch, which constitutes the new baseline for BepiColombo (now scheduled for a launch in 2016). The two thrust arcs on the 1:1 orbit from departure (1) to the Earth swingby (2) effectively increase the relative velocity (1:1 ΔVGA). The Earth swingby provides the large declination (37° S) required for reaching Venus on a type 3 transfer. The two Venus swingbys combined with some braking thrust (red arcs) make it possible to reach Mercury (5). A ΔVGA (green arcs) on a 5:4 orbit (5–6) combined with braking arcs near perihelion reduces the relative velocity to Mercury down to 1.8 km s^{-1}. A 180° transfer (6–7) further reduces it to 1.2 km s^{-1}, at which stage an end-game strategy using 3-body effects (Jehn et al., 2008) cheaply inserts the BepiColombo composite in orbit around Mercury (8).

2.4 AU, and then Ceres, at 2.8 AU, already requires very large solar panels. Therefore, SEP is totally inappropriate for outer solar system missions. Nuclear reactors are the only power source that can provide several 10 kW at large distances from the Sun, so as to power ion thrusters (NEP). The smallest nuclear reactors provide several 100 kW, with a mass of several tons. The scale of NEP missions is daunting: JIMO, the mission to Galilean satellites, which was extensively studied in 2000–05, consisted of an 8 t spacecraft, with 5 t for the reactor and shield, and a thrust of 8 N. In the outer solar system, a JIMO level acceleration (1 mm s^{-2}) far exceeds the gravitational pull of the Sun (0.23 mm s^{-2} at 5 AU). Therefore, trajectories are non-Keplerian, which makes it possible to reach Saturn, Uranus, or Neptune in a fraction of the time, which would be required on a Hohmann transfer orbit (8 years for Saturn and 29 years for Neptune). Such fast trajectories require ΔV budgets >20 km s^{-1}, as one has to accelerate and then brake at arrival. Fortunately, ejection velocities can be very high (~100 km s^{-1}) as there is a lot of available power; hence, 20 km s^{-1} of ΔV only uses up ~20% of the mass as fuel. The cancelation of JIMO by NASA in 2005 was a severe setback for NEP, which is undoubtedly an enabling technology for a systematic exploration of the outer solar system beyond Saturn.

10.22.8 The Specific Challenges of Sample Return Missions

Implementing a sample return mission is a very challenging task, as one can consider it as a rendezvous mission followed by its mirror image. This view is to a large extent correct. However, there are some mitigating circumstances. First of all, the Earth has a dense atmosphere, which is quite capable of braking sample return modules at large velocities. It is 'only' required to set the spacecraft (or the sample return capsule, provided that it can survive alone) on a trajectory that intersects that of the Earth. In terms of ΔV budget, one gets rid of the huge cost of leaving the sphere of influence of the Earth. However, one has to launch from the target body.

Asteroids and comets represent relatively easy targets for a landing and sample collection, as escape velocities are either low or negligible. A specific case is constituted by the Stardust mission, which brought back samples from comet Wild-2 in early 2006. After a launch in early 1999, a 2 years' ΔVGA maneuver increased the relative velocity so that an Earth gravity assist in January 2001 set Stardust on its way to Wild-2 on an orbit with a period of nearly 2.5 years. The samples were collected at a high velocity (6.1 km s^{-1}) during a flyby in early 2004, and a small maneuver was then required to encounter the Earth in January 2006, 5 years after the Earth gravity assist, after two full orbits. Due to the high impact velocity, only very small grains can be captured relatively unaltered. For a comet nucleus sample return (once the baseline of Rosetta that was then considered in collaboration with NASA), two large maneuvers are needed so as to rendezvous with the comet and then leave it toward the Earth. Figure 5 illustrates the specific difficulty of implementing a comet nucleus sample return with a chemical propulsion mission: cheap rendezvous strategies arrive after aphelion, and by symmetry, cheap returns depart before aphelion. One would need to wait nearly a full orbit around the comet. Hence, the duration would be that of a rendezvous mission plus 6 years (typical period for a comet) plus 3 years for the return, for a total of 15–20 years. Much shorter sample return missions can be achieved with ion propulsion, as the rendezvous then occurs after perihelion; hence, the return trip can be initiated almost immediately (e.g., Kawaguchi, 2002). An example is given in Figure 10 for comet Wild-2. It constitutes a first illustration of the mirror-image character of the return trip. The 1:1 ΔVGA loop after launch can be skipped for the return leg as there is no need to reduce the relative velocity to the Earth, which will be cheaply dissipated in the atmosphere of our planet.

The very first SEP sample return mission has been the Japanese Hayabusa missions. After a launch in 2003, it achieved its rendezvous with asteroid Itokawa in September 2005. Contact with the spacecraft was lost and then recovered after many attempts. SEP again proved its versatility as a new return strategy could be found, and a few mg of asteroid dust could be recovered in 2010. As Itokawa is an Earth-crossing asteroid, the ΔV budget was relatively low. The Japanese space agency (JAXA) has scheduled a reflight (Hayabusa 2) to a primitive Earth-crossing asteroid (162173 1999JU3), which will be launched in late 2014. A sample return from a main belt asteroid would have similar requirements ($\Delta V \sim 10$ km s^{-1}) and the same mirror spiral trajectory as a sample return from a cometary nucleus.

Among large bodies, the Moon is by far the easiest target for a sample return mission. It has a relatively low escape velocity and surface gravity (see Table 6), which more than offset the lack of an atmosphere. Furthermore, the trip to the Moon and back is very cheap: a Moon-crossing orbit is obviously adequate. The approach (or departure) velocity is 0.8 km s^{-1}, so that the ΔV for reaching or leaving a low circular lunar orbit from a transfer orbit is only 0.8 km s^{-1} (the two are equal by coincidence). Table 8 shows that the ratio between the mass approaching the Moon and the landed mass is in the 3.5–4

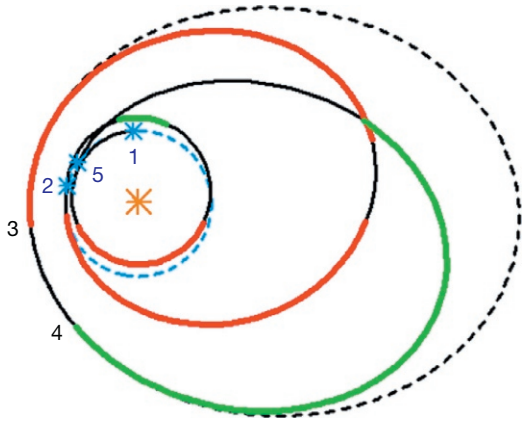

Figure 10 SEP comet sample return mission to Wild-2. A lunar swingby in December 2022 provides a departure velocity of 1.4 km s^{-1} (1). A two-arc 1:1 ΔVGA increases the relative velocity to 5.9 km s^{-1} (2). Rendezvous (3) is achieved in September 2021 by accelerating nearly continuously for 2.5 years (red arcs). After 3 months near the comet, the SEP propulsion system is reactivated, braking during 3 years (long green arc) so as to deliver the return capture in February 2031. The total ΔV is an acceptable 10.14 km s^{-1}; the round-trip duration is 9.14 years.

range, with a similar ratio between the mass leaving the lunar surface and the mass escaping toward the Earth. Therefore, a 50 kg return capsule requires only about 800 kg approaching the Moon, with one rocket stage for landing and one rocket stage for departure (similarly to the Apollo Landing Module). Indeed, the soviet missions Luna 16, Luna 20, and Luna 24 of the 1970s are until now the only successful automatic sample return missions from a large body (including a 2 m deep core), at a small fraction of the cost of the Apollo program.

The next easiest targets for a sample return mission are expected to be the two planets that are easiest to reach for a rendezvous, Mars and Venus. In both cases, it is possible to use aerobraking at arrival, which improves the mass budget. However, Mars and even more so Venus are large planets, with escape velocities of 5.02 km s^{-1} and 10.36 km s^{-1}, respectively.

The escape velocity of Mars is even larger than that of Mercury (4.26 km s^{-1}). As we have seen in **Section 10.22.5**, such levels of ΔV are almost out of reach of a single stage. Trade-offs for such a mission are presented in Donahue et al. (2006). The circular velocity (3.553 km s^{-1} at the surface) is more manageable, as it is closer to the exhaust velocity of bipropellant propulsion systems. The logical scenario for a Mars sample return mission is therefore that that was considered for a joint mission between NASA and several European countries (France, Germany, Finland, etc.) before its cancelation in 2002:

- A large orbiter spacecraft is launched toward Mars, where it implements an aerocapture maneuver into a low circular orbit so as to maximize the mass in orbit. It carries the return capsule.
- A large direct entry module is launched independently. It carries a small surface to orbit module. Once on the surface, samples are collected and then transferred to the surface to entry module, which sends a small sample cannister in orbit.
- The orbiter collects the sample cannister, which is transferred to the sample return module.
- When the return window opens, the sample return module is launched toward the Earth.
- The sample cannister is recovered after a direct entry into the Earth atmosphere.

Figure 11 provides an example of a Mars sample return mission launched in late 2013. The symmetry of the mission design is immediately apparent. The ΔV budget for the return is in this case very low (2.03 km s^{-1} from a circular orbit to a departure velocity of 2.5 km s^{-1} toward the Earth). A mass budget of ~200 kg is probably achievable for the sample return module. Arrival at Mars (2) is during southern summer storm season, which is not a problem for the orbiter, but may constitute a risk for the lander. A launch in September 2013 with one full additional orbit around the Sun arrives earlier in the seasonal cycle, but the Mars operational sequence would need to be completed in 2 months so as to catch the end of the return window in early 2016, and even then the departure velocity would be 3.5 km s^{-1}, with a higher ΔV 2.5 km s^{-1} (plus gravity losses) for the sample return module.

Venus is a relatively easy case for the round-trip issue. **Figure 12** gives an example of such a mission launched in late 2016, which takes nearly 2 years. The problem is that Venus is almost as large as the Earth (escape velocity of 10.35 km s^{-1} instead of 11.78 km s^{-1}). The hot and very thick atmosphere (90 bars at the surface, 450 °C) adds to the difficulty. At arrival, one can use aerocapture so as to retain a large fraction of the mass budget in low circular orbit or on the ground. At departure, the sample return module will need a ΔV of 3.36 km s^{-1} (plus gravity losses) from a low circular orbit, which requires by itself a large propulsion system. Recovering anything from the surface is a major issue: This is energetically similar to a launch in Earth orbit, with mass ratios higher than

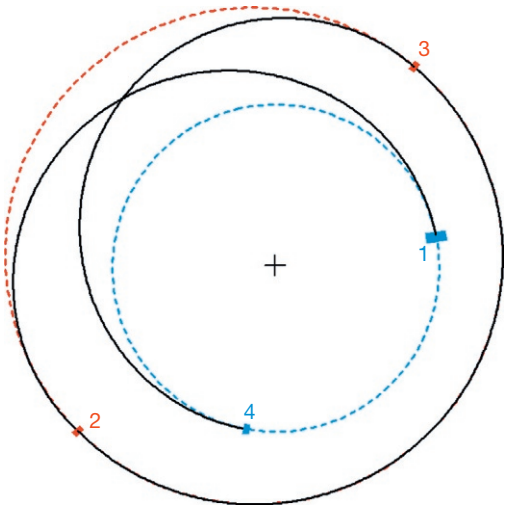

Figure 11 Favorable window for a Mars sample return mission, with a launch (1) in October 2024 (departure, 3.35 km s^{-1}, and Mars approach, 2.46 km s^{-1}). A type II transfer reaches Mars in September 2025 (2). One must wait 0.9 years at Mars (2–3), so as to reach a favorable type II return window, departing in August 2026 (3) at 2.68 km s^{-1} and delivering the sample in June 2027 (4), with a low Earth approach velocity (3 km s^{-1}). The nearly symmetrical round-trip takes 2.7 years.

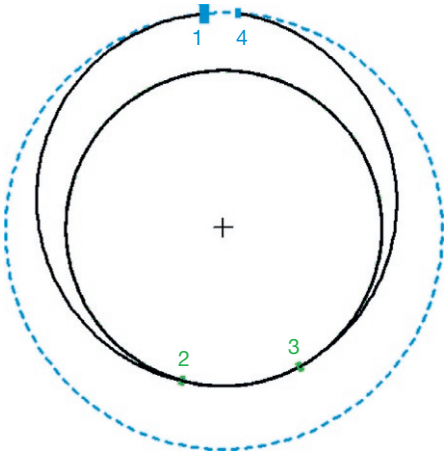

Figure 12 Venus sample return mission launched in January 2025 (departure velocity: 2.8 km s^{-1}). A type I transfer reaches Venus in April 2025. One must wait more than two full periods of Venus (1.2 years from 2 to 3) so as to reach a favorable type I return window, with a departure in August 2027 at 2.9 km s^{-1} and a sample delivery in December 2027, with a low approach velocity (4.25 km s^{-1}). The round-trip takes slightly <2 years. The symmetry between the departure and return legs is readily apparent.

20, but the launcher has to start under the equivalent of 900 m of water (400 m at the top of Maxwell Montes, the highest mountain of Venus). Until now, the record of survival at the surface, held by a Soviet Venera lander, stands at 2 h. It is therefore clear that enabling high-temperature technologies need to be validated by successful long-duration in situ missions (see, e.g., Landis, 2006) before addressing the daunting mass budget challenges of a Venus sample return mission from the surface itself. Recovering a sample from the upper atmosphere is a much less challenging task (Sweetser et al., 2003).

When considering the major technical issues, which had to be solved for an ambitious orbiter mission to Mercury and the very large mass budget required to land any useful mass on the surface, a sample return from Mercury appears very far-fetched indeed, unless solar sail technology becomes mature (McInnes, 2003). The same applies to large natural satellites of giant planets, where major steps in terms of orbiter mission and in situ studies need to be achieved before a sample return can be considered. Therefore, the most likely targets for sample return missions in the foreseeable future are small bodies (asteroids and comets), the Moon, and Mars, even if one cannot exclude a return of a sample of the upper atmosphere of Venus.

10.23.1 Introduction

The bodies making up our solar system are usually divided into different groups (see **Chapter 10.01**). Often, we simply distinguish between inner and outer planets, moons, and small bodies, namely, comets and asteroids. However, if we wish to find ways to investigate these bodies through planetary exploration missions, we need to first identify those of their basic properties that are relevant for the definition of the mission. Different solar system objects need different study strategies and therefore different types of instrumentation. Specifically, we have to distinguish between the measurements needed to understand

- terrestrial planets and large moons with atmosphere;
- terrestrial planets and large moons without atmosphere;
- giant planets and their environment, for example, Jovian magnetosphere, Io torus, and Saturn rings;
- dwarf planets and trans-Neptunian objects (TNOs);
- small bodies without atmosphere, for example, asteroids and small moons;
- comets; and
- interstellar and interplanetary dust particles.

Apart from the obvious need to design an exploration mission to any of these objects in accordance with the conditions expected during the transfer from Earth to the object and at the object's location (e.g., thermal and radiation environment), the mission scenario and scientific instrumentation need to be specifically tailored to the properties of the object itself. For instance, the requirements are very different for landing on a terrestrial planet or a small body with low gravity. Similarly, the requirements on exploring an airless body are very different from those required for a body with a thick atmosphere. In addition, the selection of the mission scenario depends decisively on what we already know of the object(s) from other investigations and past missions. For example, if a certain object has been visited and studied by remote-sensing techniques from orbit to an extent that no epoch-making results can be expected from another remote-sensing mission, the logical next step should be to obtain *in situ* measurements. Depending on the type of body, the *in situ* measurements would involve the study of the atmosphere, surface/subsurface, or both.

Generally, one can distinguish between three broad classes of measurements, namely, remote sensing, environmental sensing, and *in situ* sensing. For missions to solar system bodies (planets, moons, asteroids, and comets), remote sensing, even from Earth, would usually be the first step of any investigation. Remote sensing from a spacecraft largely benefits from the simple fact that the measurements can be obtained very close to the object to be investigated, rather than from observatories on Earth or in Earth orbit. Typical remote-sensing instruments would cover the classical measurement triangle: spatial (imager)/spectral (spectrometer)/intensity (radiometer). In addition, any mission focusing on remote sensing of a solar system body from orbit or during a flyby would also include a number of instruments for environmental sensing of any existing plasma or magnetosphere around the object. For the next step, *in situ* measurements, the choice of mission scenario, and payload depends critically on the object to be investigated, as well as on which aspect of this target shall be studied. For example, if we wish to perform *in situ* measurements of the atmosphere of a body, the requirements for the mission will be very different from those for *in situ* investigations of the (sub)-surface composition. For the latter, it is mandatory to actually land on the object under investigation, while the former might for some objects (comets, asteroids, and planets/moons with exosphere) be accomplished by simply adding to the payload instruments with *in situ* measurement capabilities, such as mass spectrometers. In other cases, particularly for bodies with dense atmospheres, such as Venus, Titan, and the gas giants, an atmospheric entry probe is required. An overview is provided on possible instrumentation for various types of planetary exploration missions adjusted to the strategies required for the respective investigations.

10.23.2 Building on Past Missions

Spacecraft have visited each of the eight planets of our solar system, as well as a number of moons, comets, and asteroids. The levels at which certain objects have been investigated go hand in hand with the types of missions that have been conducted so far. At present, samples from the Moon and cometary dust have been returned to Earth. The Stardust mission has collected dust particles from the coma of comet 81P/Wild 2. The sample return capsule with the dust particles stowed into aerogel was safely returned to Earth on 15 January 2006 (Brownlee et al., 2006) and Hayabusa, launched in 2003, returned dust grains from Itokawa (Yoshikawa et al., 2010).

Few bodies have been investigated *in situ*. The thick atmospheres of Venus, Jupiter, and Titan were studied through atmospheric probes, whereas the thin but spatially hugely extended atmospheres of comets were investigated *in situ* by selected instruments capable of performing *in situ* measurements on flyby missions. For Venus and Titan, also the surface could be reached. The first landing on Venus took place in 1975 (Veneras 9 and 10). Almost 30 years later, the Huygens probe successfully reached the surface of Titan to return the first images of this unusual moon. After the first landing on Mars in 1976 (Vikings 1 and 2), the up-to-then tremendous interest in this planet (21 missions in 15 years) stagnated for about 10 years. Subsequently, Mars investigations suffered severely from a number of mission failures (six of nine missions failed between 1988 and 1999). However, Mars has become a prime target for comparative planetology and the search for the roots of life, and Mars exploration is nowadays regarded as one of the key elements in solar system studies (e.g., Hauber and Neukum, 2006). Mars is after the Moon within our solar system the most visited place, where the extended *in situ* investigation with landers and rovers is initiated.

The exploration of any solar system body usually includes investigations with global coverage, as well as dedicated *in situ* analysis and sample return from specific regions of particular importance. This general scheme is normally being followed for the first 'round' of space missions to a solar system body, although owing to technological constraints, their exploration has practically always started with flyby missions before global characterization from an orbiting spacecraft could be achieved. At present, the only object for which all the consecutive steps mentioned earlier have actually been performed is the Moon. However, even though several hundred kilograms of Moon matter have been returned to Earth for in-depth analysis, we recently have begun a return to the Moon for global mapping, even without landing, some 35 years after the lunar sample returns. Why? Actually, we are going back for various reasons. First, it has to be verified whether the results of the detailed physical and chemical analysis of the lunar samples in the laboratory indeed apply globally to the Moon and do not just reflect some odd behavior of the particular regions, for which samples were returned. Second, a lot of progress was made over the past 35 years in modeling the formation and evolution of

solar system bodies in terms of their accretion and subsequent alteration through endogenic and exogenic processes. These models have not yet been verified through detailed measurements, largely because appropriate instruments were not available in the 1970s. Finally, a lot of new knowledge has been gathered in recent years concerning, for instance, the presence of volatiles in polar regions. All these issues can only be addressed by returning to the Moon with innovative instrumentation. To fully understand how the existence of the Moon constrains our models for the formation and evolution of the terrestrial planets, we need knowledge on its global composition, interior structure, and thermal properties, such as the surface heat flow.

By now, Mercury, Venus, Mars, Jupiter, and Saturn have been explored from orbiting satellites; Uranus and Neptune were investigated in part through flyby missions, while Pluto is still awaiting its first encounter in July 2015. Messenger is orbiting Mercury; BepiColombo is under development (Benkhoff, 2013). Rosetta is approaching 67P/Churyumov–Gerasimenko to land on the comet nucleus. While we have had a number of asteroid and comet flybys, so far, a close study from orbit has only been taken on Eros and on Itokawa by the NEAR and Hayabusa missions, respectively. Hayabusa returned around 1500 grains from asteroid Itokawa, and the Dawn mission visited Vesta and is on its way to Ceres. Venus, Mars, Jupiter, and Titan have been investigated with *in situ* probes.

Of course, we all understand that due to financial constraints, only a very limited number of space missions can be conducted at all in the next few decades. It is therefore of utmost importance to plan these mission well ahead in terms of which targets need to be visited, in which time frame, and what measurements have to be obtained of any specific target in the near and long-term future. To be able to take these important decisions, one must review the results of past missions, with a view to establishing which questions have been answered and which have remained unanswered or have not yet been addressed and why. We then have to find the appropriate strategy with a view to covering as many of the important open issues as possible within the financial and technological constraints. This approach highlights in many cases that the scientific return from past missions simply reflects the technology limitations of their time. This is particularly valid with respect to sensitivity, as well as spatial and spectral coverage of remote-sensing instrument and the availability of *in situ* measurements, suggesting that progress in scientific research goes hand in hand with the progress made in the technology of scientific instrumentation, at least for space missions.

10.23.3 Exploration Strategies and Associated Techniques

The exploration of the different types of solar system objects involves different mission strategies, as well as matched instrumentations. This, however, does not mean that a dedicated mission is required every time to one target only. Missions have been designed to combine whenever possible investigations of several objects and to cover various aspects of the chosen targets. The Galileo mission flew past two asteroids before it had its encounter with Jupiter, and Rosetta did the same before encountering its target comet. The most famous example of taking advantage of rare, but extremely fortunate, geometric constellations in the solar system is Voyager 2 using the once-every-189-years alignment of the outer planets, which allowed this spacecraft to visit all outer giant planets. However, although science can greatly benefit from spacecraft visiting various targets by the side, the mission and payload were always optimized for the investigation of the main target, and in most cases, the additional scientific return was mainly limited to images of any additionally visited body.

Future exploration strategies should therefore take advantage not only of fortunate geometric circumstances but also of advances in technology of instrumentation, which includes sensor development, as well as low-resource approaches for support and control electronics. In the following sections, some considerations are presented for shorter-term and longer-term strategies for the exploration of the inner and outer solar system.

10.23.3.1 Exploration Strategies for Near-Future Perspectives

At this point in time, planetary space exploration includes missions to Saturn and Titan (Cassini/Huygens), Mars (Mars Express, Mars Reconnaissance Orbiter, Mars Exploration Rovers, Phoenix, and Curiosity), Venus (Venus Express), Mercury (Messenger and BepiColombo), Jupiter (Juno, Juice), the Moon (Smart-1, Chandrayaan, Chang'E, and Grail), and various comets (Rosetta and Stardust) and asteroids (Hayabusa and Rosetta). Some of these missions actually represent the realization of the 'next step' in a strategic exploration approach as defined earlier. For instance, Rosetta represents the 'next step' after cometary flyby missions; Cassini represents the return to the Saturn system after Voyager, with dedicated payload and with the Huygens probe for detailed *in situ* investigations of the Titan atmosphere. When reviewing the current and past missions in relation to the status of a repeated four-step exploration approach as outlined in Section 10.23.2 (flyby, orbiter, lander, and sample return), it becomes clear that for most targets (Mars, Venus, Mercury, asteroids, and comets) in the near future, missions will need to concentrate on further *in situ* investigations from landers (atmospheric entry probes in case of Venus) and the preparation of sample return missions. After Voyager and Galileo, it is obvious that we need to return and explore the Jovian system to obtain a clear understanding of Jupiter and its magnetosphere (Juno), as well as the Galilean moons (Juice). At some point, a decision is needed on which targets to concentrate on and what type of missions to design. Three scenarios are in principle competing candidates for near-term future missions:

- Exploration of the Jovian system
- Landing on terrestrial planets
- Sample and return from low-gravity environment

We will briefly introduce possible strategies for these three types of planetary missions.

10.23.3.1.1 Exploration of the Jovian system

A staggered approach is envisaged with the final goal of having explored the major aspects of the Jovian system in a detail that

allows us to understand the formation and evolution of the system as a whole, as well as of its individual components. The Juno mission (Bolton and The Juno Team, 2012), launched in 2011, is the next step in further exploring the Jovian magnetosphere and the gravitational field, followed by ESA's Juice mission, which is in preparation for launch in 2022 (Grasset et al., 2012). Owing to the hostile environment, particularly with regard to radiation, it is difficult to investigate the inner Galilean moons over a long time. The reasonable lifetime of a Europa Orbiter is limited to approximately 60–100 days once in Europa orbit owing to the extremely harsh radiation environment. Juice took the solution to have flybys at Europa, followed by a complex tour with many flybys at Callisto, and finally an insertion into an orbit around Ganymede, the largest moon in the solar system. Remarkably, both spacecraft (Juno and Juice) are solar-powered, avoiding nuclear power generators.

Following Galileo, a very interesting scientific contribution would be provided by a new Jovian entry probe, capable of penetrating the denser layers of the atmosphere, if possible up to a pressure of 100 bar. The Galileo probe entered a dry region of the Jovian atmosphere, preventing the assessment of critical key measurements such as representative O/H ratios. To avoid duplication, a different entry strategy is required, such as entering at higher latitude, and preferably with multiple probes. The orbits required for a high-latitude entry can, however, result in higher approach velocities, hence increasing the entry velocity of the probe. This will increase the heat load on the thermal protection structure, which is already stretched to the limit of current capabilities for equatorial entry of the Jovian atmosphere.

On the longer perspective, landing on the Galilean moons (Europa and Ganymede particularly) would provide a great opportunity for surface *in situ* investigation and potentially subsurface access (by means of drilling or melting probes), though technically challenging due to the high delta-v involved for transfer to the target and the landing on the surface. An alternative solution could be the deployment of hard penetrating probes, released by a flyby or orbiting spacecraft. But accounting for the high impact velocities and related high impact shocks, the possible deployed payload would be rather limited. Further advances in miniaturization of high g-load-resistant technologies could open this perspective.

10.23.3.1.2 Preparation of landing on terrestrial planets

Depending on the presence and the thickness of their atmospheres, the landing on the terrestrial planets requires different strategies. For atmosphereless bodies such as Mercury and the Moon, the decent and soft landing must rely solely on propulsion systems and air bags. For landing on Mars and Venus, on the other hand, the descent goes through the atmosphere, which requires an atmospheric entry shield. Closer to the surface, the deceleration process can be supported by parachutes and the touchdown by air-bag systems.

Mars has become the target of prime interest for landing and *in situ* exploration. In preparation for a landing mission to Mars, two aspects need to be considered in parallel. (1) A number of improvements of the existing entry decent and landing systems will secure the safe landing on Mars, including autonomous hazard avoidance and pinpoint landing capabilities. Improved navigation accuracies before release of the entry probes, active controlled reentry with compensation of the highly variable Mars atmosphere effects during the entry, and optimization of parachutes and landing systems will further improve the safety of the landing and allow for an increase of the scientific payload deployed on the surface and access to locations yet not reachable. (2) As the landing on Mars shall be the first step toward a sample return mission, it is of utmost importance that a large area around the landing site is studied. A rover equipped with a deep drill and with science packages that include biochemical and geophysical instrumentation is required. ExoMars (under preparation for 2016 onward) and Curiosity (successfully landed in 2012) are piloting this step.

The Moon would remain as an excellent test bed for the velocity-controlled pinpoint landing system and also for the performance verification of the mobile elements and science packages. Operational sequences could be tested and improved. It has the major advantage of being very close to Earth, which reduces the travel time (and therefore complexity and cost) and simplifies communication and commanding loops. A landing system leading to a safe pinpoint landing including hazard avoidance on the Moon can provide a solid heritage for pinpoint landing on Mars, of course apart from the additional entry system and the parachutes, which decrease the required thrust proposed by a propulsion system. The mobile surface elements and science packages can be fully tested on the Moon before being sent to Mars, or even Mercury.

10.23.3.1.3 Sample and return from a low-gravity environment

Small solar system bodies, such as comets, asteroids, and TNOs, are believed to be relics of the formation of our planetary system. The near-Earth objects (NEOs) are very attractive targets for sample returns missions, because the technological challenges are less demanding than for the high-gravity environment of a planet or the volatile composition of a comet. Many NEOs can be reached on much shorter timescales than Trojan asteroids, centaurs, or TNOs. An additional benefit offers the COSPAR planetary protection classification (Category V) with a nonrestricted return from NEOs (cf. Romstedt et al., 2008). No complicated sample sealing is required to protect Earth from a potential contamination, as required for Mars or Europa sample return missions.

Dynamic calculations have shown that their orbital lifetime is small on cosmogonic timescales and that they are continuously being replenished from other sources, either from the main asteroids belt or from comets. A sample return mission needs to return a scientifically significant sample of the surface material of one or multiple NEOs. The amount of material will influence the research that can be performed. It would be advantageous to have enough material to apply all desired measurement techniques and tests. Most laboratory instruments require a very small amount of material ($\ll 1$ g) and only some investigations need a few grams. The sampling size required for one set of measurements is therefore of the order of several tens of grams. However, some redundancy is required and some additional material should be kept for future analysis. Furthermore, a larger amount would provide a better representation of the sampled area.

Retrieving a sample from a low-gravity body is significantly different from a sample return from a planet. The latter

requires a dedicated lander, an entry and/or descent system, and a launcher to return to orbit. For a low-gravity environment, no dedicated launch vehicle is required after sample collection, and also, the descent requirements are very different. A sample return from a NEO, a main belt asteroid or one of the Martian moons, can be achieved with a relative small spacecraft that can be launched on a 'low-cost' launcher, if the relative velocity between the spacecraft and the target body is low enough to permit a rendezvous mission. Upon arrival, the spacecraft will first go in orbit to perform a number of remote-sensing measurements of the surface and subsurface, as well as an accurate mapping of its gravitational properties, which will be a key prerequisite in the detailed determination of the navigation sequence for sampling maneuvers. A large number of potential sampling sites on the surface need to be examined in order to select the optimal locations for sampling maneuvers. For this, high-resolution imaging in the visual and near infrared (IR) is the minimum requirement; however, depending on the available mass, other instruments should be added to determine the global elemental and mineralogical surface composition of the target, as well as some information on the subsurface.

There are two main options to retrieve a sample from a low-gravity solar system body: (1) collecting the sample directly from the surface or (2) creating a debris cloud of asteroid material and collecting a sample from that cloud. The Hayabusa mission to asteroid Itokawa has realized the first option whereby a touch-and-go sampling approach was used. Upon a brief contact with the surface, a projectile is fired and the debris is then funneled up a cone as the spacecraft retreats from the surface. The second option has not yet been space-proven; however, the results of the Deep Impact mission to comet Tempel 1 can be used to roughly estimate the constraints for collecting a sample of some hundred grams with this method from a nonvolatile asteroid.

The samples have to be stored and sealed into a sample canister inside an Earth-entry vehicle. To reduce propellant requirements for the transfer back to Earth, the sampling mechanism and empty tanks can then be jettisoned. The spacecraft will return to Earth, where the Earth-entry capsule will perform a direct hyperbolic Earth entry.

10.23.3.2 Longer-Term Goals for Exploration

The high-priority goal is of course a sample and return from a specific set of locations that have been previously studied by *in situ* landers or their associated rovers like on Mars. While there are many differences between a sample and return mission to Mars and that to a NEO or Phobos, some technologies such as the sample encapsulation and Earth-entry vehicle may be similar. Certainly, a mission to a NEO or Phobos may be a natural test-bed precursor to this important further step on Mars.

10.23.4 Instruments

The challenge of any scientific mission is to define the scientific objectives (what is of highest priority to be observed), refine them in detailed scientific requirements, and select the instrument(s) to satisfy these requirements. The instrument accommodation drives the spacecraft design and strongly influences the overall cost of the mission. Numerous iterations are required to fit the actual selection and implementation details within the available resources (Figure 1). Trade-offs on the type of instruments, the instrument measurement principle, and combination of instruments and level of involved new technology are needed, together with the verification that the scientific objectives of the mission are still fulfilled. Usually, many compromises have to be made in the instrument selection and accommodation. Several textbooks are dealing with the space mission design approach (e.g., Wertz and Larson, 1999).

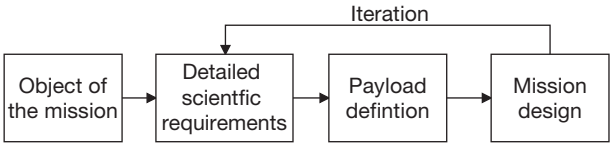

Figure 1 Definition process of a space mission.

To satisfy the objectives of the mission, a set of physical quantities have to be measured and observed by employing various observation methods. A classification of instruments according to these measurement principles should assist the reader in obtaining a structured overview of the types of instrumentation required for planetary space missions.

10.23.4.1 Measurement Principles

Planetary exploration covers a wide area from astronomy, geology, morphology, geophysics over magnetospheric and plasma science, to exobiology, just to name, but a few of the involved disciplines. A wide and ever-growing set of instruments are employed driven by new measurement requirements and new scientific disciplines on the one side and emerging new technology on the other side, enabling enhanced and new instruments. A classification of detection principles should assist in categorizing the existing range of instruments based on their measurement approach. We distinguish principles of

- direct and indirect detection
- remote and *in situ* sensing
- passive and active sensing principles

10.23.4.1.1 Direct detection

The detection principle is based on a direct measurement of the interesting physical phenomena by observation of physical quantity such as temperature (thermal sensor), pressure (pressure sensor), and particle flux by means of either remote-sensing or *in situ* observation.

10.23.4.1.2 Indirect detection

Indirect detection is performed when a direct detection is not possible or too demanding. The observation of the interesting phenomena is done by interpretation of a single or combination of several physical by-products, which are easier to access for observation than a direct measurement. Indirect detection often relies on a combination of measurements performed with a set of instruments and very often involves modeling

and simulation to derive the physical result of interest. Many processes and physical phenomena have to be measured indirectly because direct access is not possible due to demanding or inadequate space-qualified sensor systems.

Tracing of radon as product of radioactive decay of ^{238}U to conclude on volcanic activity on planetary surfaces is an example of an indirect observation of geophysical phenomena (although in many cases, volcanic activity could be detected directly by imaging, e.g., provided that visibility is given and no opaque atmosphere like on Venus or Titan blocks the direct observation). Another example is a spacecraft performing aerobraking in a planetary atmosphere, to derive the density of the atmosphere from measured decelerations.

10.23.4.1.3 Remote sensing

Any observation without directly contacting the object in question is considered remote sensing. Mainly electromagnetic waves allow for remote detection of physical qualities either directly or indirectly. The detection of electromagnetic waves covers a wide wave-band range (submillimeter (terahertz), thermal IR, far and near IR, IR, visible, ultraviolet (UV), extended UV, to x-ray and γ-rays). The reflection, scattering, and emission of photons from a planetary surface allow for the characterization, definition of chemical composition, morphology, mineralogy, etc. Due to the propagation of these photons, it is possible to detect them remotely without direct interaction of an instrument at the origin or location of the phenomena. This is exploited with remote observation either from Earth (as far as the atmospheric attenuation allows) or outside the Earth's atmosphere with space telescopes (Hubble and JWST) or in closer vicinity with remote-sensing spacecraft (flybys or in orbit). A major limiting factor for remote sensing is the distance from the observed phenomena due to the $1/r^2$ dependence from distance resulting in a limited detectable signal strength and signal-to-noise ratio (SNR). Spatial and spectral resolution is restricted by both the photon wavelength, as well as the limited instrument apertures (size, mass, and cost of an instrument), and available signal strength. Temporal resolution is limited by the minimum required exposure time. Of course, the benefit of remote sensing is that in many cases, a wide coverage on an object can be achieved. Examples of remote-sensing instruments are (telescopic) imagers, laser altimeters, and radars.

10.23.4.1.4 In situ sensing

Being at the place of a physical phenomenon (e.g., flying or floating through a planetary atmosphere with an aerobot or being on a planetary surface with lander and rovers) allows measurement of the physical qualities directly at the location. *In situ* sensing is the only possible means to investigate phenomena, which have no emission of or interaction with electromagnetic waves (or where the propagation of waves is suppressed or strongly attenuated). Due to the vicinity very often, much-lower intensity or less-disturbed signals can be measured. In most cases, *in situ* observations are of local nature (unless a high level of mobility is provided by long-distance rovers, aerobots, or orbiting spacecraft), leading to a restricted coverage. Nevertheless, it is important to provide ground truth for remote-sensing measurements, which rely often on modeling and simulations (required due to indirect measurement principles) to derive the desired information. A further benefit of *in situ* instrumentation is the possible physical interaction with the object, for example, by use of mechanical means such as grinders or drill, allowing for access of pristine and 'unweathered' material below the surface.

A major drawback for most *in situ* instrumentation is the increased complexity of the required equipment, as the instruments have to be brought to the targeted location under specific, often very challenging environmental conditions (e.g., radiation at Jupiter or extreme temperatures at Venus and Mercury). In many cases, *in situ* observations drive the mission design and increase the mission complexity, as the instruments cannot remain at a remote location but have to be brought by landers, aerobots, impactors, etc., to the location of interest.

Some examples of *in situ* instruments are dust mass spectrometers, plasma analyzers, laser mass spectrometers (LMSs), and magnetometers. Note that the return of a sample from a planetary surface (such as during the lunar Apollo program, Genesis, or for Hayabusa) also belongs in principle to the *in situ* observation category.

10.23.4.1.5 Passive detection

Passive instruments do not provide their own illumination or stimulation, but they rely on either illumination from natural sources (e.g., by the Sun) or luminescence, fluorescence, or emission of radiation. Passive instruments do not need illumination capabilities, but are directly dependent on the illumination or emission source.

Major parts of the solar emission spectra are reflected from planetary surfaces and altered by the surface and atmosphere interaction. A relative comparison of the reflected spectra with the original impinging solar spectrum reveals many surface properties. In the case of variable illumination (as in the case of solar illumination, but dependent on the wave band), a reference measurement is required to derive the relative ratio caused by the surface interaction, whenever absolute information is required. Some examples of passive instruments are microwave sounders, radiometers, x-ray spectrometers (could be also active), and magnetometers.

10.23.4.1.6 Active detection

Here, the instrument provides its own illumination using an emitter. A signal source is used to illuminate the region of interest (footprint). The sensing part is coaligned with the illuminating beam and detects the reflected signal. The benefit is of course the independence from other sources of illumination (e.g., use on the night side of a planet) due to the well-known emitted signal characteristics (time of emission, spectral features, power, etc.). The modulation of the emitted signal (e.g., with pseudocodes) can dramatically increase the SNR and assist in the detection of the emitted signal even under noisy conditions. No direct dependence on, for example, solar aspect angle (illumination aspect) or solar variability is required with this technique. The drawback is the increased complexity and resource requirements for active illumination (mainly in mass, volume, and power). It is not necessarily the case that the emitter must be in close vicinity of the receiver, but can be on another spacecraft, lander, or even located on Earth. Some examples of active instruments are radars, laser altimeters, permittivity probes, and LMSs.

Another benefit of active detection is the elegant realization of a spectral analyzer: for illumination, a source with limited wavelength emission is swept over an extended range and a detector measures the response from a target of interest.

10.23.4.2 Imager

Imaging is used to provide spatial information about the distribution of any interesting physical quantity. Imaging can be achieved either with a scanning principle like push broom and whisk broom using a single detector or line detector or by means of a two-dimensional (2-D) detector array employing multiple sensor pixels synchronously. A scanning principle either requires a mechanical moving platform or relies on the motion of the instrument (e.g., provided by an orbiting spacecraft). Scanning is used not only in cases where the detection principle is complicated and a complex and demanding instrument setup is required but also in cases where the required pixel number is exceeding the (currently) available detector array sizes or rather high-resolution spectral information is required. The imaging quality is subject to the pointing accuracy and stability of the mechanical scanning platform or the orbiting spacecraft.

In many cases, detector arrays can be used for simultaneous measurements, simplifying or even avoiding the scanning platform, but an appropriate optic is required to produce a sharp image on the detector array.

Very often, individual image frames have to be put together to provide a global image of a large spatial area. This can become rather complicated if observation distances, aspect angles, and illumination conditions are varying between individual images.

Imaging is very important to recognize features, structures, surface morphology, and context for other instruments or simply for orientation and navigation purposes. An imaging instrument uses optics such as lenses (refractor) or mirrors (reflector) to project a focused image onto a detector. The detector converts the image into electric signals, which are digitized before they are further processed with a digital data processing unit. Color imaging requires multiple exposures of the same target through different color filters. The combination of three color-filtered images in complementary colors such as red, yellow, and blue provides natural colored images. In several applications, filter wheels have been used to place the required filter in the optical path. More recent developments, however, make use of interference filters applied directly on the detector array, which does, in principle, save mass. False color images are used to highlight mineralogical composition or other specific features within the image.

Imagers consist typically of a solid-state array based on either charge-coupled device (CCD) or an active pixel sensor (APS). In earlier times, also, direct recording on film material was used.

Light falling on a detector pixel is absorbed by a photoconductive substrate such as silicon and releases a quantity of electrons proportional to the intensity of light. The stored accumulated electric charge in a pixel represents the light level integrated over the exposure time. These charges are read out for conversion into digital data. Typical CCD and APS are sensitive over a wide wave band (including UV and IR) and can be optimized for specific wave bands by selection of the detector semiconductor material. Their sensitivity can also be increased to enable the detection of single photons at specific wavelengths.

Not all imagers require 2-D detector arrays, as explained earlier. Imaging can be done also with a single-element whisk-broom sensor, multielement whisk-broom sensor, sensor line in a push-broom arrangement, or in matrix configuration. A single line detector arranged perpendicular to the spacecraft velocity vector can be used in a scanning mode (push-broom mode). A 2-D image is built up as the spacecraft moves along its velocity vector (following its orbit), requiring appropriate spacecraft attitude stability (to avoid image distortion during the scan) and precise pointing knowledge. An optical correlator system can significantly reduce stability requirements for the satellite attitude system.

The simplest approach for image sensing is through a detector array (typically 1024×1024 or larger), where a complete image is obtained in a single 'shot.' The stability requirement is now driven by the exposure time, as the platform has to remain stable during the exposure time within one pixel. The imager optics is of either a reflecting (e.g., Schmidt, Cassegrain, or triple-mirror anastigmat (TMA)) or refractive type (teleoptic or lens triplets).

10.23.4.2.1 Wide field imager

A wide field imager (WFI) has an extended field of view (FoV) with a limited ground pixel resolution intended to give an overview over a larger terrain and hence is used to provide context information for other instruments such as high-resolution cameras or spectrometers. Planetary WFIs can be rather small and low mass as the larger ground pixel size allows for a reduced aperture and reduced focal length. WFIs are usually also used in connection with stereoscopic imaging. One of the best-known WFIs is the Wide Field and Planetary Camera 2, which was installed at the Hubble Space Telescope in 1993 (Peg, 1993).

10.23.4.2.2 High-resolution camera

High-resolution imagers are used on remote-sensing spacecraft to resolve small details (typically in the meter range or even better) on the observed body surface. In combination with filters, some high-resolution compositional information can be provided as the typically employed detector arrays (CCD or APS) are also sensitive in the IR and UV region.

CCDs provide an advantage in the case of low photon counts as they have higher quantum efficiency than APS, although more recent developments in this area indicate that APS sensors can also achieve high efficiency. One significant benefit of CCDs is that time delay integration can be easily implemented due to their construction principle. The exposure time can be increased by shifting the pixel information from one pixel to the adjacent pixel by appropriate clocking of the charge transport mechanism of the CCD against the projected spacecraft velocity to allow for accumulation of photoelectric charges over time. If the shift is chosen in the right speed (determined by the ground track velocity of the spacecraft and the focal length of the optics), the spacecraft motion can be fully compensated and hence the exposure time per ground pixel increased until either saturation is achieved or the edge of

the CCD is reached. Every individual ground pixel projection is shifted through a defined number of CCD cells, before readout.

To overcome diffraction limit, the aperture of the optics has to be adapted to the required spatial resolution. The overall mass of the instrument scales with the cube of the required aperture and is significantly more demanding than the WFI. The spacecraft attitude control subsystem has to provide appropriate pointing stability and absolute pointing capabilities to avoid blurred and smeared images, and finally, a huge amount of data has to be handled by the spacecraft data handling and the telemetry subsystems. Usually, the high-resolution channel is combined with a WFI, which provides context information. Due to the amount of provided information, high-resolution imaging requires a high data rate. Image compression has to be used carefully to avoid artifacts in the final data product and loss of desired information. The high-resolution stereo camera (HRSC) on Mars Express (Neukum et al., 2004) has a ground resolution of up to 2 m per pixel; HiRise on MRO has 0.3 m per pixel at 200 km altitude (McEwen et al., 2007).

10.23.4.2.3 Stereo imager

Stereo imaging is needed to gain topographic information and to construct digital elevation models (DEMs) of planetary surfaces. Either two camera heads mounted with a spatial separation but pointing at the same target or a single camera head is used, which images a specific area at a certain time and reimages the same area under a different aspect angle (achieved by side viewing of the spacecraft) at a revisit. The first case provides stereo information with single site visits and without spacecraft off-nadir pointing. The achievable height resolution is limited by the spatial separation of the camera heads, which is usually restricted. The second solution provides almost any required separation but needs multiple revisits at different times for stereo imaging and phases of spacecraft off-nadir pointing. A reasonable compromise between both cases is the use of a second camera, which is mounted off-nadir pointing.

In all cases, complex image processing is required to retrieve the elevation of the terrain and to create 3-D images. Cameras with stereo capabilities are on board the orbiters of most planetary missions with the currently most impressive one being the HRSC on Mars Express (Neukum et al., 2004).

10.23.4.2.4 Scanning platform

Scanning platforms are used to provide flexible pointing of optical instruments independently of the spacecraft's attitude. However, most modern spacecraft designs do not include such scan platforms in order to avoid moving mechanisms, which are potential for failure. The alternative is to rotate the entire spacecraft so as to point the optical instrument in the required direction. This is particularly easily done with three-axis stabilized spacecraft, which use reaction wheels for their attitude control. The repointing can be performed without propellant use (neglecting the wheel offloading, which is required from time to time to keep the rotational rate of the reaction wheels within a specified range).

10.23.4.2.5 Panoramic camera

A panoramic camera is a high-resolution stereo imager used to image the surface and surroundings from a lander or rover. Two camera heads are spatially separated and typically mounted on top of a mast (a kind of scanning platform), allowing for an elevated view. A mechanism with two degrees of freedom permits the cameras to rotate by 360° azimuth to obtain a panoramic view and provides pointing at various elevations.

Images can be used to create 3-D maps of the area where, for example, the rover has to navigate. Mechanical filter wheels in the optical path, or fixed linear or interference filters directly mounted in front of the detector, offer multispectral imaging capabilities and color imaging. Images taken at various wavelengths are used to study mineralogical composition of interesting rocks and soils. Examples for such systems are on the Mars rovers Pathfinder, Spirit, and Opportunity (e.g., Bell et al., 2006), as well as on the Rosetta lander Philae (e.g., Willnecker et al., 2006).

A difficulty, however, arises from the large volume of data and the associated limitations given by the proximity link via an orbiting relay spacecraft. In most of the cases, a direct data transfer to Earth from the surface element is not possible.

10.23.4.2.6 Microscopic imager

The microscopic imager is a combination of a microscopic optic and a camera head. It provides images of small-scale features of rock and soil, reveals the fine-scale texture, and resolves individual grains targets, which are often further analyzed by other instruments like alpha particle x-ray spectrometer (APXS), LMS, Raman spectrometer, and Mössbauer spectrometer. Such cameras can provide multicolor images with a typical spatial resolution on the order of 50–100 μm per pixel. Illumination devices are used when night images or images in shadow regions are taken. Color information can be provided either by active illumination with light-emitting diodes at different limited wavelengths or with wideband illumination and filtering. Modern microscopic imagers can have a mass in the order of 100 g, with a power consumption of about 1 W. An example is the ROLIS imager on the Rosetta lander (Mottola et al., 2006).

10.23.4.3 Spectrometer

Spectroscopy of electromagnetic waves is a primary tool of remote sensing. It is the separation of electromagnetic waves into its component wavelengths within the full range of the electromagnetic spectrum starting from very low frequency (VLF) in the radio frequency (RF) band with wavelength of hundreds of kilometers to extreme high frequency (EHF) with several centimeters wavelength. The microwave region covers wavelengths between 0.1 and 30 cm; higher frequencies are in the millimeter and submillimeter wavelength region. The IR and visible range covers 10^{-3}–0.4×10^{-7} m, followed by UV range from 0.4×10^{-7} down to 10^{-8} m. Extremely short wavelengths are expressed in angstroms (1 Å $= 10^{-10}$ m). x-Rays are covering 100 Å down to 1 Å and below 1 Å are high-energy γ-rays.

The various spectral regions reveal specific features: radio waves for mapping gross surface properties, UV wavelengths for atmospheres and magnetospheric ions, and the near IR for understanding of mineralogical composition of solid surfaces. x-Ray and γ-rays provide data on the surface and near-surface

elemental abundances. Spectrometers measure signal intensities at individual wavelengths. Spectral information can be provided by grating, interferometric principles, filtering, heterodyne mixing, or illumination with spectrally limited and variable emitters. The spectral information can be used to reveal chemical and elemental composition, distinguish isotopes, and characterize energy distributions or to define specific atomic energy levels. There are many applications requiring spectral analysis. Of course, spectroscopy is very often combined with imaging to provide information on spatial variations and context.

The wide extent of the electromagnetic spectrum requires different detector types:

- Antennas and electromagnetic coils for the RF and microwave bands
- CCDs, APSs, microchannel plates (MCPs), and bolometer for the IR, visual, and UV bands
- Various semiconductor detectors, MCPs, and scintillators for x-ray and γ-ray

Also, the optics for the various bands is very different:

- Parabolic antennas (reflectors) and antenna groups are required for the higher-RF bands, as well as patch antennas.
- Refractive and reflective optics in the visual, IR, and UV bands.
- Microchannel optics for x-rays is a more recent development.

For high-resolution spectroscopy, the instrument stability is a key issue. Thermal stabilization of the detector and readout is often necessary. Cooling is required for low-noise applications. Calibration sources are required to eliminate instrument drifts. Sensitive detectors with very low readout noise and long observation times are required for faint objects or high-resolution spectroscopy.

10.23.4.3.1 Visual and IR mapping spectrometer

Visual and IR mapping spectrometer provides mineralogy and elemental composition in the visible and near-IR bands (around 0.7 μm to several micrometers). Improved performance can be achieved by extending the wavelength range into the thermal IR (up to around 60 μm). In the surface reflection, spectral features occur as minima due to volume scattering bands or Christiansen features and as maxima by Reststrahlen peaks and transparency features. IR mapping spectroscopy (IMS) can be used to map the surface minerals and their abundances, identify the phases and mixtures of the surface minerals, and map the mineral distributions and their correlation with images in the visible band. In addition, such an instrument can also determine the atmospheric cloud structure and its layering, the temporal and spatial variations of the constituents of the atmosphere, and the temperature versus altitude profile and define water vapor content, as well as the abundance of dust. The instruments visible and IR thermal imaging spectrometer (Coradini et al., 1999) and mercury thermal IR spectrometer (MERTIS) (Hiesinger et al., 2010) are examples for near-IR and thermal IR imaging spectrometers.

The IR light passes a baffled instrument aperture toward an optical lens or mirror system (TMA) providing the required mapping resolution. An optical filter might be applied to reject the solar flux outside the band of interest and an entrance slit in the optical path to reduce stray light. A wave-dispersing element, which could be a beam splitter cube, a prism, a variable linear filter, a grating, or a Fourier transformation (FT) concept, is used to create and project the spectral image onto the detector array. Detectors such as InGaAs, CdTe, and HgCdTe form the focal plane assembly, which requires active thermoelectric or passive cooling. New developments in the field of uncooled bolometers allow for operation up to room temperatures but still however require thermally stabilized focal plane assemblies. Typical achieved instrument spectral resolutions are of the order 20 nm or less. A tiltable mirror in the optical beam is used to alternatively expose the instrument to a calibration source.

To extract reliable compositional information from IMS spectra, a thorough understanding of the spectral features from laboratory spectroscopy on analog materials is required. Of course, local ground truth, which can be achieved through *in situ* instrumentation on landers and rovers, is very important so as to allow for the definitive interpretation of global remotely captured spectra.

10.23.4.3.2 UV spectrometer

UV spectrometers are used to determine surface composition and structure of atmospheres, the loss rates of volatile gases, and compositions and dynamics of exospheres and to search for surface layers of ice. The reflective properties of natural satellite surfaces in the UV are useful to determine the composition and physical state of the materials that comprise the surface and hence complement measurements performed with IR spectroscopy and elemental compositional information obtained from x-ray and γ-ray spectrometers. The range from 70 to 800 nm contains major resonance lines of many elements and molecules such as Ne, Ar, Na, S, Mg, Al, Fe, OH, CO_2, and H_2, even though it is difficult to cover the entire range with a single grating and detector.

For atmospheric limb observations, the level of stray light is of major concern as it decreases the SNR of the measurement. Scanning of the different atmospheric layers during limb observation is done with a movable mechanical scanning mirror. A slit in the optical path must be used to suppress the strong background of the planetary disk. A compact instrument design can be achieved with a common Rowland spectrometer configuration. Current instrument designs use third-generation holographic gratings (Singh, 1992), which produce the UV spectra on a photon-counting MCP through a planar MgF_2 window in front of the MCP. KBr or CsI photocathodes are used as detectors for the EUV and CsTe or RbTe photocathodes for the FUV and common CCD or APS imaging array for the UV and visible range.

10.23.4.4 Radiometer and Polarimeter

Radiometers provide precise intensity data by simply establishing the brightness (or the intensity of energy radiated) from targets. Polarimeters are optical instruments that measure the direction and extent of the polarization of light. They consist of a telescope fitted with a selection of polarized filters and optical detectors. Careful analysis of polarimeter data can infer

information about the composition and mechanical structure of the objects reflecting the light, such as the various chemicals and aerosols in atmospheres, rings, and satellite surfaces, as these all reflect light with differing degrees and types of polarization. Of course, a polarimeter may be integrated into another instrument, such as a camera or a photometer.

Both instrument principles require calibration sources when absolute measurements have to be provided.

10.23.4.4.1 Thermal IR radiometers

A thermal IR radiometer measures the intensity of IR energy radiated by a target, in order to determine the atmospheric and surface thermal properties and in particular the thermal inertia. When the instrument's FoV completely includes the disk of a planet, its total thermal output can be determined and as a consequence the planet's thermal energy balance derived, which in itself reveals the ratio of solar heating to the planet's internal heating, provided the latter is large enough. Thermopile arrays or bolometers are used to measure accurately parts of the Planck curve so as to establish the surface temperature. Note that the blackbody curve peak lies between several micrometers for hot bodies (e.g., Mercury) and 60–70 μm for very cold bodies (e.g., Europa). The Galileo photopolarimeter/radiometer experiment measured thermal radiation in five spectral bands between 15 and 100 mm (Hiesinger et al., 2010; Russell et al., 1992; Spinhirne et al., 2001).

10.23.4.5 Nephelometer

A spaceborne nephelometer is an instrument for measuring suspended particles (aerosols) in an atmosphere to obtain information about particle properties by scattering light in a volume containing many particles (**Figure 2**). The instrument consists in its simplest form of a light source and a light detector, which is mounted offside the direct light beam. The aerosols in the light beam produce scattering, which is measured by the detector. The light reflected into the detector is a function of the particle density, shape, color, and reflectivity. In the simplest version, only the backscattering coefficient is defined. In a more complex version, the instrument measures the elements of the scattering matrix (the matrix that relates the Stokes parameters of the scattered to the incident light in the far-field limit) (Bohren, 1983). The ultimate goal is to obtain the size distribution, particle density, and refractive indices while avoiding ambiguities caused by nonsphericity of the particles. Newer developments are based on polarimetry, as the advantages are (1) increased sensitivity to microphysical properties, (2) higher achievable accuracy, and (3) angular features insensitive to multiple scattering (Castagner and Bigio, 2006).

A light source, typically a laser operated at various wavelengths, is used with a photoelastic modulator made of a piezoelectric transducer coupled to a block of amorphous quartz to produce a periodic retardance. The incident laser light is linearly polarized and then passes through the modulator. The polarization state of the emerging light alternates between left and right circular polarization. Both the DC and the AC components of the detected scattered signal have to be measured to determine the important elements of the scattering matrix and therefore finally derive the characteristics of the suspended particles.

10.23.4.6 x-Ray Spectrometer

An x-ray spectrometer is used for remote sensing, as well as for *in situ* characterization of elemental composition through the detection of the secondary x-ray photons energy (dispersive) or photons wavelength (diffraction). Various principles are used as described in the following sections.

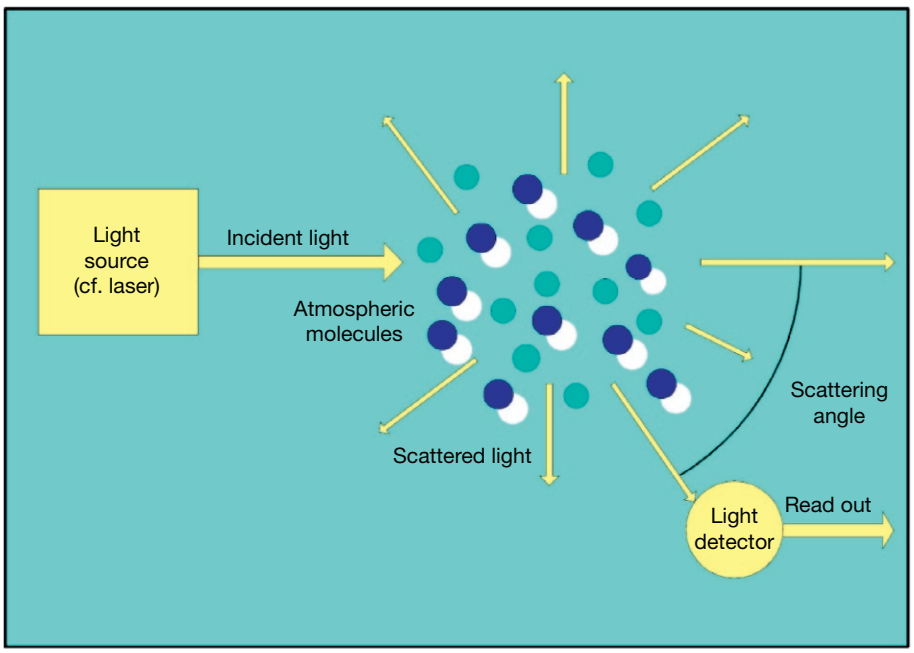

Figure 2 A nephelometer analyzes the scattering of a light source in the gas to define molecular constituents.

10.23.4.6.1 x-Ray fluorescence

x-Ray fluorescence (XRF) is based on the observation of x-ray photon emissions of atoms, which are induced into an excited state by irradiation with x-rays (e.g., originating from the Sun) causing the removal of a core electron (K, L, or M shell) from the atom. The vacant inner shells are filled by electrons from outer shells of the same atom. The difference in energy between the two electron orbitals appears as an emitted x-ray photon, which can be measured with an x-ray spectrometer either by wavelength dispersion in a diffractometer (x-ray diffraction (XRD)) or by energy dispersion with a semiconductor sensor (XRF). In both cases, this leads to information on the mineralogical composition through the determination of major-, minor-, and trace-element abundances (Meyer et al., 1996).

The XRD technique has an excellent resolution where XRF is so far more often used in space because of the smaller mass and reduced complexity. XRD instruments for space application are under development for ExoMars and Chemin (Blake et al., 2009) is successfully operating on the MSL rover Curiosity.

In an imaging XRF, a micropore optic based on a classical Wolter-I geometry (coaxial, confocal conic sections are used to form grazing incidence imaging systems as proposed by Wolter in 1952) produces a focused x-ray spot on a detector pixel array (Bavdaz et al., 2002). Semiconductor sensors based on GaAs allow for even room-temperature operation.

Remote-sensing applications of the XRF technique rely on the irradiation of the target surface with x-rays for the surrounding environment (e.g., the Sun). Solar x-ray monitors are used to observe the solar x-ray emission and to remove its spectral dependence from the XRF measurements. This is essential due to the high variability of the illuminating solar x-ray emission and the time variation and spectral hardening of the solar spectrum above 3 keV.

In situ instruments also use high-energy incident radiation sources such as an α-particle, proton or electron sources, and primary x-rays from the radioactive decay of radioisotopes such as ^{55}Fe, ^{109}Cd, and ^{238}U (Clark et al., 1977; Surkov et al., 1986). This technique can therefore be used at night or in shadow regions and thus does not depend on an external source of radiation such as the Sun.

10.23.4.6.2 Particle-induced x-ray emission

Particle-induced (or proton-induced) x-ray emission uses bombardment with ions of sufficient energy (usually MeV protons) causing inner-shell ionization of atoms in the sample. As described for XRF, outer-shell electrons drop down to replace inner-shell vacancies and x-rays of a characteristic energy are emitted. An energy-dispersive detector is then used to record and measure these x-rays and the intensities are then converted to elemental concentrations (e.g., Isabelle, 1994).

10.23.4.6.3 Alpha particle x-ray spectrometer

The APXS is used to determine *in situ* the chemical composition and absolute abundances of elements at the outermost few micrometers of soil samples (Gellert et al., 2006; Rieder et al., 1997). Also, α-particles emitted from radioactive gases (such as radon and polonium) leaking out from a planetary interior can be detected.

The APXS has evolved from the simpler α-particle instrument (APS), which uses an α-source such as Cm^{242} for target irradiation. The energy distribution of the backscattered α-particles is measured to identify light elements (except hydrogen) including rock-forming elements like Na, Mg, Al, and Si (Meyer et al., 1996). When a backscattered α-particle hits the silicon wafer detector, a small track of charge is created, which is sensed with a charge-sensitive amplifier (CSA). The charge produced is directly proportional to the energy of the backscattered alpha particle. By measuring integrated count rates over energy distribution, the elemental composition of the sample can be defined.

An improved version of the instrument, the APXS, also analyzes the x-rays produced in the sample. A ^{244}Cm source with a typical activity of around 50 m Ci emits energetic α-particles and x-rays, which are used to irradiate the surface of the target sample area at a very close distance. Hard x-rays induce fluorescence of elements with high atomic number. Medium atomic number elements, such as Ca, are excited by α-particles and x-rays. All emitted x-rays are measured with a small solid-state silicon detector over an extended period of time, and a spectrum is determined. The energy peaks in the spectrum characterize the elemental composition. The intensity in the peaks reveals the concentration of each element. The APXS is sensitive to major elements, such as Na, Mg, Al, Si, K, Ca, and Fe, and minor elements, such as P, S, Cl, Ti, Cr, Mn, and Ni. Due to the short ranges of α-particles and x-rays, the sampling depth is less than 10 μm. The APXS typically requires long integration times of order 1–2 h per sample to achieve sufficient counting statistics. Longer measurements and cold environment (night measurements) improve the counting statistics of peaks of lower intensity from elements having a lower abundance.

The APXS is preferably mounted on a robotic arm or a rover to provide mobility and access different locations for chemical compositional analysis.

10.23.4.7 Gamma-Ray Spectrometer

Gamma-ray spectroscopy (GRS) is used for determining the surface elemental composition of planetary bodies either from orbit or directly on planetary surfaces. *In situ* measurements on surfaces are preferable since they are less prone to atmospheric effects or other disturbing contributions. Direct surface measurements can provide ground truth for orbital measurements but are in most cases limited to local measurements only.

The detected gamma rays arise from two sources: (1) gamma rays emitted spontaneously by naturally occurring radioactive elements like K, Th, and U and (2) cosmic ray-induced gamma rays emitted by elements like H, C, O, Si, and Fe. Each chemical element produces a unique set of gamma-ray lines, and gamma spectroscopy allows for distinctive identification of these fingerprints and determination of the relative abundance of a specific chemical element. The ambient cosmic-ray flux produces neutron-induced reactions on elements in the planetary surface, which in turn produce the characteristic γ-rays that are used to determine the elemental concentration. A scintillator (e.g., cesium iodide (CsI), LuAP, or $LaBr_3$) is used to convert the γ-ray into light emission, which is detected by sensitive large photodiodes. The background provided by cosmic rays and by

the spacecraft is a source of noise. Mars Odyssey GRS, for example, was mounted on a 6 m boom to reduce the S/C background for the measurements (Boynton et al., 2004). Anti-Compton shielding is used to improve the GRS spectra quality to rejection of γ-rays from cosmic-ray interactions with the spacecraft material or other unwanted sources (Meyer et al., 1996). Important instrument factors are the precision of the scintillator material, sensitivity to radiation damage, quantum efficiency of the readout photo diodes, and the capability to suppress background counts. Since the γ-ray spectrometer sensitivity increases with the square root of the integration time, the expected integration times range from several orbits for the natural radio nuclides to several months for the cosmic ray-induced events. Of course, the sensitivity is also a strong function of the efficiency and energy resolution of the instrument.

Surface compositions finally are deduced from a comparison between the γ-ray spectra emitted by an area of the planetary surface with simulations based on calculated fluxes of assumed surface composition. By applying an iterative process, it is possible to derive a chemical composition that best fits the measured in-orbit fluxes.

Examples of γ-ray spectrometers based on either Ge detectors or scintillators are the γ-ray and neutron spectrometer on Messenger (Burks et al., 2004) or the Mercury gamma-ray and neutron spectrometer (Kozyrev et al., 2006) on the BepiColombo mission to Mercury.

10.23.4.8 Neutron Spectrometer

A neutron spectrometer (e.g., the HEND instrument on Mars Odyssey; Mitrofanov et al., 2002) detects free neutrons, which are produced when galactic cosmic rays interact with planetary matter. The measured neutron flux and its energy distribution depend on the chemical composition of the surface and the moderation, which takes place in the interaction of matter with the neutrons. Hydrogen is known as good moderator of neutrons, and therefore, a main application of a neutron spectrometer is the detection of hydrogen in the upper layer of the planetary surface, buried water ice, or even liquid water.

The neutron detector is, for example, a neutron-absorbing boron-loaded plastic scintillator (e.g., BC454 and GS20 glass). When neutrons pass the scintillator, material collisions occur, causing an energy loss of the neutron and creations of ion-electron pairs. When recombination occurs, photons are emitted, which can be detected with a photomultiplier tube (PMT) or photodiodes with a high sensitivity. Coincidence and anticoincidence logic is used after the readout to separate different energy bands and flux directions. The energy of these neutrons can be measured by determining the amplitude of the scintillator's light flash. The instrument data outputs are histograms of the measured amplitudes integrated over time. Thick sheets of cadmium are used to shield parts of the detector to achieve some crude spatial information or to make the detector only responsive to neutrons having energies above a certain range. It is essential to distinguish neutrons coming directly from the planetary surface and the background neutron flux. This can be achieved by using separate detectors facing different directions in combination with appropriate types of shielding.

A detector facing in the direction of the spacecraft velocity vector encounters thermal neutrons, which travel slower than the spacecraft. An additional backward detector detects thermal neutrons coming from the planetary surface. Using the combination of geometry and velocity, a separation of background and from spacecraft originated neutrons by the planetary surface is possible. The difference in counting rates between the forward and backward detectors yields a measure of the flux of thermal neutrons.

Differentiation between the different energy bands (thermal, epithermal, and fast) of the neutrons can be established through the use of different scintillator types in combination with shielding and moderation.

10.23.4.9 Laser Altimeter

A laser altimeter (also called light detection and ranging or laser image detection and ranging (LIDAR)) transmits laser pulses (energy in the order of several tens of mJ per pulse) toward planetary surfaces with a typical pulse rate of 10–30 Hz. The instrument measures the round-trip time of the light pulse between emission and the returned surface reflection to determine the distance of the spacecraft with respect to the surface. A laser altimeter operates in a very similar way to radar technology, which uses RF pulses instead of light pulses. The laser pulses are produced, for example, with a neodymium-doped yttrium aluminum garnet (Nd:YAG), which is optically pumped with laser pumping diodes. Active or passive Q-switching is used to produce the controlled laser pulses. The laser pulse emission is in the IR for a Nd:YAG (mainly 1064 nm), but with different YAG doping emission in UV, visible, or near IR that can be produced. A laser has a very narrow beam, emitted via a transmitter optic, which introduces a designed beam divergence, which allows the mapping of surface features with much higher spatial resolution compared to radar.

An optical telescope is used to collect the received reflected laser pulse photons onto an avalanche photodiode (APD). An APD is a high-biased Si-photodiode, which is very sensitive to photons and creates a charge avalanche, which is further amplified with a CSA. A very precise time measurement between pulse emission and return signal detection is used for the precise altitude estimation. For SNR increase and reduction of false trigger (e.g., by environmental photons), a very narrow filter with several-nanometer pass window at the laser emission wavelength is placed in the receiver optical path. The MLA flying on Messenger and BELA on BepiColombo (Thomas et al., 2007) are examples of laser altimeter instruments.

Repeated measurements over consecutive orbits are used to understand the morphology of planetary surfaces and construct precise topographic maps and DEMs. Repeated measurements over the same area at various seasonal periods reveal stress and strain and flexural properties of the lithosphere, determine tectonic movements and tidal deformations, and can be combined with gravity data to study the density distribution in the planetary crust. A LIDAR instrument is highly sensitive to aerosols and cloud particles in the transmission path, which opens many applications in atmospheric research and meteorology.

The receiver of a laser altimeter can be further used as a passive radiometer measuring the radiance of the surface at the instrument-sensitive wavelength.

Single photon-counting laser altimeters emit laser pulses at much higher repetition rates in the order of 20 kHz, but at much-lower energy (typically 20–50 μJ). Due to the low photon counts of the return signal, a statistical analysis of many pulses needs to be performed to retrieve the range measurement. Planetary single photon-counting laser altimeters are currently under development and promise significant reduction in mass and power.

10.23.4.10 Radar

Several solar system objects are covered by clouds or haze, making optical imaging difficult or impossible. But their atmospheres are transparent to RF waves and hence use can be made of radio detection and ranging (radar) instruments. Radars are active instruments, which illuminate a target with microwaves allowing detailed observations at any time, regardless of weather conditions, opaque atmospheres (in UV, IR, and visual bands), or presence of sunlight illumination.

In principle, the full range of the radio spectrum (Table 1) from kilometer to submillimeter wavelength can be used, according to the application and the particular requirements. The selected frequency depends on considerations, such as required footprint size, antenna size, thermal background noise, wave interaction with the target surface and wave interaction along the transmission path, and the interaction with a potential ionosphere.

10.23.4.10.1 Radar altimeter

Radar altimeters send either radio pulses (pulsed radar) or continuous wave signals (CW radar) straight down to a planet's surface (the nadir) to measure variations in the height of the terrain. In the case of the pulsed radar, the signals are timed from the instant they leave the instrument until they are reflected back. From the round-trip time, the distance can be obtained. Actual terrain height is then deduced based upon precise knowledge of the spacecraft's orbit – derived by laser or radio ranging.

CW radar altimeter often uses frequency modulation (FM) with a relative linear ramp function (for practical reasons, a triangular frequency modulation is used). During the round-trip time of the emitted signal, the local oscillator increases its frequency following the applied ramp modulation, causing a frequency difference between the transmitted and received signal. The longer the round-trip time, the larger the frequency difference becomes. The measurement of the frequency difference determines the range to the target (see Skolnik, 1980, pp. 70–92).

Laser altimeters generally have a smaller footprint, and thus higher spatial resolution, than radar altimeters. They typically also require less power. Nevertheless, there are many applications where the use of radar altimetry is beneficial, particularly for Earth observation (Gommenginger et al., 2006).

10.23.4.10.2 Ground-penetrating radar

Ground-penetrating radars (GPRs) use relatively low frequencies in the megahertz range, because signal penetration depth into matter primarily decreases with increasing frequency. Low frequencies require long antenna with several tens of meters length. For instance, the MARSIS instrument on Mars Express has 40 m long antennae (Biccari et al., 2002). With frequencies in the megahertz range, ground penetration in dry soil down to several kilometers can be achieved, with the drawback of poor spatial resolution due to the long wavelength. A large part of the signal intensity is reflected at the surface, but a significant fraction of the signal travels through the planetary crust and is reflected at subsurface interfaces between layers of different materials, including water or ice. Water is a strong attenuator due to its high permittivity, and hence, subsurface layers of liquid water can be relatively easily detected by GPRs. Nevertheless, the surface reflection and surface clutter make the GPR data analysis difficult. Ground penetrating can be used from

Table 1 Electromagnetic wave-band definition and radio spectrum nomenclature

Radio spectrum nomenclature

ELF (Hz)	*SLF (Hz)*	*ULF*	*VLF (kHz)*	*LF (kHz)*	*MF*	*HF (MHz)*	*VHF (MHz)*	*UHF*	*SHF (GHz)*	*EHF (GHz)*
3	30	300 Hz	3	30	300 kHz	3	30	300 MHz	3	30
30	300	3 kHz	30	300	3 MHz	30	300	3 GHz	30	300

Band name	*Frequency range*	*Wavelength range*	*Instrument application*
HF	3–30 MHz	100–10 m	Ground-penetrating radar
P	<300 MHz	1 m	
VHF	30–300 MHz	1–10 m	
UHF	300–1000 MHz	1–0.3 m	
L	1–2 GHz	30–15 cm	
S	2–4 GHz	15–7.5 cm	
C	4–8 GHz	7.5–3.75 cm	
X	8–12 GHz	3.75–2.5 cm	
K_u	12–18 GHz	2.5–1.67 cm	
K	18–27 GHz	1.67–1.11 cm	Water vapor measurements (22 GHz)
K_a	27–40 GHz	1.11–0.75 cm	
Mm	40–300 GHz	7.5–1 mm	Millimeter wave cloud radar
V	40–75 GHz	7.5–4. mm	
W	75–110 GHz	4–2.7 mm	Millimeter and submillimeter sounder

orbit (like MARSIS or SHARAD) or locally deployed on the surface as foreseen on the ExoMars rover (Ciarletti and The WISDOM Team, 2012).

10.23.4.10.3 Synthetic aperture radar

Synthetic aperture radar (SAR) synthesizes the angular resolving power of an antenna many times the size of the antenna aperture actually used. The SAR illuminates its target along the side of its velocity vectors and travels a distance in orbit while the reflected, phase shift-coded pulses are returning and collected. The SAR emits a permanent series of pulses as it moves along the orbit and the amplitude and phase of the individual returning signals are recorded.

A single pulse from the antenna is still rather broad (several degrees) because the diffraction limit would require a larger antenna to produce a narrower beam. The results from many pulses are combined using extensive onboard computer processing to mimic a synthetic aperture much larger than the length of the actual antenna used. The spacecraft's position and velocity must be known with great precision, and its attitude must be controlled tightly for the complex data processing, based on FT techniques (see Skolnik, 1980, pp. 517–529). The required complex data processing on board the spacecraft and the high produced data volume make the use of SAR for planetary mission difficult, and hence, SAR is mainly used for Earth observation missions.

10.23.4.10.3.1 Interferometric SAR

An interferometric SAR exploits the phase information of the returned pulses. Any phase difference of the return signals obtained simultaneously by two spatially separated antennas contains information about the angle from which the radar echo returned. Combining this with the distance information, the position in three dimensions of the image pixel can be derived.

If accommodation of two receiver antennas is not possible, measurements separated in time, perhaps from two different orbits, can be used to derive the information based on the phase shift. Even a terrain shift between observations (e.g., due to tides or earthquakes) is represented in the return phase difference and hence can be detected, provided the overall system resolution is sufficient and proper orbit and attitude data are available.

10.23.4.10.3.2 Polarimetric SAR

Anisotropic materials reflect different polarizations with different intensities. Some materials also convert one polarization into another. By emitting a mixture of polarizations and using receiving antennas with a specific polarization, several different images can be collected from the same series of pulses. Such images can be used as kind of color information in a synthesized image. Interpretation of the resulting colors requires significant testing of known materials.

10.23.4.11 Radio Science

Radio-science experiments are performed to determine masses and internal structures of bodies from spacecraft tracking data and to determine satellite radii and atmospheric structure from radio propagation information.

10.23.4.11.1 Celestial mechanics and the gravitational field

The spacecraft communication radio subsystem can be used to sense small changes in the trajectory of the spacecraft caused by gravitational field variations. For range-rate (or velocity) measurements, the spacecraft's radio transmitter sends a signal at a well-known stable frequency, generated by an ultrastable oscillator on board the spacecraft. Any velocity change of the spacecraft causes a frequency change of the radio signal received on Earth due to the Doppler effect. A spacecraft is pulled by the gravity when it passes close to a planet, moon, or any other massive body, causing its speed to change. The introduced change depends on the distance, on the total mass of the body, and on the internal mass distribution. Thus, by measuring the change in frequency (Doppler) of the Earth-received radio signal, the mass and internal structure of planetary bodies can be assessed. Only velocities in the direction of the wave propagation (along the ground station to satellite line) cause a frequency change; hence, observations are limited to spacecraft velocity changes along that direction. The closer a spacecraft approaches the body, the stronger it encounters the gravitational effects. But atmospheric drag or spacecraft internal perturbations limit the achievable resolution. A three-axis high-sensitivity accelerometer on board the spacecraft allows for separation of gravitational from other forces. Properly optimized detection of local subsurface mass concentrations (mascons) is possible.

By precise measurement of the transmission time from the ground station to the spacecraft and back (the spacecraft just 'echoes' the received signal with a slight frequency offset), an absolute distance from ground station to spacecraft (called range) can be derived. Plasma effects and any other propagation distortions in atmospheres (like rain, water content, or change in the total electron concentration (TEC)) along the line of transmission influence the measurements. A simultaneous dual-frequency link (e.g., X- and Ka-band) can be used to compensate for such effects and increase the resolution (Iess and Boscagli, 2001).

10.23.4.11.2 Radio propagation at occultation

The spacecraft radio signal can be used to investigate planetary atmospheres and ionospheres. This is performed with radio occultation experiments, when the spacecraft passes behind a planet or satellite as viewed from Earth.

The radio signal propagating from the spacecraft to Earth experiences refraction and scattering in the atmosphere of the occulting body. This causes changes in frequency and amplitude of the signal received at the ground station on Earth. Analysis of these changes yields information about the atmospheres and ionospheres. Unfortunately, the signal has to pass (in most cases unless there is a satellite-to-satellite radio experiment) also the ionosphere and atmosphere of the Earth and is influenced in the same way as described previously. However, the influence of the Earth's atmosphere can be estimated by means of additional measurements (water content definition and total electron content measurements, to mention just a few) and by selection of the location of ground stations at positions on Earth where the influence is minimal.

10.23.4.12 Microwave Sounder

Microwave sounders are remote-sensing instruments complementing IR measurements with (sub) millimeter band

measurements. A microwave sounder can be configured as continuum radiometer or a high-resolution spectral analyzer to measure naturally occurring microwave thermal emission from planetary surfaces or atmospheres or to remotely sense vertical profiles of atmospheric gases, temperature, pressure, and cloud ice (Gulkis et al., 2006). Numerous frequencies have to be analyzed to reveal atmospheric vertical temperature profiles or to determine the water vapor content (clouds, precipitation, and humidity) at various altitudes. Microwave observations are particularly sensitive to the reduced forms of oxygen and nitrogen (water and ammonia). This can be used to analyze, for example, abundances in the deep, well-mixed portion of the Jovian troposphere (Huestis et al., 2002). Data are collected to determine horizontal and vertical variations in abundances, circulation of the atmospheres, and the nature of convective and cloud-forming processes. Microwave sounding is therefore a uniquely suited remote-sensing technique to address key questions about planetary atmospheres (Huestis et al., 2002).

Not only the benefit of a passive microwave sounder is given by the global coverage, compared to local measurements of *in situ* probes like that of the Galileo probe, but also the technical realization is less challenging than for entry probes.

A parabolic antenna (or an antenna group) receives and focuses the natural microwave emission onto the very low-noise amplifier (LNA). Depending on the application, either several very narrowbands, for particular molecular abundance characterization, or a wider band for thermal emission characterization is used.

10.23.4.13 Particle Detector

10.23.4.13.1 Heavy ion counter

A heavy ion counter (HIC) instrument analyzes very high-energy heavy ions hitting the detector. Heavy ions observed during solar flares have, for example, been analyzed to determine the composition of the Sun. Measurements are also of engineering interest as heavy ions can cause random errors in spacecraft electronics. Heavy ions detectors use a stack of single-crystal silicon wafers, able to measure heavy ions with energies from a few up to hundreds of megaelectronvolts per nucleon. An example is the HIC on the Galileo spacecraft (Garrard et al., 1992).

10.23.4.13.2 Energetic particle analyzer

An energetic particle analyzer uses silicon solid-state detectors (SSDs) and a time of flight (TOF) detector system to measure the energy and angular distribution, composition, and stability of trapped radiation within a planetary environment. They are essential for the study of the interaction of energetic particles with natural satellites and with the solar wind to derive thermal plasma flow velocities and plasma temperatures and to examine adiabatic and nonthermal processes in the trapped radiation. They measure the number and energies of ions and electrons that exceed about 20 keV, define the direction of travel of such particles, and can determine the ion composition. For more information, see Funsten et al. (2004).

10.23.4.13.3 Neutral particle analyzer

A neutral particle analyzer (NPA) needs to discriminate charged particles from neutrals. This is done by applying a high voltage (in the order of a few kilovolts) across collimating optics, which repels charged particles. By switching off this voltage, the instrument is also able to measure charged particle (super thermal ions and electrons). The mass analysis of the neutrals is based on a TOF principle. An ultrasonic chopper located at the entrance point of the instrument provides a time masking, which allows neutrals to enter only at discrete very short time interval. The time difference between passing the chopper and the impact on the MCP or SSD is used to constrain the mass of the neutrals, which is given by the impact energy and the measured TOF. Detectors can be designed to have a spatial resolution (pixilated SSD or MCP with sector readout), which allows not only for TOF measurement but also for trajectory definition of incoming particles. NPAs are used to measure, for example, the escaping neutral gas composition and dynamics of planetary atmospheres and exospheres and their interaction with the solar wind, solar radiation, and meteor bombardment. The Rosina instrument on board Rosetta has unprecedented capabilities in determining the composition, velocities, and temperatures of both neutrons and ions (Balsiger et al., 2007).

10.23.4.14 Mass Spectrometer

Mass spectrometry is useful to characterize atoms or molecules in a sample, as well as determining chemical and structural information about molecules. Mass spectrometers use the difference in the mass-to-charge ratio of ionized atoms or molecules to separate them from each other. All commonly used mass analyzers use electric and magnetic fields to apply a force on charged particles (ions).

The general operational steps for a mass spectrometer are to

- create gas phase ions,
- separate the ions in space or time based on their mass-to-charge ratio, and
- measure the quantity of ions of each mass-to-charge ratio.

Different principles for mass spectrometer in use are

- magnetic focusing analyzer,
- quadrupole mass analyzer (QMA),
- ion trap,
- Wien filter,
- TOF mass analyzer.

10.23.4.14.1 Magnetic focusing analyzer

Magnetic sector-field mass spectrometers consist of an ion source, a magnetic momentum analyzer, and channeltron electron multipliers or MCPs as detector. Ions formed by electron bombardment are accelerated and focused by an applied electric field in the ion optics and collimated into a beam, which then traverses a magnetic field that bends it onto a collector slit. The ions that successfully traverse the curved path of the mass spectrometer and pass the slit are a function of the applied magnetic field strength, the mass-to-charge ratio, and the ion momentum. This principle is used to select different ion masses. Some spectrometers use multiple collectors, with multiple different path radii focused simultaneously on multiple collector slits, to cover a wide mass range. In this way, multiple mass peaks may be monitored simultaneously.

Behind each slit high-counting-rate channeltron, electron multipliers are counting the arriving ions. A specific ion mass can be selected with a particular voltage applied to the ion optics. Scanning through a voltage range provides a counting rate, which is a function of the applied voltage, and allows for the determination of a mass spectrum as the resulting output.

Magnetic mass spectrometers may be combined with electrostatic analyzer to achieve double focusing for both bending angle and energy, which leads to a higher mass resolution than single-focusing magnetic analyzers.

10.23.4.14.2 Quadrupole mass analyzer

The QMA utilizes four parallel cylindrical or hyperbolically shaped rods (Figure 3). The rods must be long relative to the inner surrounding diameter, to minimize fringing fields on the active length of the rods. A quadrupole potential is established by applying a time-varying potential on alternate rods with an RF (up to several megahertz frequency) and a DC component.

The ions are injected into the rod arrangement, and only those ions having the correct mass-to-charge ratio can pass to the exit aperture without colliding into one of the rods. Hence, the quadrupole arrangement works as a mass filter. A full mass spectrum is obtained by sweeping the DC offset and the RF amplitude at a fixed frequency and detecting the transmitted masses over the sweep at the quadrupole exit with a Faraday cup or particle multiplier. The resolution of the device depends on the rod geometry, frequency, rod length, and axial and radial ion injection energies. An example of a recently flown QMA is the SAM instrument on MSL (Mahaffy and The SAM Team, 2011).

Improved QMAs make use of hyperbolic rods with narrow wings, resulting in a better mass resolution. A miniature quadrupole array has already been constructed with a mass of several grams (excluding control and readout electronics). The future challenge is to miniaturize the control and readout electronics, as well as the ionization source.

10.23.4.14.3 Ion trap

A quadrupole ion trap uses three electrodes to trap and accumulate ions in a small volume (Figure 4). A middle ring electrode separates two hemispherical electrodes that are connected to ground potential. The middle ring is connected to an RF voltage with frequencies up to several megahertz with some DC offset. Ions brought into this arrangement are trapped in the RF field and perform stable oscillations between the electrodes. Ions of a particular mass-to-charge ratio can be ejected by increasing the RF signal amplitude. A full mass spectrum is obtained by sweeping the electrode voltages over the full range to eject all ions having different mass-to-charge ratio from the trap into an electron multiplier. A full spectrum can be obtained by counting the events at the electron multiplier output as function of the electrode control voltage. Ion traps have a very excellent mass resolution with good signal-to-noise behavior as the trap effectively works as an accumulator of input ions. Full ion trap analyzers can be designed with a mass of less than 100 g.

10.23.4.14.4 Wien filter

In a Wien filter, ions are injected in a perpendicular direction to a crossed electric and magnetic field. Only ions with the matched injection energy will pass this region linearly, when the electric force (Coulomb force depends on ion charge and electric field strength) matches exactly the magnetic deflection (Lorentz force is dependent on ion velocity, ion charge, and magnetic field strength). Ions with different injection energy will follow a nonlinear trajectory as the electric force does not match the magnetic force. A spatially extended detector (MCP, CCD, or multianode detector) after the Wien filter is used to

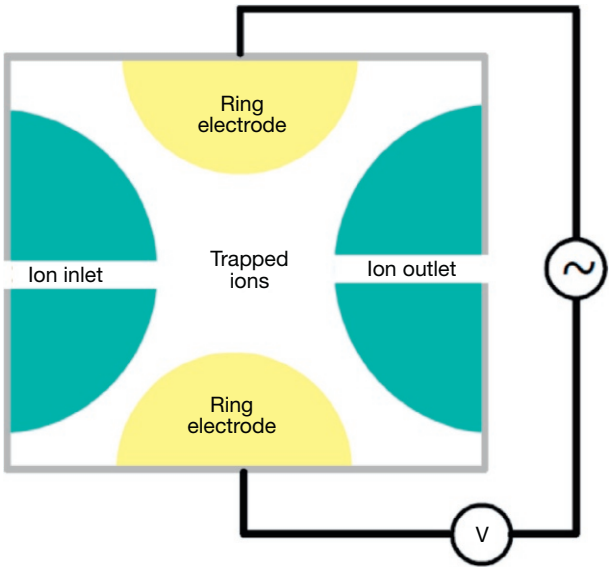

Figure 4 Principle of an ion trap.

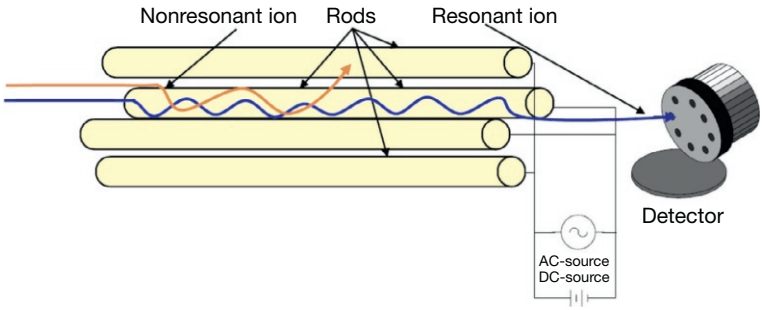

Figure 3 Principle of a quadrupole mass spectrometer.

detect different deflected ions and a mass spectrum can be derived. A Wien filter is also used to remove ions of unwanted isotopes and impurities, multiple charged ions, and neutral particles.

10.23.4.14.5 Gas chromatograph–mass spectrometer

Gas chromatography–mass spectroscopy (GCMS) is used to measure abundances and isotopic ratios of noble gases (He, Ne, Ar, Kr, and Xe) and the abundances of minor gas constituents like SO_2, COS, CO, HCl, H_2S, and H_2O (nonexhaustive) in planetary atmospheres. A pump system controlled with valves is used to generate a low gas flow rate at a reduced pressure to obtain new gas samples from the ambient atmosphere, which are combined with a carrier gas (such as hydrogen) and injected into the gas chromatograph (GC). The GC section provides a time-dependent separation of the gas components prior to a molecular identification in the mass spectrometer (MS). The output of the GC section is ionized with, for example, electron impact ionization before arriving in a quadrupole mass filter, followed by an ion detector. But other methods for the MS can be used as well.

Gas chromatograph–mass spectrometer systems are powerful analytic tools for chemical analysis of many compounds and especially of gas mixtures, but relative complex instruments. GCMS instruments have been flown, for example, on Huygens (Niemann et al., 2002) and the Rosetta lander Philae (Goesmann et al., 2006; Wright et al., 2006) or more recently on the MSL mission (Mahaffy and The SAM Team, 2011).

10.23.4.14.6 TOF mass analyzer

A TOF mass spectrometer consists of an ion source, accelerator, timing gates, a long field-free flight tube, and particle detector. The source ions are accelerated in an electric field and injected into the drift region of the TOF. Gates at the entrance of the drift tube are opened only for a short time to allow a group of ions to enter the drift tube. Ions having a different mass-to-charge ratio take different transit times through the drift region. Lighter ions have a higher velocity than heavier ions and hence reach the detector at the end of the drift region faster. To avoid mass-aliasing effects, additional gates are introduced in the drift region, before the detector, and at the end of the drift region. A TOF analyzer has a relatively large mass range and a good sensitivity provided the drift tube is not too small.

10.23.4.14.7 Laser ablation mass spectrometer

A short well-focused pulsed laser beam is used to ablate small amounts of a target surface material and to convert it into low-energy plasma. The ablation can be done even without prior sample preparation. Emerging ions are analyzed within a TOF mass spectrometer, which determines elemental and isotopic composition of the ablated material. The electrostatic fields in the reflectron of the TOF are designed to cancel energy dispersion of the ions over a broad energy range to achieve an ion TOF from the point of ablation to the MCP being independent of ion energy and proportional to the square root of ion mass. For compact instruments, the TOF ranges from a few microseconds (for H) to <100 μs (for >200 amu). The MCP current as a function of time relative to the laser pulse provides a mass spectrum of the analyzed material. The MCP output signal can be digitized with high accuracy and high time resolution, thus providing isotopic mass resolution for various elements. A laser ablation mass spectrometer was flown on the Phobos mission, LIMA-D (e.g., Pellinen et al., 1990). Modern instruments are small and of low power and low mass (250 g instruments are under development), making them ideally suited for missions to planets and small bodies in the solar system to provide quantitative analysis for major elements and isotopes present in a sample down to levels below 100 ppm. See Brinkhoff (2005) for an analysis of the application to small bodies.

10.23.4.14.8 Laser-induced breakdown spectroscopy

Laser-induced breakdown spectroscopy (LIBS) or laser-induced plasma spectroscopy is atomic-emission spectroscopy with high-energy laser pulse as the excitation source. It consists of a solid-state laser and a spectrometer. The laser emits short (typically 10 ns) focused pulses with a local power density of around $10^7\ W\ m^{-2}$, focused onto a very small point on a sample. Such high energy ablates small amounts of material and converts it into a plasma plume, which breaks down into excited ionic and atomic species. At these high temperatures, the plasma emits continuum radiation and cannot be analyzed, but the plasma rapidly expands and cools (within 10 μs) and consequently reveals the characteristic atomic-emission lines of the elements contained, which is analyzed with a spectrometer with a polychromator (Echelle type) and a CCD or APS detector for readout. The spectrometer range is typically from 1.1 μm to 170 nm covering almost all elements and within the sensitivity range of a classical CCD or APS detector.

The major advantage of the LIBS technique is its ability to provide a depth profile of a sample by repeatedly focusing the laser pulses on the same spot and analyzing the generated plasma. Spectra can be produced within seconds (compared to hours with APX or Mössbauer). LIBS also allows for some remote analysis of samples by employing telescopic optics. For proper measurements, the laser output needs to be kept stable.

A LIBS utilizes many components that are also used for a Raman spectrometer. A combined LIBS–Raman spectrometer allows for both atomic and molecular characterization of a sample. The LIBS–Raman principle is described in Giakoumaki et al. (2006). Currently combined miniaturized LIBS–Raman instruments for space applications are under development (Rull et al., 2011).

10.23.4.14.9 Raman spectrometer

Raman spectrometer (Sharma, et al., 2005) uses the inelastic (Raman) scattering of light to analyze vibrational and rotational modes of molecules. Monochromatic light, produced from a laser in the visible, near-IR, or near-UV range, is scattered by a molecule or by a crystal. One photon of the incident radiation is annihilated and, at the same time, one scattered photon is created. In the case of elastic Rayleigh scattering, the energy of the scattered photon is equal to that of the incident one. Alternatively, the energy of the scattered photon is different to that of the incident one, when inelastic Raman scattering occurs. Spontaneous Raman scattering is very weak, and separating the weak inelastic scattered light from the intense Rayleigh-scattered laser light is the main challenge.

The spectrum of the scattered light consists of a strong exciting line of the wavelength of the incident laser light due to the Rayleigh scattering together with the weaker Raman lines at different wavelengths. The individual shift in wavelength gives information about the phonon modes in the illuminated matter. The lines having longer wavelength are called Stokes lines, the others anti-Stokes lines.

In a Raman spectrometer, the sample is illuminated with a laser beam. The light from the illuminated spot is collected with a lens and sent through a monochromator. Wavelengths close to the laser emission line are filtered out (to remove the elastic Rayleigh scattering), and those in a certain spectral window away from the laser line are dispersed onto a detector. Holographic diffraction gratings and multiple dispersion stages are typically used to achieve a high degree of laser rejection. A photon-counting PMT or a CCD can be used to detect the Raman-scattered light.

10.23.4.15 Mössbauer Spectrometer

A Mössbauer spectrometer determines *in situ* the mineralogical composition of soil samples and provides quantitative analysis of Fe-bearing materials. It can determine the composition and abundance of these minerals, as well as their magnetic properties to a high level of accuracy. It makes use of the resonance absorption of γ-rays by Fe^{57} nuclei, based on the Mössbauer effect. The absorption provides information on the nuclear energy-level splitting of Fe-bearing materials. The splitting reflects the nuclear levels occupied by surrounding electrons.

Co^{57} is normally used as the γ-ray source. In general, the structure of the nuclear energy levels of the soil samples differs from that of the Co^{57} γ-ray source because of different oxidation states, chemical environment, and magnetic order. To achieve resonance with the soil samples, the energy levels of the emitted γ-rays from the source are modulated to overlap with energy levels of the sample. The Co^{57} source is mounted on an electromechanical velocity transducer and moved with respect to the target, leading to velocity-modulated energy levels of the emitted γ-rays due to the Doppler effect. Accordingly, the energy increases if the source moves toward the sample and decreases when moved away. Phase and the oxidation state of the target can be determined from the peak locations in the resulting spectrum. The concentration can be estimated from the peak intensities in this spectrum.

Analysis of material can be performed by either transmission or backscattering, although the transmission method is limited to thin targets directly placed between the source and the detector.

With the backscattering principle, only the surface of the sample contributes to the received spectrum. The average diagnostic depth for a backscattering Mössbauer spectrometer is in the order of 100–200 μm (assuming basaltic rock composition). The backscattering approach is generally preferred for planetary applications.

The Mössbauer spectrometer is sensitive to temperature variations, which should not exceed about $\pm 10\,^{\circ}C$ during acquisition of a single spectrum to minimize the temperature-dependent parameter variations and the resulting spectral smearing. Measurements are taken by placing the instrument's sensor head directly against a rock or soil sample. A Mössbauer measurement typically can take about 12 h. Mössbauer spectrometers are preferably mounted on microrovers or robotic arms to provide mobility (e.g., Klingelhöfer et al., 2003; Wade et al., 1999).

10.23.4.16 Dust Analyzer

A dust detector instrument is an *in situ* instrument used to measure the mass, electric charge, and velocity of incoming dust particles. The detectable masses of dust particles are typically in the range 10^{-16}–10^{-6} g. The speed of these small dust particles is measured over a typical range of 1 km to several tens of kilometers per second at impact rates from 1 particle per 100 days to several hundreds of particle impacts per second. The instrument aperture is the important characteristic to guarantee a proper count rate for a specific application. The length of the flight path of the TOF mass analysis section defines the achievable mass resolution and contributes, together with the aperture, to the overall instrument size. Dust compositional analysis instruments have flown on various comet missions (e.g., Kissel et al., 2003).

10.23.4.16.1 Quartz crystal microbalance

A quartz crystal microbalance (QCM) can detect tiny mass deposits on the sensor crystal by the resonance frequency change introduced by the addition of the small mass. Frequency measurements can be made with high precision; hence, it is easy to measure small mass increments with a QCM. Correlation between mass and frequency is achieved by means of the Sauerbrey equation (Sauerbrey, 1959). For compensation of the strong temperature dependence, a sealed reference quartz system is required, which is exposed to same temperature, but is protected from additional particle deposits. An example of a QCM flown in space is that forming part of the Electric Propulsion Diagnostic Package on board SMART-1.

10.23.4.17 Radiation Environment Monitor

Radiation monitoring during cruise phase and operational phase of a space mission is not only important from an engineering point of view but also scientifically of high interest. Observations of solar flares or measurements of the Earth or very strong Jovian radiation belts are some examples. A radiation monitor has to cover a wide energy range starting at several kiloelectronvolts up to gigaelectronvolts and must be sensitive to electrons, protons, heavy ions, and galactic cosmic rays. Only a combination of various detectors (SSDs, scintillator, and scintillating fiber) can satisfy these requirements. Important issues are (1) the flux measurement to derive the energy spectrum and (2) the measurement of the total (integrated) dose.

Newer technologies employ thermoluminescent dosimeters for local dosimetry and radiation-sensitive field effect transistor (metal oxide semiconductor structures sensitive to ionizing radiation) as real-time dosimeters (Bühler et al., 1996). Several new radiation monitors are under development (see Taylor et al., 2011).

10.23.4.18 Scanning Tunneling and Atomic Force Microscope

A scanning tunneling microscope (STM) is used to image surfaces of electrically conducting materials at atomic scales. An atomically sharp metal tip is brought very close to the surface, and a voltage is applied between the sensing tip and the sample, driving a small tunneling current whose magnitude depends on the distance between the tip and the surface. As the tip is moved laterally across the surface, a feedback mechanism moves the tip up and down to maintain a constant tunneling current. 2-D raster scanning with the tip across the surface produces a topographic map of the surface.

An atomic-force microscope (AFM) works on a similar principle, but is not restricted to electrically conductive materials. The AFM tip is sensitive to atomic and intermolecular forces (such as van der Waal forces) and moves up or down on its supporting cantilever. The movement of the tip is monitored with a laser beam reflected from the tip and read out with a photodiode array or by piezoresistive elements, which follows the movement of the tip and is then read out by a Wheatstone bridge with picometer resolution. Raster scanning the tip across the surface produces a topographic map of the surface with atomic resolution. Piezoceramics are used for the 3-D positioning of the tip at high precision. A major difficulty of STM and AFM for space application is the sample preparation and sample positioning in front of the tip, which requires complicated and sensitive mechanisms. The Midas instrument is an AFM flying on Rosetta (Riedler et al., 2006).

10.23.4.19 Scanning Electron Microscope

A scanning electron microscope (SEM) provides high-resolution 3-D images of a sample surface. An electron beam (few hundred electronvolts to 50 keV) thermionically emitted from a tungsten or lanthanum hexaboride cathode or alternatively by field emission (FE) is accelerated toward an anode and focused by a magnetic lens into a beam with a focal spot the size of a few nanometers. Electromagnetic coils are used to steer the electron beam in a scanning mode over a rectangular area of the sample surface.

The electrons hit the surface and are inelastically scattered by atoms in the sample. The scattering process spreads the focused beam up to a few microns onto the surface of the sample leading to emission of electrons and x-rays. The low-energy (<50 eV) secondary electrons can be detected by a scintillator–photomultiplier device, and due to the raster scan, a 2-D intensity distribution can be displayed as an image. The number of secondary electrons reaching the detector is translated into the brightness of the image. Emitted x-rays can be analyzed with dispersive x-ray spectroscopy. Also, the backscattered electrons can be detected and analyzed as an electron backscattered diffraction image to determine the crystallographic structure of the sample surface.

The spatial resolution of an SEM depends on the size of the focused electron spot defined by the electromagnetic coil system and the extension of the volume in which the electron beam interacts with the sample material. The resolution of the SEM is not sufficiently high to image down to the atomic scale. A miniaturized (11.9 kg) design of a spaceborne SEM has been developed for the (cancelled) Comet Rendezvous Asteroid Flyby mission (Albee and Bradley, 1987).

10.23.4.20 Plasma and Wave Instruments

Plasma, the most common phase of matter in the universe, consists of partially or fully ionized gas. It contains an equal number of positive and negative charge carriers and hence behaves quasineutral in the stationary state. There are quite a number of different geophysical plasmas with a wide spread in their characteristics, ranging from lower density and lower temperature to high-density and high-temperature plasmas (Baumjohann and Treumann, 1996). Basically, there are two set of instruments required for plasma studies investigating either the associated electromagnetic waves (plasma wave analyzers (PWAs)) or the charge carriers of the plasma (plasma analyzer).

10.23.4.20.1 Plasma wave analyzer

PWAs measure the electrostatic and electromagnetic components of plasma waves. The instrument receiver is sensitive to the wavelengths from several hertz to several hundred kilohertz in some case to the megahertz range. PWAs are used for a wide range of plasma investigations, for example, magnetospheres, ionospheres, solar wind, atmospheric lightning detection, or events when dust particles strike the spacecraft.

Plasma particles are bound to the natural magnetic field. Motions within the plasma will cause changes with time of the electric and magnetic fields detectable as plasma waves. An electric dipole antenna is used to measure the electric field component in the plasma, while (tri-axial) search coils are used for the magnetic field components. In the case where very low electric field frequencies have to be analyzed, long dipole antennas are required, sometimes exceeding 50 m single tip length (Gustafsson et al., 1997, 2001). Such booms are usually designed as wire booms and accommodated on spinning spacecraft providing gyroscopic stiffness to the wire booms. The deployment of such booms can be problematic and risky for the spacecraft but is by now demonstrated successfully by several space missions.

The received antenna signal is amplified with wideband electrometer preamplifiers or a set of band-limited preamplifiers for frequency-selective analysis. Low-noise design and high impedance with guard feedback systems are required for low-density and weak-field analysis to minimize the disturbances of the environmental plasma and to achieve enough sensitivity. The preamplified signals are usually further amplified for frequency analysis with either discrete filter banks or computational Fourier analysis using digital signal processing (DSP). The same DSP and analog-to-digital conversion chain can be also used for the magnetic field search coil system. Nearly simultaneous measurements of the electric and magnetic field spectrum allow electrostatic waves to be distinguished from electromagnetic waves.

Examples of PWAs are the wideband plasma wave investigation for the Earth's magnetosphere on Cluster II (Gurnett et al., 1997), the low-frequency PWA (LFA) on board the Planet-B spacecraft for Mars (Matsumoto et al., 1998), and the Huygens permittivity, waves, and altimetry

analyzer (PWA) for the atmosphere of Titan (Hamelin et al., 2000).

10.23.4.20.2 Plasma analyzer

Plasma analyzers are used to assess the elemental and isotopic composition, the associated energy levels (temperature), density, velocity, and 3-D distribution of interplanetary, planetary ionospheric and magnetospheric, and solar wind plasma. They are further used to determine the sources of the magnetospheric plasma, investigate the interaction of ambient plasma with moons and planets, and study magnetosphere dynamics, corotational forces, field-aligned currents, and magnetic reconnection and the nature of the equatorial current sheet of magnetospheres.

Plasma analyzers are in most cases combinations of instruments to satisfy the wide scope of measurements:

An electrostatic analyzer (ESA) is used to measure the deflection of the ions (and electrons) in a static electric field to define their E/q ratio (energy (E) over charge (q)).

A TOF section is used to measure TOF of the (static preaccelerated) ions and their energy with an SSD (see Solar Wind Ion Composition Spectrometer (SWICS) on Ulysses; Gloeckler et al., 1992). From the ESA and TOF measurements, simple equations can be used to estimate the energy E, charge state q, and mass m of the ions.

An electron analyzer system (EAS) is used to define the energy of electrons (typically up to a few kiloelectronvolts). It consists of two or three combined sensor heads and an ESA with electrostatic deflection (e.g., SWOOPS on Ulysses; Bame et al., 1992). See also ASPERA-3 on Mars Express, which measures ions, electrons, and high-energy neutral atoms in the outer atmosphere of Mars.

10.23.4.20.3 Langmuir probe

A Langmuir probe is used to determine the electron temperature, electron density, and plasma potential, by inserting one or more electrodes (segmented Langmuir probe) into the plasma, with a time-varying electric potential between the electrode and the surrounding plasma. The measured currents over the applied potentials (I–U curve) allow for determination of the main physical properties of the plasma. Although the measurement itself is rather simple, the interpretation of the data requires deeper understanding of the Langmuir probe theory for a spherical probe in unmagnetized plasma (Schott, 1968).

The instrument consists of a short boom (to overcome the Debye length and associated plasma distortions) with the sensitive electrode and guard system. The instrument controller applies a time-varying potential to the electrode and measures with a current-sensitive amplifier the associated current to or from the plasma (the current direction depends on the relative applied potential).

One example is the ISL Langmuir probe experiment on board DEMETER (Lebreton et al., 2006).

10.23.4.20.4 Electron drift instrument

An electron drift instrument (EDI) measures the displacement of a weak (<1 μA) artificially injected electron beam in an ambient electromagnetic field at different electron energies and beam directions. The electromagnetic field introduces a drift of the electron beam. A detector on the opposite side of the spacecraft detects the beam only at some specific geometric and energetic conditions, dependent on the ambient electromagnetic field strength, the angle between injection and magnetic field vectors, and injection energies of the electron beam. Two beams and two detectors allow for continuous direction monitoring, and by triangulation, the displacement can be derived. For small magnetic fields, the displacement is achieved from TOF difference of the two beams. Supplementary data from magnetometer measurements (fluxgate and search coil) combined with the EDI TOF and triangulation are used to constrain the ambient electric field. A key advantage of the EDI technique is that the beam probes the ambient electric field at several kilometers away from the spacecraft and hence under undisturbed conditions. As a by-product, the measured TOFs provide a precise measurement of the magnetic field magnitude (Paschmann et al., 1997).

The narrow ejected electron beam must be controlled within a hemisphere. Electrostatic multipoles are used to deflect the electron beam in the desired direction. Also, the detector has a selectable direction over a wide range. A complex optic in combination with an annular MCP is used to adjust the observational direction of the detector (Paschmann et al., 1997). A scanning algorithm employing various emission and detector directions combined with several electron beam energies and beam currents is used to find conditions where the beam returns back to the detector via the ambient field after single or multiple gyrations. The beam, produced by a tungsten filament, is pseudonoise-coded to allow for TOF analysis by correlation (Nakamura et al., 1989).

10.23.4.20.5 Active spacecraft potential control

Measurements of electric field potential are subject to distortions from interaction of the spacecraft with the plasma and by photoelectrons. Occurring spacecraft floating potentials may prohibit measurement of cold ambient plasma (at several electron volts), as low energetic ions and electrons are repelled by the potential of the spacecraft. To allow for measurements of lower energetic plasma, an active spacecraft is required. A Langmuir probe (or similar instrument) is used to measure the actual spacecraft potential, and an active ion source is employed to compensate the spacecraft charging by emission of an ion beam. A liquid-metal ion source has been used for active spacecraft potential control on Cluster II (Riedler et al., 1997): A solid needle usually made from tungsten is mounted in a reservoir with heated melted indium (at about 520 K). A potential of several kilovolts is applied between the needle and an extractor electrode, which causes the liquid metal to be pulled toward the extractor electrode. Positively charged ions are evaporated in the strong field of the needle and the hydrodynamic flow causes liquid metal from the reservoir to follow. The controlled emission of the ions is finally used to reduce the charge of the spacecraft.

10.23.4.21 Magnetometer

Magnetometers are used to map magnetospheres of planetary bodies and analyze their dynamics and fluctuations. Magnetometers are usually mounted on the tip of long booms to reduce the magnetic background introduced by the spacecraft

and its components. However, not all these effects can be eliminated by separating the instrument by a boom. An additional magnetometer (inbound magnetometer) mounted at a specific boom length fraction can help distinguish spacecraft-produced fields from ambient fields. In case of high-resolution measurements, the spacecraft has to undergo a magnetic cleanliness program, with specific design rules and material selection constraints, which introduces cost issues for the mission. Another source of potential error in measurement comes from bending and twisting of the long magnetometer boom. Increase of the boom rigidity (mass increase) or measurement of the actual bending (e.g., with a small stellar compass) can be used to mitigate the influence. In some cases, the use of an active boom bending control (smart structures) can be applied. The Ulysses magnetometer uses two sensors representing the two major measurement principles: a fluxgate and a vector helium magnetometer (Balogh et al., 1992). The magnetic fields of the planets and techniques of interpreting magnetic field measurements are discussed in **Chapter 10.07**.

10.23.4.21.1 Fluxgate magnetometer

A fluxgate magnetometer (FGM) sensor consists of three coils wound around a ferromagnetic ring core, with the primary and secondary windings aligned within the plane of the sensor core, and an additional calibration winding. The primary windings are driven by a current pulse train at a frequency f_0 such that the core is in its region of saturation. In the presence of an external magnetic field, a second harmonic (at the frequency $2f_0$) is generated in the pickup coil (secondary winding), with its amplitude proportional to the coaligned component of the external field. The phase relation between the pickup signals and the primary drive signal represents the direction of the magnetic field component.

Usually, three identical single-axis fluxgate sensors in an orthogonal arrangement are used to measure the three orthogonal components of the magnetic field. FGMs provide in general sufficient sensitivity but are subject to some long-time drift, which has to be compensated.

10.23.4.21.2 Vector helium magnetometer

Vector helium magnetometers are based on the influence an ambient magnetic field has on the efficiency with which a metastable population of helium gas in the triplet ground state can be optically pumped (Zeeman effect). A good example is the Cassini vector/scalar helium magnetometer (Dougherty et al., 2004): Metastable helium is generated in a helium-absorption cell by RF discharge. An incident radiation produces a distribution of atoms in nonthermodynamic equilibrium among the various energetic substates by optical pumping. Circularly polarized light of wavelength 1.08 μm is used for the pumping. The presence of an ambient magnetic field affects the pumping efficiency, which is exploited in the vector mode of the magnetometer: An IR detector senses the changes in absorption in the helium cell. For a constant light output, the change in pumping efficiency is measured, which depends on the magnetic field strength and angle between the magnetic field vectors with respect to the optical axis of the system.

In the scalar mode of the V/SHM magnetometer, IR radiation and an AC magnetic field are simultaneously applied to the absorption cell. The efficiency of the optical pumping is minimal, and the absorption is greatest when the frequency of the applied AC field is at the Larmor frequency (precession frequency of the magnetic moments of electrons, atomic nuclei, and atoms around the direction of an external magnetic field), which is directly proportional to the ambient magnetic field. Vector helium magnetometers are very sensitive and tend to less drifting compared to FGM (Dougherty et al., 2004).

10.23.4.21.3 Search coil

Search coil magnetometers are based on Faraday's law of induction and used to measure the AC magnetic field. Several turns of conducting wire are wound around a highly permeable ferromagnetic material core. A varying magnetic field passing through the coil induces a voltage, which is proportional to the time variation of the magnetic field. The sensitivity of search coil magnetometer directly depends on the area of the coil, the number of turns, the permeability of the core, and the rate change of magnetic flux. Specially designed low-noise and low-power amplifiers are used to read out the induced voltage from several hertz to several kilohertz (Coillot et al., 2006).

10.23.4.22 Accelerometer and Seismometer

Accelerometers are used to sense acceleration of vehicles such as rovers, aerobots, descent probes, landers, and spacecraft to

- derive atmospheric parameters (density and drag) during descent/entry phases,
- detect spin rate,
- derive nongravitational perturbations acting on the spacecraft to determine the actual gravitational field in combination with radio-science experiments,
- investigate seismic events, and
- perform inertial navigation.

During the entry and descent phase of an entry probe, the interaction with the atmospheres causes drag on the probe, leading to a strong deceleration, which can be measured with accelerometers. Out of the measured data, an estimation of the atmospheric density can be derived (Fulchignioni et al., 2002).

For the entry probe stabilization during the descent, a spin is often introduced. The spin rate can be measured with accelerometers. This is, besides the engineering aspects, of importance as auxiliary information for scientific measurements performed during the descent (Lorenz, 2004).

The direct solar radiation and the thermal emission from the planetary surfaces exert a force upon an orbiting spacecraft that, if not accounted for, destroys the accuracy of orbital parameter determination (cf. spacecraft tracking). Very sensitive three-axis accelerometers are used on board spacecraft to separate these nongravitational from gravitational components (Iafolla and Nozzoli, 2001).

Various types of accelerometer exist based on the following main principles:

- Piezoelectric effect
- Capacitive effect
- Microelectromechanical systems (MEMS)
- Electromechanical servo principle

Piezoelectric accelerometers use a proof mass, which causes a shear stress to the sensing piezoelectric crystals due to the

acceleration. This stress results in a proportional electric output signal of the piezoelectric material. With this technique, rather simple accelerometer can be constructed. A drawback is the thermal sensitivity of the crystal material, which requires an appropriate thermal stabilization of the sensor.

Capacitive accelerometers utilize a spring-suspended proof mass, mounted between two capacitor plates. Any acceleration of the proof mass causes a small displacement, leading to a capacity change of the arrangement. The capacitive sensor is applied as frequency-defining component in an oscillating circuitry (with a typical bias frequency in the order of 10 kHz; used to reduce the low-frequency flicker noise contribution of the electronics). Even the slightest acceleration of the capacitive sensor causes a frequency modulation. The oscillator output signal is read out via a bridge arrangement with a LNA and demodulated to the base band. The minimum detectable acceleration of such an accelerometer is limited by the Brownian noise of the proof masses (and hence its temperature) and by the amplifier noise (Iafolla and Nozzoli, 2001). Thermal control of the sensor unit within at least 1 °C is required for such a system to allow for extremely low-noise performance.

10.23.4.22.1 Seismometer

Seismometers are specialized very low-noise accelerometers to detect seismic waves in planetary bodies. Seismic waves can be used to map the interior of planets and measure and locate quakes and other motions of the lithosphere (see also **Chapters 10.03** and **10.02**, the latter for internal structure modeling).

To define the propagation direction of a wave, usually, a three-axis seismometer is required. A servo principle is used: a proof mass, confined by electric forces, is kept at the equilibrium position by the control electronics in a closed loop arrangement. Any vibration of the proof mass, detected by capacitive, inductive, or optical means, is counteracted by the control electronics. Any change of the required electric force is recorded as the output signal of the seismometer.

For sophisticated seismic analysis, a seismometer network is required to constrain the origin, location, and propagation paths of the seismic waves, to disentangle surface waves from interior waves, to distinguish compression (P-waves) from shear waves (S-waves), and finally to constrain the interior structure of a planet or planetary body and its dynamic processes. Such a seismic network requires deployment from multiple planetary landers (cf. NetLander).

So far, only the Apollo seismic network has returned useful seismic information from the Moon (Lognonne, 2005). The Viking probes had simple seismometer mounted on their legs (Anderson et al., 1977), and the InSight mission foreseen for launch in 2016 (Banerdt et al., 2012) will bring a seismometer (and a heat flow probe) to the Mars surface (Mimoun et al., 2012). Miniaturized seismometers for planetary application are under development (e.g., Banerdt and Pike, 2001). Seismology as a tool for planetary exploration is discussed in **Chapter 10.03**.

10.23.4.23 Thermometer

Thermometers are used to measure the atmospheric temperature during entry and decent phase and at stationary landers and moving rovers. They can also be used to define *in situ* temperatures of planetary surfaces and are used to derive subsurface temperature and heat flow, for example, when integrated into a mole or drill system such as HP^3 (e.g., Spohn et al., 2014) Thermometers also play an important role as housekeeping sensors to monitor the temperature of instruments platforms or other spacecraft components. Many scientific instruments are sensitive to thermal variations, and hence, precise knowledge of the temperature is important to calibrate their measurement results.

Various types of thermometer principles are in use:

- Electric resistance thermometers
- Thermistors
- Thermocouples
- Microbolometers

The basic principle of resistance thermometer is that the conductivity of most conductors and semiconductors strongly depends on their temperature (in most cases a nonlinear dependence). By applying a small constant current, the resulting voltage over the resistor can be measured and with proper calibration the temperature derived. Such a sensor principle has been used, for example, to derive the precise atmospheric temperature during the decent of the Huygens probe in the atmosphere of Titan (Fulchignoni et al., 2005).

Thermocouples are used to measure temperature differences based on the thermoelectric or Seebeck effect. They can be used for wide temperature measurements but are rather limited in accuracy.

A microbolometer is a thermal sensor with very high resolution and sensitivity to IR radiation, hence a remote-sensing thermal sensor. The microbolometer reacts with a resistance change when exposed to IR radiation. This resistance change is measured and processed into temperatures. Microbolometer can be made very small and arranged in an array configuration allowing for thermal imaging – even without cooling of the detector array.

10.23.4.24 Pressure Sensor

Pressure sensors are used in atmospheres and exospheres to measure *in situ* the static pressure profile, derive the density profile during atmospheric descent, and measure the diurnal and seasonal changes of the ambient pressure on static or mobile landers and rovers. Two major sensor principles are in use:

- Semiconductor strain gage
- Capacitive systems

The semiconductor strain gages are thin Si-based membranes, which change their resistance due to deformation of the membrane caused by pressure changes. The piezoresistive changes of the detector are sensed in a bridge configuration with reference resistors to eliminate thermal drift. The very small bridge output voltage (e.g., 100 mV/350 mbar) is proportional to the sensed pressure and has to be amplified with a low-noise differential instrumentation amplifier.

Capacitive systems are based on the distance change of thin capacitor membranes (similar principles as a condenser

microphone), which results in a capacitance change. This change is usually sensed in an oscillator circuit where the sensor capacitor is used as a frequency-defining component. Hence, any change in pressure results in a change of the output frequency, which can be easily and precisely measured with a digital counter and precision timing gate.

The pressure sensors are used in three different measurement configurations:

- Absolute pressure
- Differential pressure
- Gauge pressure

For absolute pressure measurement, the sensor membrane is working against a reference pressure (e.g., vacuum) in a closed system. When the reference pressure is 1 atm, then the sensor is called a gauge pressure detector. For differential measurements, the membrane works in an open system and hence is sensitive to the pressure gradient.

The pressure profile instrument on board the Huygens probe (Harri et al., 1998) is an example of an absolute pressure capacitive system.

10.23.4.25 Microphones

Microphones are used for atmospheric acoustics (Petculescu et al., 2006) to study acoustic waves and acoustic events and to derive speed of sound. The detector used as a microphone in the Huygens permittivity and waves analyzer (Hamelin et al., 2000) is a differential pressure system based on a semiconductor strain gauge detector, which operates down to 90 K (Falkner 1999).

10.23.4.26 Microgas Sensors

Microgas sensors are foreseen to be used for *in situ* measurement on aerobots, landers, and rovers to detect and analyze specific constituents and trace gases of planetary atmospheres. Various principles for microgas sensors exist. Some are based on miniaturized IR sensors with emitters employing micromachined Fabry–Pérot interferometers, tuned to wavelengths of an absorption line of a certain gas. To resolve narrow absorption lines, a narrowband emitter coupled with a narrowband detector is required. The attenuation between the emitted signal and the received signal is measured to conclude on the concentration of the absorbing gas.

To achieve a narrowband emission, a microcavity with two mirrors (made, e.g., from CdHgTe) with a typical thickness of about 3–5 μm is employed. The microcavity is pumped with a laser diode (classically in the range from 0.6 to 0.9 μm wavelength), resulting in a beam with wavelength of 3–6 μm. As detector microbolometer can be used.

Another development is based on the so-called electronic nose principle, where integrated sensor arrays are employed. Individual sensor elements like polymer film are tuned to a specific gas component and respond with a change of volume and resistance when a specific gas reached the sensor. The resistance change can be easily measured. Using an array of different modified polymers creates very specific resistance change patterns, which are used to identify the gas. Electronic neuronal networks can be used to train the sensor to easier recognize a gas or gas mixture.

Microgas sensors and electronic noses are miniaturized alternatives to (rather bulky) gas chromatograph–mass spectrometer and currently under development for space applications and already widely used in laboratory and commercial applications.

10.23.4.27 Surface Dating

Luminescence dating is used to estimate the age of sediments by determining how long ago mineral grains were last exposed to daylight. The amount of unstable trapped electrons in the crystal structure of minerals like quartz or feldspar is used to define the age of the sediment. Trapped charge accumulates in minerals through time due to energy absorption from ionizing radiation like cosmic rays. Through heating (thermoluminescence dating) or optical stimulation in the case of the optical stimulated luminescence, the trapped electrons recombine and the energy is released by luminescence. The brightness of the luminescence corresponds to the amount of trapped charge, which is a measure of the total ionizing radiation received by the crystal since its last exposure to light (Aitken, 1998). With the knowledge of the ambient radiation dose rate (based on either measurement or modeling), the age can be derived.

The instrument consists of a heat or light source for stimulation and a photon detector with appropriate filter to detect the luminescence. Access to buried material and sample preparation are difficult to realize for robotic planetary missions. OLS instruments are widely used in geosciences on Earth, although spaceborne applications for use on Mars are under development (Kalchgruber et al., 2005).

Another approach to surface dating is based on crater counting as a technique for estimating surface ages over a more extended age range (see **Chapter 10.06**).

On Earth, the radiometric dating technique is widely used for surface dating. The same technique has been used also for Moon samples, which have been returned by Apollo and Soviet Luna missions. Unfortunately, this technique is not (yet) feasible for robotic space missions.

10.23.5 Instrument Suites for Exploration

Individual instruments as described in the previous section can never alone satisfy all objectives of a planetary exploration mission. In most cases, a combination of instruments is needed to provide new results when exploring our solar system planets and their moons and small bodies. All missions so far have had a more or less complex set of instruments on board. This approach will remain for future exploration missions, simply because most of the instruments need context information and additional data provided by other instruments on board the spacecraft.

In essence, all (geo-)scientific investigations performed on Earth would also be of interest on planets, moons, asteroids, and comets, but restriction due to technology and resource limitations (mass, power, volume, data rate, etc.) have limited what has been achieved up to now and also what can be done in the near future. Due to the high delta-v requirements of

planetary missions (see Chapter 10.17), the propellant consumes a large fraction of the overall spacecraft mass, often exceeding 50% or even 60%. Ever shrinking financial space-science budgets limit the size of future explorative missions to small and medium size. Giant missions such as Cassini/-Huygens are in the current budgetary environment unlikely for most of the world's space agencies. Selective and carefully considered priorities of the investigations are required. Focused science objectives and use of appropriate spacecraft and payload technology, paired with cautious trade-offs on mission risk and new technology, are desirable.

Smaller spacecraft require optimization of the spacecraft subsystems and in particular of interfaces between spacecraft and payload. Overheads on interfaces, implemented to simplify spacecraft engineering, integration, and assembly, compete with additional instrumentation and hence with the scientific performance of a mission.

An interdisciplinary view comprising spacecraft engineering, payload engineering, and science needs to be applied. A resource-saving approach is given by instrument suites tailored to the scientific requirements rather than collections of individual instruments (Figure 5). A careful instrument suite design based on well-defined scientific requirements allows for significant resource reduction and returns high-level scientific results even on smaller exploration missions.

The following section describes examples of instrument combination for various disciplines. The examples provided are intended as illustration and are under no circumstance exhaustive.

10.23.5.1 Planetary Size, Mass, Shape, and Interior

The precise measurement of a planet's size, its mass, and its shape, in particular deviations from the spherical shape by determination of the J-terms (zonal coefficients), and localization of mass irregular concentrations (mascons) are fundamental and also required for many other scientific investigations, as well as for precise spacecraft navigation. Interior structure and dynamics, in particular of the terrestrial planets (see Chapter 10.02), division of core/mantle/crust, and their motion have to be obtained. Although from gravity and magnetic measurement, some key information can be derived, seismic data measured on the surface are also important (see Chapter 10.03). Of course, landing on a planet is necessary to deploy a seismic station or even preferably a network of stations (see Chapter 10.03). Deployment of an instrument suite by means of a high-speed penetrator, as a cost-reducing alternative to soft landing, has been considered (e.g., Deep Space 2 Mars penetrator or JAXA's Selene – a lunar penetrator), but so far not successfully demonstrated in space. Small penetrators are under development (Vijendran et al., 2010) and were proposed for Juice mission or could be used for Mars missions as piggyback.

Measurement of the heat flow is important to constrain internal heating and temperatures. Temperatures have to be measured under the surface at various depths with high precision. The development of self-penetrating mole equipped with instrumentation to measure the heat flow (the heat flow and physical properties package HP^3) is ongoing (Spohn et al., 2014) and will be implemented in the InSight mission (Banerdt et al., 2012) to be launched to Mars in 2016. Magnetometers play an important role by measuring the magnetic field and hence electromagnetic material properties of the interior and constraining the internal field generation. Both measurements from orbit and at the surface are of importance.

10.23.5.2 Surface and Subsurface

Surfaces are analyzed via remote-sensing and *in situ* observations. A long list of interesting phenomena exists, resulting in a huge variety of possible instrumentation. Nevertheless, a kind of standard set of instrumentation has emerged, including imaging and observation in the electromagnetic spectrum (spectroscopy and radiometric measurements),

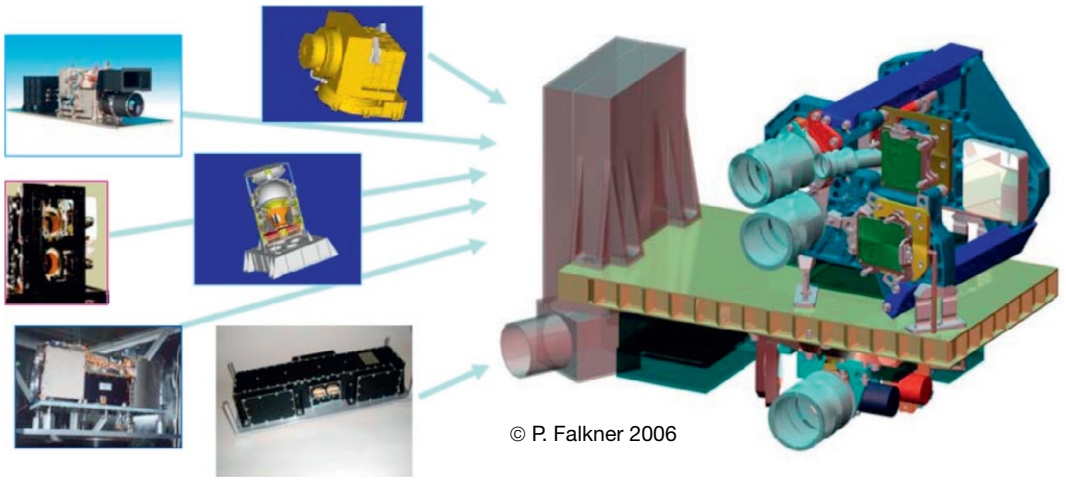

Figure 5 Evolution of collection of instruments into an optimized highly integrated instrument suite (HIPS). Stereo imager (middle top), laser altimeter transmitter (small optics, upper right), highly integrated broadband radiometer and imaging spectrometer (right bottom), and UV spectrometer (left bottom and left top) and supporting DPU with power supply (left bottom box between UVS and UVS).

from radio waves to γ-rays, mainly to define morphology and chemical composition. Laser and radar altimeters are used for topographic studies on the surfaces and to measure gravity tides and surface roughness (Table 2). GPR (cf. Mars Advanced Radar for Subsurface and Ionospheric Sounding (MARSIS) on Mars Express; Picardi et al., 2004) or SHARAD on MRO (Seu et al., 2007) is used for subsurface investigations because of the deep-penetration capabilities of low-frequency waves. An interesting application for GPR is the search for subsurface water or to investigate the ice–water interface like on Europa, although penetration of the full thickness of the ice layer is rather challenging. High-resolution imaging is important to provide photogeologic details and morphological and topographic information (particularly in combination with stereo imaging and laser or radar topography) and is also used for surface dating based on crater counting.

High-resolution spectral analysis in UV and NIR is used to define the chemical mineralogy possibly enhanced with elemental compositional information provided by XRF and GRS. Important factors are a high spatial resolution and the possibility of correlation with images provided by high- and medium-resolution imagers in the visual range, under the restriction that no dense atmosphere prevents optical access to the surface from an orbiting spacecraft. Imaging spectroscopy in the various bands with coaligned pointing to the visual imager and the star trackers, which are needed to derive the absolute pointing knowledge, can be best realized in an integrated suite approach. The instrument optics and focal planes are mounted very close together on common small platforms (Falkner et al., 2004; Kraft et al., 2005). This avoids structural problems (bending and thermoelastic expansion), which are more difficult to handle when distributed instruments and navigation subsystems are accommodated on an extended instrument platform. A simplified exchange of data from the instrument suite can be easily introduced in the design of the highly integrated payload suite (HIPS) data handling system.

Magnetometers are used to map magnetospheres and analyze their dynamics and measure fluctuations in the ambient magnetic field. Most recent developments of a single-chip low-power ASIC for complete three-axis FGM, using higher-order sigma-delta conversion and digital filtering (Magnes et al., 2008), demonstrate the possible route for miniaturization of instruments.

Another class of measurements can be done *in situ* on planetary surfaces. Surface access to planets remains challenging due to local environmental conditions (e.g., high temperatures on Venus or Mercury and radiation in the Jovian system), high delta-v requirements (e.g., Mercury, Galilean moons, and Titan), and overall technical complexity. Nevertheless, many missions have achieved successful landings and new ones are under preparation. Initial stationary landers such as the Viking landers on Mars (Soffen and Snyder, 1976) have been enhanced with mobile rovers (e.g., Mars and Moon) and self-penetrating moles, and drills are under preparation (Richter et al., 2005). Subsurface access has been just recently demonstrated by the Curiosity (MSL) rotary-percussive sample acquisition device. New instrumentation with significant miniaturization and the use of advanced technology, particularly state-of-the-art microelectronics, are required. Table 3 lists some of the instrumentation already used, planned, or under development for *in situ* observations.

Table 2 Instrument examples to constrain planetary size, mass, shape, and interior

Remote sensing	In situ
Laser or radar altimeter	Seismometer
Radio science and accelerometer	Heat flow experiment
Ground-penetrating radar	Magnetometer
Imager	

10.23.5.2.1 Surface station

A surface station is a stationary platform deployed on a planetary body, providing the infrastructure (power, thermal environment, data handling, communication, etc.) for the scientific instrumentation (see Table 3 under *in situ*). Deployment mechanisms are required to permit the instruments unobstructed access to the surface and give some degree of freedom for the sample selection and positioning. Several instruments require

Table 3 Instrument examples to analyze planetary surfaces and subsurface by means of remote-sensing and *in situ* instruments

Remote sensing	In situ
• High-resolution imager (visual)	• Panoramic camera
• Stereo camera	• Laser mass spectrometer
• Spectral Imager (UV, NIR, FIR, visual)	• LIBS/Raman spectrometer
• Surface and subsurface radar	• Alpha particle x-ray spectrometer
• Laser altimeter	• x-Ray diffractometer
• x-Ray, gamma-ray, and neutron spectrometers	• Attenuated total reflection spectrometer
• Microwave sounder, submillimeter sounder	• Mössbauer spectrometer
• Magnetometer	• IR Fourier spectrometer
• Thermal infrared (IR) radiometer	• Gas chromatograph and mass spectrometer
	• UV spectrometer
	Microscopic imager
	• Heat flow and physical properties package
	• (Miniature) Thermal emission spectrometer
	• Magnetometer
	• Seismometer
	• Ground-penetrating radar (surface deployed)

very specific access to and alignment with the sample (e.g., LMS, APX, and Mössbauer) and hence a precise deployment mechanism. Imager and panoramic imager should be mounted on a deployable boom to provide an elevated view with a mechanism providing elevation and azimuth rotation, required for panoramic imaging. A thermometer, wind meter (anemometer), magnetometer, and many other instruments require some distance from the surface station, simply to reduce the influence and disturbances on their measurements, and are therefore preferable mounted on a (deployable) boom. A robotic arm can introduce a wider range for positioning of instruments (cf. Beagle II; Maki et al., 2011; Pullan et al., 2004).

A geophysical surface station is going to be launched to Mars in 2016. InSight (Banerdt et al., 2012) will carry a seismometer (Mimoun et al., 2012) and a heat flow package (Spohn et al., 2014). This basic payload is augmented by a radio-science package, a magnetometer, and a pressure sensor. Geophysical network stations have been discussed at NASA, ESA, CNES, and JAXA for many years (e.g., Mesur, MarsNet, Intermarsnet, and NetLander) but have never been flown. InSight will provide the first dedicated geophysical lander and may pave the way for a lander network in the future.

10.23.5.2.2 Rover

An extended range of mobility can be achieved with a rover. Impressive examples are given by both MER rovers and recently MSL Curiosity. Free-traveling rovers require their own local very efficient power supply (batteries, RTG, or solar panel), which provides energy for roving and all the required subsystems and to allow for thermal management. A remote link via a relay satellite or direct-to-Earth is required for data transfer and commanding and sufficient on-board autonomy for navigation and traveling are mandatory, as usually only limited communication windows with ground control exist. A surface station is a stationary platform deployed on a planetary body, providing the infrastructure (power, thermal environment, data handling, communication, etc.) for the scientific instrumentation (see **Table 3** under *in situ*). Deployment mechanisms are required to permit the instruments unobstructed access to the surface and give some degree of freedom for the sample selection and positioning. Several instruments require very specific access to and alignment with the sample (e.g., LMS, APX, and Mössbauer) and hence a precise deployment mechanism. Imager and panoramic imager should be mounted on a deployable boom to provide an elevated view with a mechanism providing elevation and azimuth rotation, required for panoramic imaging. A thermometer, wind meter (anemometer), magnetometer, and many other instruments require some distance from the surface station, simply to reduce the influence and disturbances on their measurements, and are therefore preferable mounted on a (deployable) boom. A robotic arm can introduce a wider range for positioning of instruments (cf. Beagle II; Maki et al., 2011; Pullan et al., 2004); navigation and traveling is needed, as usually only limited communication windows with ground control exist. The locomotion system with the required structures and the collection of all needed subsystems drive the minimum size and mass of such a rover (cf. MER, ExoMars, MSL) in a range from 150 to 1000 kg, allowing for an accommodation of an enhanced and meaningful payload suite.

A small rover can carry only a much miniaturized payload suite (e.g., APX and Mössbauer and a microscopic camera). In the simplest form, the rover is connected to the surface station via a thin tether for power supply, data transfer, and commanding. Due to the tether, the range is limited to several tens of meters (cf. Nanokhod; Bertrand et al., 2000). Small untethered rovers are limited to the near surroundings of the landing platform (cf. Sojourner rover) and have limited obstacle negotiation capabilities.

10.23.5.2.3 Subsurface access

Access to the subsurface is of interest to understand layering, have access to unaltered material, measure heat flux from the interior of the body, and define soil characteristics. Nonintrusive access is given by means of subsurface-penetrating radar or to some limited extent also with a microwave sounder. A drill allows for local subsurface access either to deploy embedded sensors or to retrieve samples (cf. ExoMars drill and MSL drill; Maki et al. (2011)). Another possibility is the use of a mole (cf. Pluto on Beagle 2). On ice-covered bodies (e.g., comets, Europa, and Mars poles), a melting probe can be used for ground penetration by sampling the medium as the probe melts through the ice (Kaufmann et al., 2009).

10.23.5.2.4 Mechanical tools

Mechanical tools are used for removal of the top layers on samples to provide access to unaltered pristine material and are often referred to as a 'geologist's hammer.' A grinder is a rotating device able to create a hole of a few centimeters in diameter and a few millimeters in depth in rocks, which is then further explored with *in situ* instruments (cf. Rock Abrasion Tool (RAT) on Mars Exploration Rover (MER) or the corer-grinder on Beagle 2; Richter et al. (2002)). Understanding the differences between the original rock surface and the interior reveals information about the rock formation process and environmental conditions, which have altered the outer layer of the rock.

Another concept is the ultrasonic drill with a piezoelectric-driven mini hammer tip, which pulverizes the material for further analysis (Chipera et al., 2003).

10.23.5.3 Atmospheres, Exospheres, and Ionospheres

To understand the complex dynamics of atmospheres and their relationship with the surface, an extended set of instrumentation is essential. Also, for atmosphere research, the combination of remote-sensing and *in situ* observations is applied. Balloons, commonly used in the Earth's atmosphere for *in situ* sounding, are yet rarely used in planetary atmospheres as instrument platforms (e.g., VEGA 1 and 2 at Venus 1985). Entry and descent probes (e.g., Galileo at Jupiter, Huygens at Titan, and various Venus probes) have delivered significant data due to their capabilities to provide *in situ* compositional and thermodynamic profiles. Lander instruments play a key role in atmospheric measurements because they offer unambiguous observations of diurnal and meteorologic variations, in particular for surface–atmosphere interactions, which are difficult or impossible to observe from orbiting spacecraft by means of remote sensing (Morgan et al., 1995). Many open questions remain, due to the dynamic changes associated with

atmospheres, and many observations over long periods of time are mandatory, while comparative interpretations on multiple planets are required. Networks of surface stations capable of long observations, long-duration aerobots cruising in various altitudes, and the deployment of microprobe swarms are important for the next steps in exploration. The key problems with very small stations and microprobes are the maintenance of thermal conditions within hostile environment, the energy supply, and communication (in particular energy requirements for communication and data transfer) with the data relay (direct-to-Earth communication is difficult due to the long-range and associated space loss, the required RF power, and the energy density limits of current energy storage systems). Some key technologies for microprobes are under development such as localization and communication (Wells et al., 2004).

Remote sensing of atmospheres is performed by nadir observations and also limb sounding. **Table 4** lists a few key instruments for remote-sensing and for *in situ* investigations. Imagers are important to observe the dynamics of an atmosphere. Very high resolution is usually not required; a wide FoV is preferred to guarantee longer-term observations of time-dependent variations and dynamic processes. Spectrometers are used to study the composition in various wavelengths. Atmospheric weighting functions have to be applied to perform sounding at different altitudes. These functions are describing the layer of the atmosphere, from which the radiation measured at a particular wavelength was emitted (Elachi, 1987, pp. 302–311). Measurements performed at various wavelengths reflect peak emissions from different altitudes. Similar principles are used for microwave and submillimeter sounders. Microwave sounders are in particular sensitive to reduced forms of oxygen and nitrogen (water and ammonia). Laser altimeter can be used to define the local atmospheric opacity and atmospheric aerosol loading (Ivanov and Muhleman, 1998).

Radar signal transmission through an atmosphere is dependent on the TEC with additional phase shifts and damping occurring in the ionospheres. Both effects are exploited with radar measurement. Precipitation and water vapor content measurements are also classical applications for radar observations. Also, limb sounding and observations by occultation (e.g., of telecommunication radio link signals) are used by radio science to define, for example, the density profile of an atmosphere.

Lightning detectors are accommodated either on orbiting spacecraft or flyby spacecraft (e.g., Radio and Plasma Wave Science on the Cassini orbiter; Fischer et al., 2005) or by *in situ* instrument such as the HASI permittivity, waves, and altimetry analyzer (PWA), installed on the Huygens probe (Fulchignoni et al., 2005).

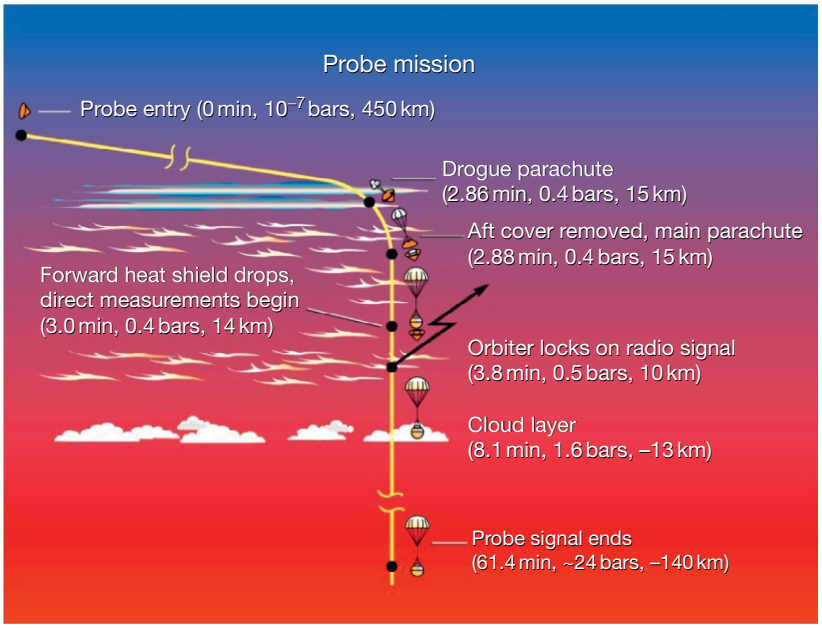
A most recent example of a mission dedicated to study the atmosphere and its interaction with the solar wind is Venus Express. Juno is another example containing significant instrumentation for atmospheric sciences to investigate Jupiter (Bolton and The Juno Team, 2012).

10.23.5.3.1 Entry and descent probes

Every *in situ* access to a dense atmosphere and to the surface of a planet with a dense atmosphere requires an entry and descent vehicle. The entry vehicle has to suffer a significant heat flux when entering the atmospheric interface due to the high entry velocities (e.g., around 9.8 km s^{-1} for Venus entry or minimum of 47 km s^{-1} for Jupiter), when performing a hyperbolic insertion. Entry is very challenging in particular for the large gaseous planets with their strong gravity field. A robust ablating thermal protection system is required to keep the subsystems and instruments within an acceptable temperature range during the entry. In some cases, the overall thermal protection system with required structure exceeds even more than half of the overall system mass of the entry vehicle. The remaining mass must be shared by all required subsystems (power, data handling and communications, etc.), leaving only a small fraction for scientific instrumentation. Miniaturization is a key prerequisite to be able to accommodate a meaningful payload also on smaller systems. Access to the environment is limited during the entry phase as the probe is usually cocooned and thermally fully isolated. Acceleration can, however, be measured in this cocooned state to define the drag in order to derive the ambient atmospheric density. Thermal sensors and strain gages embedded in the ablative material are employed to understand engineering details like the ablation processes during the entry. After the deployment (jettison) of the aft and front heat shield, all scientific instruments can be deployed. As soon as the RF system is operable (in particular after the normal blackout period), important data on the entry trajectory can be obtained by exploiting the Doppler shift of the RF-carrier signals. An example for an entry sequence and consecutive deployment of scientific sensors is given by the Huygens probe, which successfully entered the Titan atmosphere

Table 4 Instrument examples to investigate planetary atmospheres, exospheres, and ionospheres via remote-sensing or *in situ* analysis

Remote sensing	In situ
• Wide field imager (visual)	• Aerosol and dust analyzer
• Spectrometer (UV, NIR, FIR, visual)	• Pyrolyzer and mass analyzer
• Laser altimeter	• Magnetometer
• Microwave sounder, submillimeter sounder	• Nephelometer, miniature gas sensors and electronic noses
• Radar including ionospheric sounder	• Miniature gas sensors and electronic noses
• Radio science	• Anemometer
• Lightning detector	• Up- and down-dwelling fluxes
	• Composition (gas chromatograph and mass spectrometer)
	• Pressure, temperature, acceleration sensors
	• Space plasma and energetic atom analyzer



Probe mission
Probe entry (0 min, 10^{-7} bars, 450 km)
Drogue parachute
(2.86 min, 0.4 bars, 15 km)
Aft cover removed, main parachute
(2.88 min, 0.4 bars, 15 km)
Forward heat shield drops,
direct measurements begin
(3.0 min, 0.4 bars, 14 km)
Orbiter locks on radio signal
(3.8 min, 0.5 bars, 10 km)
Cloud layer
(8.1 min, 1.6 bars, –13 km)
Probe signal ends
(61.4 min, ~24 bars, –140 km)

on 14 January 2005, or by the Galileo entry probe (Figure 6). Both the Huygens probe and the Galileo probe had been designed as descent probes, able to deliver science data during the descent in the atmosphere of Titan and Jupiter, respectively.

The following list summarizes typical instruments used on such kind of descent probes (Table 5).

In many cases, the entry probes are optimized to deliver a lander (cf. Beagle), rover (cf. MER, MSL, ExoMars), or aerobot, with a strongly reduced or even no scientific payload at all installed on the probe itself, but only a dedicated payload on the delivered unit.

Table 5 Typical payload examples for entry and descent probes in planetary atmospheres

Entry and descent probe payloads
• Atmospheric structure package (accelerometer, gyros, pressure and temperature sensor, recession measurement)
• Miniaturized (spectral) imager
• (Polarization) Nephelometer
• Anemometer
• Up- and down-dwelling fluxes
• Miniaturized gas chromatograph and mass spectrometer
• Aerosol analysis
• Energetic particles and plasma spectrometer
• Doppler wind experiment (via radio science)
• Acoustic instrument (e.g., to define speed of sound)

10.23.5.3.2 Aerobots

Aerobots are aerial robotic platforms (e.g., Vega balloons) providing an excellent platform for *in situ* sensing instruments at specific altitudes in the atmosphere of planetary bodies. Aerobots have to be delivered by an entry probe before they can be deployed at the target altitude in the atmosphere of interest. Various aerobot principles exist although not many have been flown in space so far. The lighter-than-air balloons (light gas balloons, airships, blimps, and Montgolfier) are based on the buoyancy effect using a gas or gas mixture, which is lighter than the surrounding atmosphere. Heavier-than-air vehicles (gliders, rotating wings, and airplanes) are based on a relative motion through the atmosphere to provide a lift. The main challenges for both principles are the deployment of the balloon after entry and the survival of the local environmental conditions over the required observation time.

Almost all of the *in situ* instruments listed in Table 4 can also be used on an aerobot in a miniaturized form to measure, for example, atmospheric composition, horizontal and vertical winds, layering, cells fluxes, density, pressure profiles, gas mixture, elemental sources and sinks, and eventually atmospheric escape processes. Certainly, it is also possible to perform remote observations of the surface, provided the atmosphere is not completely opaque. Payload miniaturization is required as the available payload mass fraction on an aerobot is rather small. The aerobot itself is limited in (undeployed) size and mass to be accommodated within the entry probe, which on its own is already significantly mass-constrained due to the high mass fraction of the heat shield and thermal protection system (e.g., Chassefière and The EVE Team, 2009). Aerobots are also a possible platform for deployment of a single or a swarm of microprobes.

10.23.5.4 Magnetosphere

Investigation of the planetary magnetism is about characterization of frozen ambient fields in bodies, which have cooled well below the Curie point and the magnetic fields originating from a planetary dynamo (see **Chapter 10.07**). Within the planetary magnetospheres, the magnetic field dominates the behavior of electrically charged particles (Kivelson, 1981). Interesting on

one side is the interaction of the planetary fields with the solar wind and its magnetic field, resulting in a bow shock followed by the magnetopause on the upwind side and the long turbulent magnetotail on the downwind side, the magnetically trapped particles in the radiation belts, direct entry of solar wind particles into the magnetosphere through the polar cusp (aural effects), and interaction of the field with any associated moons. On the other hand, the magnetic field provides significant data about the (deep) interior of the planet.

Instrumentation follows these science lines and concentrates on the definition of the internal magnetic field to constrain the interior of the planet or to investigate the magnetosphere and the magnetohydrodynamic (MHD) processes, plasma and waves, reconnection, substorms, and turbulences in it.

For investigation of the internal field, a combination of spacecraft at different altitudes is preferred: one spacecraft on a circular polar orbit to measure precisely the internal field, a second spacecraft on an elliptical polar orbit to understand the interaction with external fields, and possibly a surface station, which provides *in situ* reference of the local surface field.

To investigate magnetospheric and plasma processes, a tetrahedron formation with four similar spacecraft with identical instrumentation is of use, such as ESA's Cluster II mission (Escoubet et al., 2001). Spinning spacecraft is preferred to accommodate long wire booms, which derive their attitude stabilization by the gyroscopic stiffness. The spin also provides 360° scan for all instruments with a radial bore sight without moving mechanism.

Space plasma dynamics involve processes on four scales: (1) the global scale, (2) the MHD scale, (3) the ion scale, and (4) the electron scale. Observation of processes can be best achieved with four spacecraft in a tetrahedron formation like Cluster II, but at least at three scales (MHD, ion, and electron scales) at the same time, thus requiring up to 12 spacecraft in total (cf. MMS Mission, Scope, or Cross-Scale). Instrumentation on a particular scale can be identical, but differ between the scales to cope with particular particle types, energy ranges, and dynamics associated with the processes at the different scales (Table 6).

10.23.5.5 Moons

Payloads for moons are basically similar to what has been described already for their mother planets, although additional topics such as the interaction of the moon(s) with the mother planet (and their rings), generated tides and associated tidal heating (cf. Io and Europa), gravity perturbations or mutual influence and interaction with magnetosphere (cf. Ganymede), and particles (cf. Io; Spencer et al., 2002) are of particular additional interest. As an exception, Titan is the only moon in our solar system with a dense atmosphere, and hence, entry probes with particular tailored payloads (cf. Huygens; Lebreton and Matson, 2002) are possible (Table 5).

Due to the lack of a dense atmosphere around the other moons, landing requires full propulsive cancellation of the orbital and gravitational velocity with chemical motors. Despite the relative lower gravity of most of the moons, high propellant mass has to be carried on board the spacecraft because of the transfer, insertion, and landing delta-v requirements, leaving only a relatively small mass ratio available to the surface payload.

Table 6 Examples of instrumentation for magnetospheres and plasma processes.

In situ
• Magnetometer (AC and DC field)
• Plasma particle package
• Electron drift instrument
• Active spacecraft potential control
• Plasma wave analyzer
• Neutral and ionized particle analyzer
• Radiation monitor
• Fast and hot plasma analyzer

10.23.5.6 Rings

As we know by now, each of the giant planets in our solar system possesses a more or less complex and unique ring system (Figure 7). Composition, origin and age, characterization of the physical properties, in-ring collision and collision processes with external material (meteorites), evolutionary processes, particle size, and distribution are some of the key topics to be addressed in the further understanding of ring systems (Gordon et al., 2002).

Ring observations usually have to be shared or compete on board the spacecraft with other instrumentation but can be performed also with Earth-based and space telescope observations (de Pater et al., 1999). Most of the instruments listed in Table 3 (under remote sensing) can in principle be used for ring observations, of the shepherd satellites and their gravitational interaction with the rings and the central body. Imaging, and in particular close-up imaging, and compositional analysis with UV and IR (imaging) spectrometer play a key role. Long-term observations, required for the understanding of ring dynamics, can be mainly sustained by observation from Earth. *In situ* observations can be done with a dust analyzer, as for the first time performed on Galileo, providing dust spatial densities, grain size distribution, and impact speed along the spacecraft trajectory (Krüger et al., 1999).

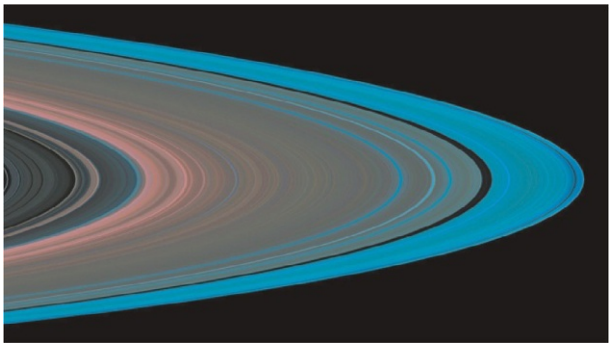

Figure 7 Saturn's ring system observed in the UV by Cassini's ultraviolet imaging spectrograph. The turquoise represents more water ice in the rings. Image NASA/JPL/University of Colorado 'PIA05075: Saturn's A Ring from the Inside Out.'

10.23.5.7 Asteroids and Comets

Comets represent the most fundamental building blocks of the solar system preserved in a low-temperature and low-gravity environment (e.g., Schulz, 2002). Most of them remain in the Oort cloud or in the Kuiper Belt outside the orbit of Neptune (see also **Chapter 10.16**). Only occasionally an object is randomly scattered into the inner solar system by gravitational perturbations, becomes active and bright, and can therefore be observed with telescopes from Earth and space or visited by spacecraft (cf. Giotto, Deep Space 1, Stardust, Deep Impact, and Rosetta). The outer comets can hardly be visited with close encounters as the travel time gets too long and the high escape velocity of the spacecraft necessary for reaching the outer parts of the solar system would require high delta-v maneuvers for transfers to a comet (cf. **Chapter 10.17**). This is hardly feasible with current propulsion technology. Mainly comets crossing the inner solar system on highly elliptical orbits can be visited. While flybys are relatively easier to achieve, orbiting missions, such as the Rosetta mission to comet 67P/Churyumov–Gerasimenko, still have high delta-v requirements because the spacecraft has to have a similar angular velocity as the comet in elliptical orbit around the Sun.

Asteroids have been divided into various classes depending on their distance to the Sun, or more specifically the type of orbit (Chapman, 2005). The asteroids in the main belt are believed to be remnant planetesimals with complex collisional and dynamic activity, whereas NEOs may be either asteroids or dormant comets (**Figure 8**). They come close to or can be on Earth-crossing orbits and are therefore potentially hazardous for a collision with Earth. Tracking and observations from Earth are important for determining the orbit ephemerides and gross physical characteristics of these bodies, such as size, shape, rotation period, and spectral class, which are important prerequisites for choosing the appropriate and most interesting targets for exploration missions.

In a flyby or orbiting mission to small solar system bodies, an accurate determination of their dimensions and rotational properties, as well as their surface, topography, and morphology, can be obtained by direct imaging in the visible band. The interior can be investigated with GPRs, like with the Comet Nucleus Sounding Experiment by Radiowave Transmission (CONSERT) experiment (Barbin et al., 1999), a bistatic radar system with the object between transmitter and receiving radar to achieve a tomography of the body.

A radio-science experiment is necessary to define the gravitational field and moments of inertia of the body and for absolute position definition, which is required in relation with altimetry measurement by radar or LIDAR. For the compositional analysis of the surface by remote sensing, multiwavelength spectroscopy is required for wavelengths from γ-rays to submillimeter range. These spectrometers can also be used to determine the outgassing rate of comets and search for activity around asteroids. Surface and subsurface temperatures can be defined with thermal IR and microwave spectrometers. The long list of possible *in situ* instruments can be used to provide local measurements on the surface and, in the case of active bodies, by flying through the coma and tail, determining the composition of the gas and dust particles ejected from the nucleus. By use of drills and moles, subsurface characterization can be achieved in a similar style as on planetary surfaces.

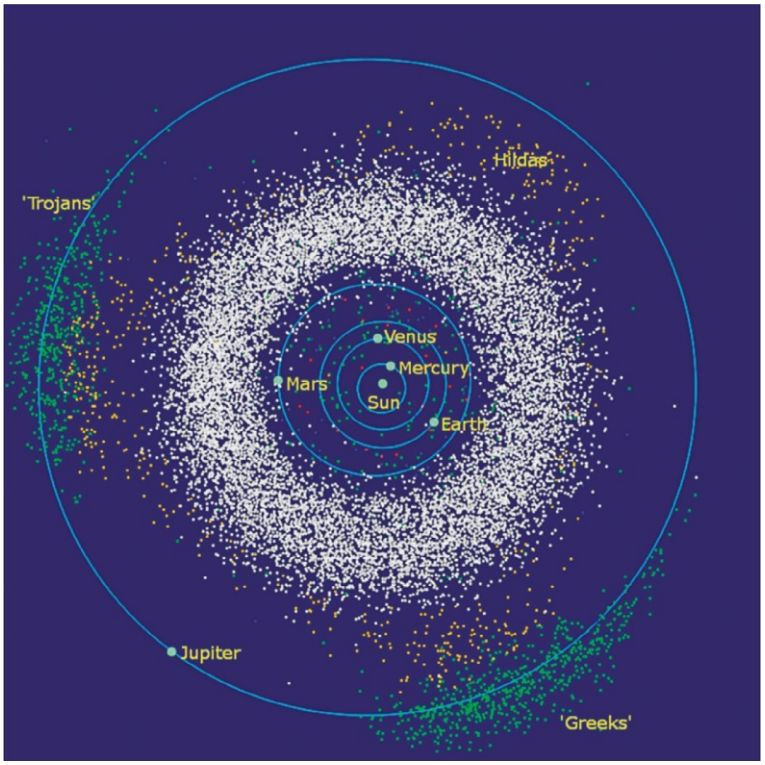

Figure 8 The main asteroid belt concentrates mainly between Mars and Jupiter. Image NASA-JPL.

Table 7 Instrument examples for remote or *in situ* sensing payloads for asteroids and comets

Remote sensing	In situ
• Imaging system • Nucleus sounding experiment by radio wave transmission • Mass spectrometers for compositional analysis of neutrals, ions, and dust particles • Radio-science experiment • UV, visible, and IR imaging spectrometers • γ-Ray, neutron, and x-ray spectrometers • Microwave sounder • Laser or radar altimeter • Dust particle analyzer	• Panoramic and microscopic imaging system • Ion mass analyzer • Impact analyzer and dust accumulator • Spectrometer for ion and neutral analysis • Ion composition analyzer • Ion, neutral, and electron spectrometer • Langmuir probe • Magnetometer • Conductivity and permittivity probe • Conductivity probe • Plasma instruments • Alpha x-ray spectrometer • Laser mass spectrometer • Evolved gas analyzer – elemental and molecular composition • Physical surface and subsurface properties • Atomic force microscope • Penetration probes and drills • Seismometer • Acoustic monitor

Table 7 summarizes potential instruments for missions to asteroids and comets.

10.23.5.8 Exobiology

The field of exo- or astrobiology (see Chapter 10.12) combines the key characteristics of astronomy, biology, and geology, and as such, so does the instrumentation. It not only comprises most of the instrumentation described so far but also involves laboratory activities, as well as in-field search of 'exotic' life forms on Earth (extremophiles), extending also to the search and characterization of extrasolar planets. Within our solar system, the focus resides on Mars, Europa, and Titan, due to the presence or assumed presence of water (cf. Europa) and organics (cf. Titan). Search and analysis of organics, search for water as prerequisite for life, search for habitable zones by remote sensing, and *in situ* search include most of the instruments given in Table 3 but require further improvement and new instrumentation, as summarized in Table 8. Due to the harsh conditions on most of the planetary surfaces, the search is focusing on subsurface niches (e.g., with GPR), requiring mobility and subsurface penetration capabilities (e.g., drills or moles), equipped with sampling mechanism and dedicated sensors for analysis of prebiotic chemistry, as well as for the search for past or present life.

Table 8 Instrument examples for exobiology payloads suites for remote or *in situ* sensing

Remote sensing	In situ
High-resolution imager (visual)	Panoramic camera
Stereo camera	Laser mass spectrometer
Spectral imager (UV, NIR, FIR, visual)	LIBS/Raman spectrometer
Subsurface radar	Alpha particle x-ray spectrometer
x-Ray, gamma-ray, and neutron spectrometer	x-Ray diffractometer
Microwave sounder, submm sounder	UV spectrometer
Magnetometer	Attenuated total reflection spectrometer
Thermal IR radiometer	Mössbauer spectrometer
	IR Fourier spectrometer
	Gas chromatograph and mass spectrometer
	Microscopic Imager
	Heat flow and physical properties package
	(Miniature) Thermal emission spectrometer
	Radon exhalation
	Magnetometer
	Seismometer
	Ground-penetrating radar (surface deployed)
	Drill system
	Life marker chip
	Radiation monitor
	Permittivity probe
	Environmental package

10.23.5.9 Sample Return

A sample return is a specific case, since the emphasis is on the return of material to be further analyzed in dedicated terrestrial laboratories, where the same strong resource restrictions are not given as for space mission instrumentation. Not only significant higher resolution in all measurements can be achieved but also

different techniques can be applied, which cannot (currently) be used on robotic missions (Sears et al., 2002). The benefits have to be traded with the increased mission complexity, as it requires a spacecraft performing the transfer to the body, soft landing on it (involving either atmospheric entry where a denser atmosphere exists or propulsive landing on atmosphereless bodies), a dedicate sample mechanism, and sample transfer unit, which brings the sample to a container, embedded in the Earth Return Vehicle (ERV). The ERV does the ascent and escape from the body (or planetary system) and return transfer to Earth, where the Earth return container has to perform the reentry and safe landing on Earth.

In a minimum configuration, there will be limited additional scientific instrumentation foreseen on board the spacecraft, for navigation purposes in particular in proximity to the body and landing and sample site selection, and some minimal instrumentation for local sample selection. Context information for where the sample is taken is also required. For the sampling process itself, the sample mechanism and its interaction with the local environment are of key importance. The easiest case is to take a sample from the atmosphere. More complex is the sampling process for the terrestrial planets, as well as moons, asteroids, and comets, requiring interaction with the surface material (e.g., regolith, ice, and rocks).

In a low-gravity environment, either an anchoring system or active propulsion is required to provide stability to the landed platform, able to counteract the introduced forces by the sampling process, or a touch-and-go procedure is applied. Of course, a low-gravity environment has the benefit of a simplified landing and return with small delta-v. In a high-gravity environment, an escape stage is needed to provide enough velocity to leave the body's gravitational field, or at least to return to an orbiter and perform a rendezvous maneuver for sample exchange.

10.23.5.10 Engineering Aspects and Operations

Usually, the payload is one of the main mission drivers for cost, mission size, and risk. It is therefore very important to understand and reflect the detailed science requirements and consider all the drivers of these requirements on the spacecraft. The ground resolution of the imaging payload, for example, might be the main driver for the spacecraft attitude control, and hence, a detailed trade-off between science requirement and implementation complexity must be performed in an iterative process. A system engineering approach with an end-to-end view is required to properly manage all interrelations and dependences, requiring interdisciplinary knowledge (Cruise et al., 1998).

10.23.5.10.1 Engineering constraints

Resources such as mass, power, data rate, data volume, and in particular cost strongly limit planetary missions. The selection of instruments must be performed in the first instance to satisfy the defined science requirements of a particular mission within the estimated available resources. The use of the latest technology might help obtain more science per resource, but is not necessarily at lowest risk and cost. A well-considered trade-off during instrument selection and instrument design is required.

The environmental conditions at the target of observation and also during transfer phases are a strong driver for the design and selection of equipment and technology for the complete spacecraft and the instruments in particular. Radiation, thermal ranges, shock, and vibration levels are just a few of the drivers that strongly influence the design solutions of instruments and instrument suites. The payload is commonly the most sensitive part of a spacecraft. Instruments require specific conditions during operation, standby, and nonoperation (thermal ranges, vibration levels, power supply stability, low-electromagnetic-cleanliness (EMC) noise environment, etc.). Different instruments require different environmental conditions, hence driving the complexity of the spacecraft and of its subsystems. In particular, the front-end instruments (optics and focal plane and sensors) have the most stringent requirements.

Coalignment of the FoV between different instruments and time synchronization of the measurements are additional drivers, requiring stable instrument platforms and precision timing capabilities.

Many low-noise sensors require either active cooling (e.g., Peltier element or sorption cooler) or passive cooling via a radiator, because noise increases with temperature. In particular, with respect to planets with a hot environment (Mercury and Venus), the thermal design becomes rapidly a strong mission driver.

Sensors requiring direct access to the environment (e.g., thermal sensor, plasma instruments, and magnetometers) must be in many cases mounted outside the protective spacecraft and are consequently exposed to harsher environmental conditions (radiation, temperature, dust, and plumes) and may require a boom for deployment. Long appendages such as booms or antennas (in particular for GPR) require mechanism for deployment and change, when deployed, the spacecraft attitude stability, and moment of inertia.

Due to long transfer times, aging, radiation, and changing environmental conditions, instruments are subject to performance alteration, drift, and increased noise levels. A calibration is required, and in many cases, regular calibration cycles with reference sources have to be performed during the full lifetime of the instrument. Stable calibration targets have to be used for reference, and repointing of the instrument to the targets requires in many cases additional mechanism.

10.23.5.10.2 Operational aspects

All the aforementioned points have to be considered not only in the design of the instrument and instrument suite but also during operation. The onboard instrument data handling system and control computer need to operate the instruments within the required conditions and have to avoid any hazardous conditions. This can be performed either with ground control and commanding or via computer-installed autonomy on board the spacecraft. Data processing is used to produce telemetry packets out of the raw sensor data, which can be transferred via the telemetry link back to Earth ground stations. In many cases, the telemetry link is not available permanently, but limited to so-called communication windows; hence, data must be stored on board the spacecraft to prevent a loss of important scientific data. A data management system is required, which takes care of the data acquisition, buffering, and transfer to the telemetry link, when available. Some

instruments require already-onboard context information from other instruments to adapt and optimize their own operation. A data exchange and data flow management must be installed in such cases.

The telemetry link is limited in data rate and data volume. Depending on the nature of the data, loss or lossless compression can be used to reduce the data volume of an instrument. For the final data analysis, it is important that no compression artifacts are introduced or that these artifacts are properly understood and acceptable.

Housekeeping data, permanently transferred together with science data, summarize the current environmental and status conditions of the instrument and the entire spacecraft, such as temperature, supply currents, voltages, deployment state, pointing elevation, and the current operational mode. This is all of utmost importance to understand later the remotely acquired data set and perform successful data calibration and interpretation.

10.23.5.10.3 Verification and testing

Not only because of the unique nature of a space mission and the high mission cost but also because most of the instruments and instrument suites are prototypes, a thorough verification (in particular against the environmental conditions) and testing after the assembly and integration are mandatory. An instrument has to be qualified at harder conditions and verified at least at similar conditions as expected during launch, transfer, and operation of the space mission. Thermal-vacuum testing, vibration testing, and radiation testing are just some of the tortures that a space instrument has to survive without damage and serious performance degradation. The particular test procedures and conditions depend finally on the nature of the mission and have to be planned and characterized during the development phase of the mission.

10.23.6 Outlook and Timeline

All our planets, as well as a number of moons, comets, and asteroids, have by now been visited by spacecraft. What remains is a more thorough exploration of all objects to further improve our knowledge and understanding. Landing on planetary surfaces is required to provide ground truth for already existing remotely sensed data (e.g., Mercury, Galilean and major Saturn moons, other asteroid classes, and comets) and provide *in situ* observations not possible for orbit. Long-term observations, deployment of meteorologic, and seismic networks on neighbor planets (Venus and Mars) should also help better understand our own planet and its environment.

Sample and return from the terrestrial planets, various moons, and selected asteroids are further goals to be achieved. Sample and return missions are definitely also technology precursor for long-term future human exploration of, for example, Mars or asteroids. The further exploration of the interstellar heliopause at some 200 AU from the Sun is another longer-term goal.

Due to the extended duration of space mission development, most of the shorter-term and medium-term goals are already under study, planning, or development and embedded in the various national and international space plans. The realization of these plans strongly depends of course on the political environment and the will and capabilities to financially support these plans.

Technology development is an important prerequisite to prepare further spectacular and striking space missions, which are able to add scientific value and allow further exploration. Research and development is definitely a longer-term endeavor, which needs financial support based on long-term planning and visions. Technology must be available or in reach when a mission planning starts, to avoid delays, fallback solutions, cost overruns, or in worst cases a mission failure.

Miniaturization and high levels of integration of instruments and spacecraft subsystems similar to what is ongoing in the consumer world; wider use of nanotechnology, systems on a chip, and MEMS; further development of space-qualified application-specific integrated circuits (ASIC) and FPGA, new detectors, sensors, and materials; and adaptation and qualification of terrestrial instrumentation principles for space application are important midterm steps in preparation of the future of planetary exploration.

Finally, it is our imagination, when coupled to the successful completion and promotion of current space missions, which will prepare the ground for future exploration.
